Relationships between recall of low and high imagery paired-associate (P- A) words and hypnotic susceptibility, and the influence of hypnosis on recall as moderated by hypnotic level were examined. Subjects were assessed on 2 hypnotic susceptibility scales [Harvard Group Scale of Hypnotic Susceptibility; Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C)]. Forty-one low (0-4 SHSS:C) and 41 highly (9-12 SHSS:C) hypnotizable college students were assigned to 1 of 4 experimental groups: waking- hypnosis, hypnosis-waking, waking-waking, or hypnosis-hypnosis. Recall was significantly better for high than low imagery words. In the more sensitive within-subjects design, high hypnotizables recalled more P-A words during hypnosis than waking, and lows did not differ. In the between-subjects design, hypnotic level was not a moderator of performance during hypnosis. Low hypnotizables recalled more words in the within-subjects design. Visualization ability was a poor moderator of imagery-mediated learning. High imagery recall correlated significantly with Marks's (1973) Vividness of Visual Imagery Questionnaire (25) and Paivio and Harshman's (1983) Individual Differences Questionnaire (IDQ) Verbal scale (29), but not with the IDQ Imagery scale, the Mental Rotations Test (Vandenberg & Kuse, 1973), or the revised Minnesota Paper Form Board Test (Likert & Quasha, 1941).

Dixon, Mike; Labelle, Louise; Laurence, Jean-Roch (1996). A multivariate approach to the prediction of hypnotic susceptibility. International Journal of Clinical and Experimental Hypnosis, 44 (3), 250-264.

The present study examined the relation between various self-report measures and two measures of hypnotizability within a multivariate framework. A group of 748 participants was tested on the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A), the Tellegen Absorption Scale (TAS), as well as the Preference for an Imagic Cognitive Style (PICS) questionnaire. One hundred ninety of these participants also completed the Paranormal Experiences Questionnaire (PEQ). Data were analyzed using hierarchical multiple regression equations, and the results of the analyses indicated that both the TAS and PICS accounted for significant amounts of unique variance in each of two 373-member samples of HGSHS:A scores. A further sub-sample of participants (n = 161) was tested on the Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) to see if these results would generalize to another measure of hypnotizability. Hierarchical multiple regression analyses revealed that although the PEQ predicted significant amounts of unique SHSS:C variance over and above that predicted by the TAS, the PICS failed to do

so. This inconsistency in results may be due in part to the generally low intercorrelation between the different hypnotizability scales and points to the need to develop new predictor variables that are orthogonal to each other. - Journal Abstract

Wallace, Benjamin; Allen, Philip A.; Propper, Ruth E. (1996). Hypnotic susceptibility, imaging ability, and anagram-solving activity. International Journal of Clinical and Experimental Hypnosis, 44 (4), 324-337.

Anagram-solving activity was examined as a function of hypnotic susceptibility level and imaging ability. In Experiment 1, anagrams that were composed of sets of letters that formed actual words (word anagrams), but when unscrambled formed other words, were compared to sets of letters that formed nonwords (nonsense anagrams). Word anagrams required more time to solve than nonsense anagrams. Also, fewer word anagrams were correctly solved compared to nonsense anagrams. Those individuals judged both high in hypnotic susceptibility and vivid in imaging ability demonstrated the best performance. In Experiment 2, anagrams that when unscrambled formed high-imagery words were compared to those that formed low-imagery words. High-imagery-word anagrams were solved more quickly and correctly than low-imagery-word anagrams. Such activity was best demonstrated by individuals who were judged to be both high in hypnotic susceptibility and vivid in imaging ability. These results are discussed in terms of strategies for solving anagrams and the individual differences that appear to be associated with using such strategies.

1995

Dywan, Jane (1995). The illusion of familiarity: An alternative to the report-criterion account of hypnotic recall. International Journal of Clinical and Experimental Hypnosis, 43 (2), 194-211.

Hypnosis increases the likelihood that participants will report incorrect material at higher levels of confidence. One interpretation of such data is that hypnosis induces individuals to lower the criterion they use to make memory reports. A lowered report criterion could account for the increase in items that participants are willing to report as memories but not for the increase in confidence that typically accompanies hypnotic retrieval. Although some participants may indeed lower their report criterion, this alone should not result in the highly confident confabulation so often observed. An alternative perspective is that for some participants, hypnosis alters the experience of retrieval such that items generated during retrieval attempts are more likely to have the qualities (e.g., perceptual fluency, vividness) usually associated with remembering. This illusion of familiarity would account for the higher levels of confidence that are so frequently observed in hypnotic recall, and adopting this perspective should lead to even greater caution in the use of hypnosis as an aid to retrieval.

Glisky, Martha L.; Tataryn, Douglas J.; Kihlstrom, John F. (1995). Hypnotizability and mental imagery. International Journal of Clinical and Experimental Hypnosis, 43 (1), 34-54.

Two studies investigated the relationship between mental imagery and hypnotizability, with the imagery measures administered in a hypnotic context. The correlation of hypnotizability with vividness of imagery was significant in one study, but not in the other; both correlations were significantly lower than that obtained between hypnotizability and absorption, assessed in the same samples. The correlations with control of visual imagery, and with various measures of the vividness of motor imagery, were even lower and rarely significant. Except for an aggregate index of motor imagery, a search for significant nonlinear relationships with hypnotizability yielded nothing that was consistent across studies. Future studies of imagery and hypnotizability should make use of better measures of vividness of mental imagery and consider the relevance of aspects of imagery other than vividness.

NOTES

1:

In the last 5-6 years we see a beginning of a consistency in this type of research on EEG and hypnosis. Baseline EEG theta for high and low hypnotizable Ss was higher significantly in frontal and temporal areas; less significantly in parietal and occipital areas. It begins to look like a signature of hypnotizability. Our research will be published in the Journal of Abnormal Psychology next year.

In Japan they see theta as sustained attention; some aspects of theta relate to MAO and also to dopamine. Betsy Faith did the same research, replicating almost exactly. There are no differences between Highs and Lows in alpha or beta; but we find differences in theta (especially frontal, and in 40 Hz more posteriorly). It may not be L-R hemisphere difference as previously thought, but more a rostral-caudal dimension.

The signature to hypnotizability is more frontal theta at baseline. This may also relate to a drop in theta after induction, but those results are not so clear. Highs have a larger drop in theta from pre to post induction than is observed in the Lows. We did a "chaos analysis" of EEG. There are three main measures, including dimensionality. Dimensionality is a measure of complexity. People demonstrate high dimensionality when asked to do tasks, low dimensionality in anesthesia.

High hypnotizable Ss start an induction with higher dimensionality than the Low hypnotizable Ss, and as we go through the induction they remain the same. So this measure shows individual differences but does not give evidence of a state (because it doesn't change).

Chaos dimensions for 2 mental math problems show lower dimensions in frontal compared to posterior areas; but for imagery [labeled on slide as positive and negative emotional tasks] the dimension is the same across areas.

For the dimension measures, lows look like they are doing mental math and highs look like they are doing imagery, in baseline.

#### **SECOND PART OF RESEARCH--DISSOCIATION.**

For 100 years dissociation and hypnosis have been viewed as similar. Two dissociation scales were used - Putnam's DES and Reilly's scale. A factor analysis found four factors: 1. absorption or derealization 2. depersonalization 3. segment amnesia 4. in situ amnesia

(Segment amnesia differs from in situ amnesia because you wake up to it at that moment in the in situ vs the segment case.)

We have 20-30 people who score very high on hypnotizability.

Colin Ross finds the same factors as our factors 1 and 2, but he finds only one amnesia factor where we find two.

The correlation between DES and Harvard ranges .05 to .18. Are the high hypnotizables related to high dissociatives, with others not related? A scatter plot did not reveal that.

FFT EEG bands during baseline for high and low dissociation Ss find no differences for high and low dissociative subjects. We conclude that dissociation and hypnosis are two orthogonal processes.

Now we are beginning to look at the pathways that lead one to become highly hypnotizable or dissociative.

#### **COMMENTS FROM THE AUDIENCE:**

**Ian Wickramasekera:** Have you introduced threat to high or low DES people?

**Answer:** High and Low DES people with happy and unhappy imagery tasks do the opposite, with the dimensionality measure. With emotionality you don't see stable baseline differences, you see reactivity differences.

**A. Barabasz:** I think the DES isn't a good measure of dissociation in hypnosis which is voluntary and not pathological.

**D. Spiegel:** Sabourin's study found more theta in left frontal during hypnosis, whereas you found less. **Answer:** That's why I don't know what to do about the state effects.

**J. Crawford:** Sabourin had Ss doing tasks, so they may have been more active than yours.

**Wallace, Benjamin; Allen, Philip A.; Weber, Timothy A. (1994).** Hypnotic susceptibility, imaging ability, and the detection of embedded words within letters. International Journal of Clinical and Experimental Hypnosis, 42 (1), 20-38.

Two experiments were conducted to determine the role of hypnotic susceptibility level (high or low) and imaging ability (vivid or poor) in the performance of a visual search for words embedded within matrices of letters. In Experiment 1, subjects searched for target words from a list; however, distractor words were also

embedded in the matrices. Results indicated that subjects judged both high in hypnotic susceptibility and vivid in imaging ability demonstrated the fastest search speed with a greater percentage of target words found. These subjects also made fewer false alarm errors (locating distractor words not on the target list). The poorest performance was exhibited by subjects judged both low in hypnotic susceptibility and poor in imaging ability. The amount of variance accounted for by hypnotic susceptibility and imaging ability was approximately equal for each dependent measure. In Experiment 2, when subjects searched for target words from a list without distractor words embedded in matrices, similar results to those reported for Experiment 1 were produced, except that the percentage of words found was equivalent across groups. This was attributed to the elimination of potential false alarm errors. The results are explained in terms of the use of either a holistic or a detail strategy in the performance of a visual search.

1993

Wallace, Benjamin; Kokoszka, Andrzej (1993, October). Within-subject variability in hypnotic susceptibility and imaging ability: Same or different?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Subjects were given the Harvard scale of hypnotizability and an imagery questionnaire (VVIQ) repeatedly. They had been asked, "when are you the most alert during the day?" and classified as Day People and Night People. People had higher scores on the Harvard for Day People at 10 a.m. and 2 p.m., for Night People at 1 p.m. and at 6, 7, 8, and 9 .m. This replicates my 1993 study.

VVIQ scores do not show that pattern; they are zig-zag. What is the relationship between peaks on the two scales? They don't peak at the same time. This may be why in the literature we don't find a strong relationship between hypnotizability and imagery ability. VVIQ scores peak before hypnotizability scores on the same people. This might mean an ultradian cycle for imaging ability.

So these abilities are not stable throughout 24 hours, despite the fact that hypnotizability scores are stable over 25 years!

Wallace, Benjamin (1993, October). The importance of considering imagery in hypnosis research. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

We looked at both hypnotizability (Harvard Scale) and imagery (Vividness of Imagery - Marks) ability in an embedded words task (like the letter matrices in newspapers). Ss were grouped on both variables, forming four groups: high-high, high- low, low-high, and low-low.

Search time in the embedded figures task was greatest for low-lows and least for high-Highs, whether the words are easy, average, or difficult. A list of the possible words was also provided.

Strategies the subjects in different groups used are different. High-high's use holistic (Crawford) or efficient (Wallace) strategies--studying the list of possible solutions as if storing the words in long-term memory. Low-low's seem to use the list as a check-off list.

Embedded in the matrix were false alarm words, that weren't on the list. The low-lows were also prone to more of these errors. Getting rid of those false alarm trials, when presented with matrices with no false alarms, we still get a differences in search time with the same relationship as before.

## CONCLUSION

It's insufficient to simply look at hypnotic susceptibility as there's an imaging component, a memory or a storage component that we should examine. The percent of variance associated with the embedded figures task success was the same-- 20%-- for each ability. The correlation between the two (imaging ability and hypnotizability) was significant at .26.

1991

Van Dyck, Richard; Zitman, Frans G.; Linssen, A. Corry G.; Spinhoven, Philip (1991). Autogenic training and future oriented hypnotic imagery in the treatment of tension headache: Outcome and process. International Journal of Clinical and Experimental Hypnosis, 39, 6-23.

The aim of the present study was (a) to investigate the relative efficacy of autogenic training and future oriented hypnotic imagery in the treatment of tension headache and (b) to explore the extent to which therapy factors such as relaxation, imagery skills, and hypnotizability mediate therapy outcome. Patients were randomly assigned to the 2 therapy conditions and therapists. 55 patients (28 in autogenic therapy and 27 in future oriented hypnotic imagery condition) completed the 4 therapy sessions and 2 assessment sessions. Patients were to practice at home. No significant main effect or interaction effects for treatment condition or therapist was revealed. A significant effect for time in analyzing scores for headache pain, pain medication usage, depression, and state anxiety was found. In the self-hypnosis condition, pain reduction proved to be associated with depth of relaxation during home practice (as assessed with diaries) and capacity to involve in imagery (as assessed with the Dutch version of the Creative Imagination Scale). After statistically controlling for relaxation and imagery, hypnotizability scores (assessed by Stanford Hypnotic Clinical Scale) were significantly correlated with ratings of pain reduction. Results are discussed in the context of the neo- dissociation and social-cognitive models of hypnoanalgesia. The clinical relevance and the methodological shortcomings of the present study are also critically assessed.

## NOTES

1:  
Unexpectedly, pain reduction occurring in AT [autogenic training] appears to be brought about by different means than in hypnotic treatment. Not only imagery skills and hypnotizability, but also level of relaxation were unrelated to pain reduction achieved during AT. Since the first two therapy sessions of AT and

hypnosis were identical and in both treatment conditions patients are explicitly instructed to relax, the absence of a relationship between depth of relaxation and pain reduction in AT cannot be easily explained" (p. 19).

**Lombard, Lisa S.; Kahn, Stephen P.; Fromm, Erika (1990). The role of imagery in self-hypnosis: Its relationship to personality characteristics and gender. International Journal of Clinical and Experimental Hypnosis, 38 (1), 25-38.**

30 volunteer Ss practiced self-hypnosis for approximately 4 weeks and wrote a record of their experiences in a diary following each session. Imagery produced during self-hypnosis was coded in 2 ways: the imagery was either reality oriented or it was fantastic and had primary process qualities. Levels of imagery production remained virtually the same over a 4-week period. Self-hypnotic imagery was significantly greater for the female Ss than for the male Ss, particularly primary process imagery. Verbal expressivity (measured as the average number of words per page of each S diary) was calculated to control for the effects of verbal production on Ss' imagery scores. When imagery scores were standardized based on verbal expressivity, female Ss still produced significantly more primary process imagery than male Ss. Personality characteristics (assessed by standardized personality inventories) were examined in relation to self-hypnotic imagery. "Impulse Expression" was positively related to primary process imagery for the female Ss. "Outgoingness" was positively related to primary process imagery for the entire sample, but especially for the female Ss.

**Nilsson, Kayla Mae (1990). The effect of subject expectations of 'hypnosis' upon vividness of visual imagery. International Journal of Clinical and Experimental Hypnosis, 38, 17-24.**

This study explored how the expectation of hypnosis and the expectation of relaxation affected the vividness of visual imagery. 63 Ss who volunteered for a visual imagination study were randomly assigned to 4 groups. Ss were administered the vividness subscale (VS) of the Vividness and Control of Imagery Scale twice. In the 3 experimental groups, expectations were varied during the 2 VS administrations. All 3 groups were presented with a relaxation exercise between VS administrations. In 2 groups, it was labeled "hypnosis," and in the third group it was correctly labeled "relaxation." A control group listened to a neutral tape between their VSs. All groups were administered the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. C. Orne, 1962) after the 2 imagery tests. The results indicated that the vividness of visual imagery was significantly enhanced (equally) in the experimental groups but not in the control group.

**Spanos, Nicholas P.; Williams, Victoria; Gwynn, Maxwell I. (1990). Effects of hypnotic, placebo, and salicylic acid treatments on wart regression. Psychosomatic Medicine, 52, 109-114.**

Subjects with warts on their hands and/or feet were randomly assigned to a hypnotic suggestion, topical salicylic acid, placebo, or no treatment control condition. Subjects in the three treated groups developed equivalent expectations of treatment success. Nevertheless, at the six-week follow-up interval only the hypnotic subjects had lost significantly more warts than the no treatment controls. Theoretical implications are discussed.

#### NOTES

1:

Study involved 15 females, 25 males (18-35 yrs old) with warts on at least one hand or foot, recruited through posters and newspaper ads; N = 10 in each condition. Hypnotic treatment consisted of 10 minute induction (modified from T. X. Barber's 1969 book) and a suggestion for wart regression that was 2 minutes in duration (the skin around warts was 'beginning to tingle and grow warm'; 'vividly imagine the warts shrinking and dissolving away'; 30 second break; repeated the suggestions). For Ss with warts on more than one limb the complete suggestion procedure was repeated for each wart-infected limb.

Results indicate psychological factors can influence course of some virally produced disorders; that self-medicating with over-the-counter products doesn't explain suggestion-induced wart regression; that expectation of treatment success is the most important variable in psychologically induced wart regression. "Hypnotic subjects attained significantly higher CURSS:S scores than did control subjects. Nevertheless, it is unlikely that between group differences in hypnotizability accounted for the group differences in wart regression. Two previous experiments (3) that used the CURSS found that hypnotizability failed to predict wart loss in either hypnotic suggestion, nonhypnotic suggestion, or placebo treatments, and even in the present study the hypnotic treatment failed to differ from either the real or placebo treatment on CURSS:S scores, and none of the treatments differed significantly on the CURSS:O scores. Our finding and earlier findings that hypnotic subjects reported more intense suggested sensations than placebo subjects is consistent with the hypothesis that vivid suggested imagery facilitates wart loss (7, 8)

"An alternative hypothesis emphasizes that only our hypnotic suggestion treatment encouraged subjects to see themselves as developing cognitive control over their own wart regression. This hypothesis suggests that subjects' subjective sense of cognitive involvement in and control over treatment outcome (as opposed to the vividness of their suggested imagery) may have been the important psychological factor in wart regression. It would be of interest in a future study to manipulate subjects' sense of cognitive involvement in their treatment independently of suggested imagery in order to assess the relative contributions of these variables to wart regression" (pp. 113-114).

Wallace, Benjamin (1990). Imagery vividness, hypnotic susceptibility, and the perception of fragmented stimuli. Journal of Personality and Social Psychology, 58, 354-359.

Two experiments were conducted to determine the role of hypnotic susceptibility level (high or low) and imaging ability (vivid or poor) in the performance of gestalt closure tasks. In Experiment 1, subjects were required to identify fragmented stimuli in the Closure Speed Test and in the Street Test. In Experiment 2, subjects reported on fragmented stimuli that were projected to the right eye and subsequently produced an afterimage. Individuals were asked to identify the composite if possible and to report on the duration of the afterimage. In both experiments, hypnotic susceptibility level and imaging ability affected reports of gestalt closure. The greatest number of correct closures was reported by those who were both high in hypnotic susceptibility and vivid in imaging ability. In addition, in the second experiment, this group also reported the longest enduring afterimage. These results are discussed in terms of the processes required to perform in a gestalt closure task.

1989

Kahn, Stephen P.; Fromm, Erika; Lombard, Lisa S.; Sossi, Michael (1989). The relation of self-reports of hypnotic depth in self-hypnosis to hypnotizability and imagery production. International Journal of Clinical and Experimental Hypnosis, 37, 290-304.

Studied multidimensional nature of self-hypnotic depth in 22 high hypnotizables who volunteered for self hypnosis research. On personality scales, they were distinguished from the population at large by: strong theoretical orientation, high level of curiosity, disregard for opinions of others, and high Mf scale on the MMPI. Used the Stanford Profile Scale, SHSS:C and HGSHS:A, which measure the entire range of phenomena ordinarily used in experimental studies of hypnosis, including ideomotor phenomena, hypnotic fantasy and dreams, hypermnasias and age regressions, analgesias, negative and positive hallucinations, amnesias, posthypnotic phenomena, and cognitive and affective distortions. They asked Subjects to experience self hypnosis for 60 minutes/day for 4 weeks. Journals were coded for imagery production by scoring for both reality-oriented and primary process imagery. Subject had been taught to monitor their hypnotic depth using a slightly revised version of the Extended North Carolina Scale (ENCS) of Tart (1979). Previously, ENCS has been used only with hetero-hypnotic Subjects. The self-reports of depth using ENCS correlated highly with hypnotizability as measured by the Revised Stanford Profile Scale of Hypnotic Susceptibility... and with imagery production. Results demonstrate that ENCS scores are also a valid indicator of self-hypnotic depth among highly hypnotizable Subjects. Furthermore, they indicate that both hetero- hypnotizability and imagery production are related to self-hypnotic depth, but that the association between imagery and hypnotizability is due to their individual relationships to self-hypnotic depth.

Kihlstrom, John F.; Register, Patricia A.; Hoyt, Irene P.; Albright, Jeanne Sumi; Grigorian, Ellen M.; Heindel, William C.; Morrison, Charles R. (1989). Dispositional correlates of hypnosis: A phenomenological approach. International Journal of Clinical and Experimental Hypnosis, 37, 249-263.

Attempted to construct and validate a questionnaire measure of hypnotic-like experiences based on Shor's (1979) 8-dimension phenomenological analysis of hypnosis. Separate item pools were developed to measure each disposition: Trance, Nonconscious Involvement, Archaic Involvement, Drowsiness, Relaxation, Vividness of Imagery, Absorption, and Access to the Unconscious. Based on preliminary testing (total Number - 856), a final questionnaire was produced containing 5 items measuring normal, everyday experiences in each domain. Results from a standardization sample (Number - 468) showed that each of the subscales, except for Archaic Involvement, possessed satisfactory levels of internal consistency and test-retest reliability. Factor analysis indicated that 6 subscales loaded highly on a common factor similar to the absorption construct (Tellegen & Atkinson, 1974), while items pertaining to Relaxation and Archaic Involvement formed separate factors. Validation testing on 4 samples receiving the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962) (total Number = 1855) showed that the Absorption and Trance dimensions correlated most strongly with HGSHS:A; the correlations with Drowsiness, Relaxation, and Nonconscious Involvement approached 0. The scales derived from Shor's analysis, however, did not improve the prediction of hypnotizability over that obtained with the absorption scale (Tellegen & Atkinson, 1974).

Van den Bergh, Omer; Eelen, Paul; Baeyens, Frank (1989). Brief exposure to fear stimuli: Imagery ability as a condition of fear enhancement and fear decrease. Behavior Therapy, 20, 563-572.

Examined fear enhancement and fear decrease during brief exposure to fear stimuli. 140 good and poor imagery Subjects (aged 14-18 years) with medium fear levels toward spiders were exposed to a live spider, either by looking at it or by thinking of an invisible, but present spider during either 60, 180, or 360 sec. Control Subjects were given a distraction task. Subjective fear and behavioral approach were measured. Brief exposure hindered fear decrease compared to the control condition. Good imagers showed more fear decrease and were less affected by the mode of exposure. Fear enhancement occurred only in poor imagers at the longer exposure duration (360 sec) during thinking. In that condition, good imagers showed their greatest fear decrease.

de Groh, Margaret (1989). Correlates of hypnotic susceptibility. In Spanos, Nicholas P.; Chaves, John F. (Ed.), Hypnosis: The cognitive-behavioral perspective (pp. 32-63). Buffalo, NY: Prometheus Books.

#### NOTES

1:

The author describes a non-linear relationship between imagery and hypnotizability and between absorption and hypnotizability. People good at imagery may be high or low on hypnotizability scales; the same is true for people high on absorption trait. However, people low on those traits generally are low on measured hypnotizability.

1988

Cross, W. P.; Spanos, Nicholas P. (1988-89). The effects of imagery vividness and receptivity on skill training induced enhancements in hypnotic susceptibility. Imagination, Cognition and Personality, 8, 89-103.

NOTES

1:

This article is cited by Spanos & Flynn (1989) as indicating that high hypnotizability requires imaginative skills that some people do not possess in sufficient degrees.

Dougherty, John E.; Payne, Paul A. (1988). The use of breathing rhythm to enhance the vividness of mental imagery. Imagination, Cognition and Personality, 8 (2), 175-179.

The study assessed Jencks' claim that responses to certain suggestions are enhanced by being paced with different phases of the breathing cycle. Following hypnotic induction, twenty-four subjects were given four treatments in counterbalanced order: 1) exhalation-enhanced suggestions paced to exhalation, 2) inhalation-enhanced suggestions paced to inhalation, 3) inhalation-enhanced suggestions counterpaced to exhalation, and 4) exhalation-enhanced suggestions counterpaced to inhalation. Subjects' reports of imagery vividness provided marginal support ( $p < .06$ ) for Jencks' hypothesis. Post-experimental inquiry indicated subjects were unaware of the breathing contingency. Results suggest that appropriate pacing may make a greater difference for the energy-confidence group of suggestions (inhalation-paced) than for the calm-relaxation group (exhalation-paced).

Katsanis, Joanna; Barnard, Joanna; Spanos, Nicholas P. (1988). Self-predictions, interpretational set and imagery vividness as determinants of hypnotic responding. Imagination, Cognition and Personality, 8 (1), 63-77.

Two studies assessed the effects of self-predictions and interpretations of suggested demands on hypnotizability. Subjects overestimated their responsiveness to suggestions. Those who believed that they would fail all or almost all suggestions invariably attained low hypnotizability scores. However, those who believed that they would be highly responsive exhibited wide variability in their actual hypnotizability. Among subjects who self-predicted high responsiveness, those who adopted a passive "wait and see" interpretation toward suggestions scored significantly lower in hypnotizability than those who believed that they should actively bring about suggested effects. Study 2 also found that the relationship between adopting an active interpretation and hypnotizability was moderated by subjects' level of imagery vividness. Theoretical implications are discussed.

Kumar, V. K.; Pekala, Ronald J. (1988). Hypnotizability, absorption, and individual differences in phenomenological experience. International Journal of Clinical and Experimental Hypnosis, 36, 80-88.

The phenomenological effects associated with a baseline condition of eyes- closed and a hypnotic induction condition were compared across individuals of differing absorption capacity and hypnotizability. The results indicated that individuals of differing absorption capacity and hypnotizability reported different intensities of phenomenological experience during the baseline eyes-closed condition. The induction further augmented intensity differences for low, medium, and high absorption and hypnotizable Ss, but more so for high (and medium) than low hypnotizable Ss. The results support both a trait and state interpretation of hypnotizability, and highlight the importance of the interaction between these factors on the resulting hypnotic experience of

#### NOTES

Based on a review of relevant literature, the authors predicted that (1) during hypnosis and a baseline condition (eyes-closed), high absorption and high hypnotizable Ss will report the phenomenological effects at greater intensity relative to low absorption and low hypnotizable Ss, respectively; (2) hypnotic induction will be associated with increased absorption; greater alterations in awareness and experience; and decreased volitional control, rationality, and memory; (3) phenomenological intensity differences (hypnosis compared to eyes-closed) will be significantly greater for high than for low hypnotizable Ss.

They used the Phenomenology of Consciousness Inventory (PCI) developed by Pekala (1982), which is a 53 item self-report instrument that is completed retrospectively in reference to a preceding stimulus condition. The PCI measures the following dimensions and subdimensions: internal dialogue; self-awareness; state of awareness; imagery (amount, vividness); positive affect (joy, sexual excitement, love); negative affect (anger, fear, sadness); altered experience (time sense, body image, perception, unusual meanings); attention (absorption, direction); memory; rationality; volitional control; and arousal.

The 217 Ss were administered the Tellegen Absorption Scale, then sat quietly with eyes closed for four minutes, then completed the PCI, Form 1, relative to that 4-minute period. They were administered a slightly shortened version of the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A); before the posthypnotic suggestion and amnesia suggestion they experienced another 4-minute silent period during which they were told to 'continue to experience the state you are in right now.' After the HGSHS:A they completed PCI, Form 2, in reference to the silent period during the HGSHS:A, before they completed the 11-point questionnaire on the HGSHS:A.

Subjects who did not have reliable PCI response forms were removed from the sample, leaving 173 Ss who were divided into high, medium, and low Absorption groups, and high, medium, and low hypnotizability groups. The statistical analysis employed MANOVA on intensity scores for first the major PCI dimensions and then the 14 subdimensions using Conditions (eyes closed, hypnosis) and Groups. There were significant main and interaction effects. Subsequent ANOVAs for each (sub)dimension, Conditions by Hypnotizability Groups (2 x 3) were then performed. Hypnosis "was associated with significantly less positive affect (joy, sexual excitement, love); negative affect (anger, sadness); visual imagery (amount,

vididness); self-awareness, internal dialogue, rationality, volitional control, and memory; and significantly more altered experience (time sense, perception) and altered state of awareness.

"Significant main effects for Hypnotizability Groups were found for positive affect (joy, love); altered experience (body image, time sense, perception, meaning); attention (direction, absorption); self-awareness; altered state of awareness; rationality; volitional control; and memory.

"Post-hoc comparisons for the eyes-closed condition revealed that high relative to low, hypnotizables reported significantly greater alterations in body image, time sense, meaning, and altered state of awareness. Medium hypnotizable Ss, compared to low hypnotizables, reported significantly increased alterations in body image and state of awareness.

"Post-hoc comparisons for the hypnotic induction condition revealed that high, viz-a-viz low, hypnotizables reported significantly increased absorbed attention; greater altered experience (body image, time sense, perception, meaning); and increased alterations in state of awareness. High hypnotizables also reported significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. Medium hypnotizable Ss, vis-a-vis low hypnotizables, reported significantly more altered experience (body image, time sense, perception, meaning); absorbed attention; and altered state of awareness; and significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. High hypnotizable Ss, relative to medium hypnotizables, reported significantly more altered experience (perception, meaning) and absorption, and significantly less rationality, volitional control, and memory.

"Concerning the significant interactions ( $\alpha = .01$ ), graphs of the means indicated significant ordinal interactions between Conditions and Hypnotizability Groups for altered experience (perception), imagery (vividness), self-awareness, altered state of awareness, rationality, volitional control, and memory. For all of the PCI (sub)dimensions, the hypnotic induction condition (compared to eyes-closed) was associated with a significantly greater increase in altered experience (perception), and altered state of awareness; and a significantly greater decrease in imagery (vividness), rationality, volitional control, and memory for the high (and medium) hypnotizable groups relative to the low hypnotizable group.

"Significant disordinal interactions were found for absorption and unusual meanings. Whereas high hypnotizable Ss reported a more absorbed attentional focus and more unusual meaning during hypnosis, low hypnotizable Ss reported being less absorbed (or more distracted) during the induction than eyes-closed. Low hypnotizables reported more unusual meanings in reference to eyes closed" (pp. 84-85).

Correlations among the major PCI dimensions, absorption, and hypnotizability differ between the two conditions. In hypnosis, the hypnotizability correlations that reached the .001 level were: --Self Awareness -.55 --State of Awareness .60 --Altered Experience .56 --Inward Absorbed Attention .44 --Rationality -.41 --Volitional control -.65 --Memory -.41 --Arousal -.28

In the eyes closed condition, the only PCI variables that Hypnotizability correlated with, at the .001 level, were: --Positive Affect .26 --Altered Experience .32

MANOVAs and ANOVAs were computed for Absorption groups in a similar fashion. Main effects but not interaction effects were significant. Results are not abstracted here.

In their Discussion, the authors note that "The three hypotheses were supported by the results. Several of the absorption group comparisons obtained in previous research (Pekala et al., 1985) involving alterations in subjective experience (body image, perception, meaning); state of awareness; and volitional control were replicated in the present research" (p. 85).

Spanos, Nicholas P.; Stenstrom, Robert J.; Johnston, Joseph C. (1988). Hypnosis, placebo, and suggestion in the treatment of warts. Psychosomatic Medicine, 50, 245-260.

Two experiments assessed the effects of psychological variables on wart regression. In Experiment 1, subjects given hypnotic suggestion exhibited more wart regression than those given either a placebo treatment or no treatment. In Experiment 2, hypnotic and nonhypnotic subjects given the same suggestions were equally likely to exhibit wart regression and more likely to show this effect than no treatment controls. In both experiments, treated subjects who lost warts reported more vivid suggested imagery than treated subjects who did not lose warts. However, hypnotizability and attribute measures of imagery propensity were unrelated to wart loss. Subjects given the suggestion that they would lose warts on only one side of the body did not show evidence of a side-specific treatment effect.

1987

Nadon, Robert; Laurence, Jean-Roch; Perry, Campbell (1987). Multiple predictors of hypnotic susceptibility. Journal of Personality and Social Psychology, 53, 948-960.

Report two experiments in which various measures thought to be related to hypnotizability were analyzed by stepwise discriminant analysis. Absorption and preference for an imagic style of thinking predicted hypnotizability. Addition of 2 other variables in Experiment 2--a Sleep-Dream score derived from Evans's Cognitive Control of Sleep Mentation subscale and Gibson's Dream Questionnaire, and the Belief in the Supernatural subscale of the Taft Experience Questionnaire--increased the correct classification of the medium-hypnotizable subjects from chance levels to 74%. Argue for a confirmatory and hierarchical approach in future studies to explore correlates of hypnotizability more fully. NOTES 1:

NOTES

The following notes were made at an SCEH presentation: [Robert Nadon, Hypnotizability: A Correlational Study Involving Experiential, Imagery, and Selective Attention Variables.]

Author used a number of variables that have related to hypnotizability in single measure studies to predict with a multiple r. 30 male and 30 female Ss, given Harvard (?) then screened on Form A, and finally on Form C. Classed as Low (0-2), Medium (5-10 without amnesia), and High (11-12 with amnesia).

Belicki, Kathryn; Belicki, Denis (1986). Predisposition for nightmares: A study of hypnotic ability, vividness of imagery, and absorption. Journal of Clinical Psychology, 42 (5), 714-718.

The relationships of nightmare frequency to hypnotic ability, vividness of visual imagery, and the tendency to become absorbed in fantasy-like experiences were examined. Subjects were 841 undergraduate university students who participated in group tests of hypnotic ability, after which they estimated the number of nightmares that they had experienced in the prior year. In addition, 406 of the subjects completed Marks' Vividness of Visual Imagery Questionnaire, and Rotenberg and Bowers' Absorption scale. Of the subjects, 76% reported experiencing at least one nightmare in the prior year; 8.3% indicated one or more per month. Individuals with frequent nightmares scored higher on hypnotizability, vividness of visual imagery, and absorption.

620, Belicki & Bowers, 1982

Investigated the role of demand characteristics in dream change by comparing dream report change following pre- and postsleep administrations of instructions to pay attention to specific dream content. This design was based on the assumption that if presleep instructions merely distort dream reports rather than influence actual dreams, report change should be observable following a postsleep instruction. 42 undergraduates were prescreened with the Harvard Group Scale of Hypnotic Susceptibility (Form A), which allowed experimenters to examine the role of hypnotizability in dream change. Significant differences were observed only following the presleep instructions. It is concluded that report distortion as a result of paying attention to a dimension of dream content was insufficient to account for dream report change following presleep instructions. Hypnotic ability correlated significantly with the amount of dream change.

Priebe, Frances A.; Wallace, Benjamin (1986). Hypnotizability, imaging ability, and the detection of embedded objects. International Journal of Clinical and Experimental Hypnosis, 34, 320-329.

40 Ss participated in an experiment designed to determine the influence of hypnotizability and imaging ability on cognitive performance. Individuals were asked to locate objects embedded within a series of pictorial scenes. For each scene, Ss were allocated a total of 6 minutes to find as many objects as possible. The objects were described to Ss prior to their search for them. Although there were no

significant differences in total number of objects found as a function of hypnotizability, high hypnotizable Ss made significantly fewer errors in locating and identifying objects. This difference was attributed to the superior ability of the high hypnotizability Ss in visualizing the hidden objects and in using produced images as a means for correctly identifying them. This did not appear to be the case for the low hypnotizability Ss.

It was this different in search strategy that may ultimately have led to the error difference between high and low hypnotizable Ss. NOTES 1:

#### NOTES

High hypnotizables "have been shown to be better able to resist distractions in a tracking task (Mitchell, 1970); to concentrate on their own breathing or on a candle flame (Van Nuys, 1973); to listen to a target story along with a nontarget story and to report what they could remember about the target story (Karlin, 1979); and to perceive Necker cube and Schroeder staircase illusory reversals (Wallace, Knight, & Garrett, 1976).

"Cognitive performance also has been shown to be influenced by imaging ability. For example, Paivio & Ernst (1971) found that when Ss were asked to identify letters, pictures, and geometric forms flashed to either the left or right visual field, those judged to be high imagers on a self-report test demonstrated better visual recognition. Similar findings were reported by Gur and Hilgard (1975) and Paivio (1978a, b).

"In addition to reports that imaging ability and hypnotizability affect performance on a variety of cognitive tasks, there have also been reports that these two variables are related, at least to some degree (Diamond & Taft, 1975; Palmer & Field, 1968; Sutcliffe, Perry, & Sheehan, 1970). Some, however, have found that ... low imagers tend to be low in hypnotizability but high imagers may not necessarily be high in hypnotizability (Perry, 1973)" (pp. 320-321). A correlation between hypnotizability and imaging ability also was found by T'Hoen (1978) in a paired associates learning task in which imagery and concreteness of the word pairs was varied; and by other investigators using other research designs (Gur & Hilgard, 1975; Paivio, 1978a, b; Paivio & Ernst, 1971).

Cognitive performance of high hypnotizable people was superior to low hypnotizables when the task was locating an imbedded letter ('Z') or completing double-digit arithmetic problems (Wallace and Patterson, 1984), possibly because highs may be using imagery to facilitate their performance. Highs performed better in detecting small differences in picture pairs when hypnotized but not when awake (Crawford and Allen, 1983). It appears that both highs and lows may use memorization of details for task performance, but only highs switch to a 'holistic' cognitive processing style, and mostly during hypnosis. Actually, Wallace and Patterson (1984) found that highs also used a holistic strategy in the waking state, not just in the hypnotized condition.

In the present study, subjects were 40 volunteers (20 highly hypnotizable subjects with scores of 9-12 on the Harvard Group Scale of Hypnotic Susceptibility, and 20 lows with scores of 0-3). The task was to locate hidden objects in pictures, with level of difficulty rated as hard, medium, or easy. The outcome data were analyzed by

analysis of variance for hypnotizability, picture difficulty, and time (six successive 1-min periods).

In Session 1 subjects were administered the Harvard Scale and the Marks Vividness of Visual Imagery Questionnaire; in Session 2 the group Stanford Hypnotic Susceptibility Scale: C was administered.

Before the actual experimental task of circling hidden pictures within larger pictorial scenes, each subject was given a list of words representing things that were embedded in the scenes, and asked to visualize each item. Then they were given six minutes to complete the item-finding task. They received three scores: the total number of objects located in six minutes, the number of objects correctly found, and number of errors. The 2x3x6 ANOVA was performed for each of these three dependent variables.

Hypnotizability was not an important variable determining the number of correct objects located, but was significantly associated with the occurrence of fewer errors. Mean errors were 4.5 for Lows and 2.7 for Highs. Furthermore, hypnotizability was associated with using a 'holistic strategy' rather than a 'detail strategy' for finding items (self report on storing a memory of the list of objects-to-be found, preparatory to making the search, rather than checking back with the list during the search). Hypnotizability correlated with imaging ability  $r = .34, p < .05$ .

In their Discussion, the authors noted that low hypnotizable people did not tend to use imagery for locating hidden objects, but would glance back and forth between the list and the picture--sometimes using a check-off mark next to items. High hypnotizables spent an average of 20 seconds looking at the list and becoming more familiar with it before starting to try to find the hidden objects. "One can assume this was a preparatory step in the formation of images for a subsequent visual search and the deployment of a holistic strategy during the search.

"When asked why they engaged in their respective behaviors, low hypnotizables generally said that they were not too concerned with the list initially because they searched for hidden items by constructing objects out of discrepancies in the picture. Only when they found what they thought had the properties of an embedded object did the list become important. At that point they would refer back to the list to determine if the object was among those to be located. The list thus served as a tool for confirming the existence of an object they had found as well as a means for enabling them to double check which items they still had to find. High hypnotizable Ss generally claimed that they formed mental images in their heads for each item on the list. Once they found an object in the picture, they compared that object to the formed, mental image rather than referring back to the actual list.

"As was previously mentioned, Crawford and Allen (1983) only found a difference in cognitive strategy between high and low hypnotizable Ss in the hypnotic state. In the present study, however, a strategy difference between these groups was noted in the waking state but only in terms of number of errors produced. A significant difference between high and low hypnotizables was not found in terms of the number of objects correctly found in a pictorial scene within a set period of time. It is possible that had cognitive strategies used in the hypnotic state been compared to those used in the waking state, our results might have been different. It is equally plausible, however, that hypnosis is not the critical factor in producing the

difference between the results of the present study and those of Crawford and Allen (1983). It is possible that high hypnotizable Ss may show a holistic strategy when they are encouraged to involve themselves imaginatively and this encouragement is naturally provided in hypnosis, but it could also be present in the waking state if the task being used is appropriately structured. The task used in the present study is one that could be said to especially encourage the use of imagery, and in this sense, it may be relatively distinct from that used by Crawford and Allen. The fact that Ss practiced imagery on the element list beforehand simply reinforces the difference. Thus, the nature of the cognitive task may be what is at issue and not the presence or absence of hypnosis" (p. 327).

Slomoff, Daniel A. (1986, March). Hypnotic susceptibility, vividness of imagery and the ability to self-regulate pain in a cold pressor test (Dissertation, Fielding Institute). Dissertation Abstracts International, 46 (9), 3231-B.

"Previous studies suggested that subjects who used more vivid images and who are good hypnotic subjects are more involved in their imagery and therefore have better pain control. In this study, subjects were given the Harvard Group Scale of Hypnotic Susceptibility and the Sheehan-Betts Questionnaire Upon Mental Imagery and then exposed to a cold pressor test for pain. Previous studies had limitations using an imagery scale which only tested for visual imagery, asking subjects to learn a new cognitive strategy, and limiting the study to female subjects. This study used both an objective and subjective multisensory test of imagery, tested for both genders, and allowed subjects to use their inherent cognitive strategies. "It was hypothesized that hypnotically susceptible subjects would demonstrate greater pain tolerance and pain intensity. This was not supported. It was also hypothesized that subjects who scored high on pain intensity control and this was also not supported. It was discussed that the instruments may not be strong enough to measure differences when pain tolerance and pain control are being looked at. "It was further predicted that there would be an interaction effect between hypnotizability and vividness of imagery for pain tolerance and pain intensity control. The results did not support this hypothesis. the author felt that it might be necessary to compare high and low imagers rather than high and medium imagers in this study. In that case the degree of difference between the groups might be great enough to demonstrate the interaction effects. As was predicted, it was found that highly hypnotizable subjects who were good imagers did use more imagery and rated this imagery as more effective and more vivid. "It is suggested that future research assess the type of imagery associated with a specific kind of pain experience. Pain as the result of temperature, pressure, or electrical stimulation might require different imagery as a cognitive coping strategy. Appropriate assessment tools will then need to be developed in this regard" (p. 3231).

Spanos, Nicholas P.; Robertson, Lynda A.; Menary, Evelyn P.; Brett, Pamela J. (1986). Component analysis of cognitive skill training for the enhancement of hypnotic susceptibility. Journal of Abnormal Psychology, 95, 350-357.

Four treatments to enhance the hypnotic responsiveness of subjects who pretested as low in hypnotic susceptibility were compared. Complete skill training included information aimed at encouraging (a) positive attitudes, (b) the use of imagery strategies, and (c) an interpretation of hypnotic behavior as active responding. Partial training included only components (a) and (b). Both training packages enhanced attitudes toward hypnosis to an equivalent degree. However, complete training was much more effective than either partial training or no treatment at enhancing behavioral and subjective responding on two different posttest scales of hypnotic susceptibility. More than half of the subjects who received complete training, but none of the partial training or control subjects, scored in the high-susceptibility range on both posttests. Subjects explicitly instructed to fake hypnosis and those in the complete skill-training treatment exhibited significantly different patterns of posttest responding. Findings support social psychological perspectives that emphasize the importance of contextual factors in hypnotic responding.

Strosahl, K. D. (1986). Imagery assessment by self report: A multidimensional analysis of clinical imagery. Cognitive Therapy and Research, 187-199.

Conducted 2 studies to test the theory that emotive-abstract, sensory modality, and control imagery are functionally distinct abilities and that emotive-abstract imagery and image control are directly related to the quality of in-therapy imagery. In Study 1, 199 undergraduates completed self-report measures of sensory modality, molar imagery, and image control and completed an analog clinical visualization task. In Study 2, 53 undergraduate test-anxious covert behavior therapy participants completed the self-report battery and provided ratings of in-therapy image clarity. Results suggest that emotive/abstract imagery, sensory modality imagery, and image control are factorially distinguishable abilities. A cross-sample factor analysis revealed some instability; however, a theoretically consistent pattern of results emerged. Regression analyses demonstrated that emotive-abstract imagery abilities were the best predictors of performance on the analog task, whereas both image control and emotive imagery were related to the clarity of in-therapy imagery. Results illustrate the qualitative difference between low- and high-order image processes and the possible interaction between emotive imagery and image control.

1985

Acosta, Enrique; Crawford, Helen J. (1985). Iconic memory and hypnotizability: Processing speed, skill or strategy differences?. International Journal of Clinical and Experimental Hypnosis, 33, 236-245.

The purported relationship between hypnotizability and speed of information transfer from iconic to short-term memory was studied in a comparison of 12 low and 12 high hypnotizable Ss. As in Ingram, Saccuzzo, McNeill, and McDonald (1979), high hypnotizable Ss showed less interference from a visual mask in the report of a briefly presented item than did low hypnotizable Ss when the mask delays were predictable. When the delay of the mask could not be anticipated, however, differences between high and low hypnotizable Ss disappeared.

It is suggested that differences in information processing related to hypnotizability may be due to differences in strategy, skills, or other factors, rather than underlying information processing speed.

## NOTES

Hypnosis may require concentrative or selective attention, which usually is measured by self-report (e.g. Absorption) or by experimental measures. Several investigations indicate that high hypnotizable people are better than low hypnotizables at focusing on a task and ignoring extraneous information (Brown, Crawford, Smith, Leu, & Brock, 1983; Graham & Evans, 1977; Karlin, 1979; Miller, 1975; Wallace, 1979; Wallace, Garrett, & Anstadt, 1974; Wallace, Knight, & Garrett, 1976). One way to study attentional processes is through the effect of presenting a mask (e.g. \$\$\$\$) shortly after presenting a stimulus (e.g. ABCDE). Ingram (1979) found that highs had faster information processing, but that might be due to anticipation bias associated with the method of limits employed. This study uses both an ascending method of limits, like Ingram, and a condition in which the mask delays were presented randomly within another block of trials.

## RESULTS

"While the present study replicated Ingram et al.'s (1979) findings when an ascending method of limits was used (the same used by Ingram et al.) differences were not found in processing when ISIs were presented randomly. Thus, these results suggest that high and low hypnotizable Ss do not differ in their information transmission rates, but rather they may differ in other aspects which mediate performance in this task" (pp. 241- 242).

"Several lines of evidence point towards strategy or skill differences between high and low hypnotizable Ss as a possible explanation for the present findings. First, it was found that when Ss could anticipate the mask delay (the ascending condition), high hypnotizable Ss outperformed the low hypnotizables. When this anticipation was controlled, as in the random condition, the two groups did not differ when the data were scored by serial position. When the data were scored by a free recall scheme, there was a nonsignificant trend for high hypnotizable Ss to score higher than did the low hypnotizables. This trend suggests that high hypnotizable Ss may be more willing to guess, and to guess more accurately than low hypnotizables, when they have partial information about a letter, and/or they may have greater skill in perceiving incomplete information. The latter suggestion finds indirect support from Crawford (1981) who reported that high hypnotizable Ss can process fragmented stimuli (Gestalt Closure tests, see Thurstone & Jeffrey, 1966), significantly better than can low hypnotizables. High imagers have been shown also to perform significantly better than low imagers in Gestalt Closure tasks (Ernest, 1980). At a speculative level, given that recent research has suggested that iconic memory may be a right hemisphere phenomenon (e.g. Cohen, 1976, but also see DiLollo, 1981), and high hypnotizable Ss outperform low hypnotizables on certain right hemisphere tasks (e.g. Crawford, 1981), it may be asked if the trends found with the free recall scoring scheme in the present study might be a reflection of differential right hemisphere processing. Such a hypothesis could be investigated in

future research by comparing the performance of high and low hypnotizable Ss, as possibly moderated by visuo-spatial ability, for stimuli presented to the left versus the right visual hemifield (Ernest, 1983).

"A second set of evidence in favor of strategy differences was found in Saccuzzo et al. (1982) which was published after the data for the present experiment were collected. In the Saccuzzo et al. (1982) paper, which was an extension and replication of Ingram et al. (1979), the same mask delay was used throughout a 10-trial block. The order of the blocks (i.e., the mask delays) was random. Thus, while S did not know which mask delay was used in the first trial of a block, the remaining 9 trials were the same and could be anticipated. During the first session, high hypnotizable Ss outperformed the low hypnotizables, but these differences disappeared on the second testing session. These results suggest that practice may have affected performance, rather than any underlying information processing speed differences" (pp. 242-243).

Nogrady, Heather; McConkey, Kevin M.; Perry, Campbell (1985). Enhancing visual memory: Trying hypnosis, trying imagination, and trying again. Journal of Abnormal Psychology, 94 (2), 195-204.

Tested visual recall memory of high (n = 24) and low (n = 24) hypnotizable undergraduates (screened under the Harvard Group Scale of Hypnotic Susceptibility and the Stanford Hypnotic Susceptibility Scale) for black and white line drawings of common objects in either hypnosis, imagination, or control conditions. Memory performance in terms of both correct and incorrect items increased appreciably across the recall tests. Neither hypnosis nor imagination enhanced recall beyond that of normal repeated testing. Hypnotizability was not related to the amount of correct material recalled but was related to the amount of incorrect material reported. High hypnotizable Ss in the hypnosis condition were more likely than other Ss to confidently rate the incorrect material as correct. Findings are discussed in terms of the impact of hypnosis on and the relevance of hypnotizability to enhancing visual memory.

Wallinga, Gary Alan (1985, January). Imagery enhancement: The effects of hypnosis and practice (Dissertation, University of South Dakota). Dissertation Abstracts International, 45 (7), 2326-B.

This study examined the imagery enhancement effects of hypnosis and imagery practice. It also compared the effects of these imagery enhancement techniques when administered to individual subjects as compared to groups of subjects. The sample consisted of 120 undergraduate male student volunteers who were randomly assigned to each of the experimental conditions: 1) imagery practice, 2) hypnosis, 3) hypnosis followed by imagery practice, 4) imagery practice followed by hypnosis, 5) inert treatment control. Each experimental condition was administered to an equal number of subjects individually and in groups. Subjects' self-reports of imagery vividness and imagery control were obtained following administration of the experimental procedures. Three standard imagery questionnaires were used: 4)

Betts' (1909) Questionnaire Upon Mental Imagery, as revised by Sheehan, 2) the Guy Emotive Imagery Scale, (Guy and McCarter, 1978), and 3) Gordon's (1949) Test of Visual Imagery Control, as revised by Richardson, (1969). According to the results obtained in the present study, the effectiveness of imagery enhancement was not supported. Imagery enhancement techniques involving hypnosis decreased subjects' imagery vividness and control while techniques using imagery practice had no effect on imaginal functioning. The results further suggested that across all experimental conditions, subjects trained in groups did not differ significantly from those trained individually. Previous research provides both conflicting and supportive evidence for these results. It is suggested that future research will need to examine differences in experimental processes, uncontrolled for subject characteristics, and alternative dependent measures, in order to reconcile these discrepant findings" (p. 2326).

1984

Billotti, Thomas J. (1984, August). The effects of rational emotive imagery and rational emotive imagery plus hypnosis in reduced public speaking anxiety (Dissertation). Dissertation Abstracts International, 46 (2), 633-634-B.

Previous investigations have demonstrated the effectiveness of rational emotive therapy in reducing public speaking anxiety and the increased benefit derived by combining rational emotive procedures with hypnosis. The present study examined the effectiveness of rational emotive imagery and rational emotive imagery plus hypnosis in reducing public speaking anxiety in subjects with high and low levels of imaginative ability. The dependent measures employed included self report, behavioral and physiological measures of anxiety. "47 undergraduate students who reported anxiety while speaking in public served as subjects in the study. The subjects were divided into high and low levels of imaginative ability and randomly assigned to one of three experimental groups as follows: rational emotive imagery, rational emotive imagery plus hypnosis, and an instructional control group. It was hypothesized that subjects in the rational emotive imagery plus hypnosis group would evidence significantly less anxiety than subjects in the rational emotive imagery and instructional control group, and that subjects with high pre-treatment levels of imaginative ability would evidence significantly less anxiety than subjects with low pre-treatment levels of imaginative ability. "The results of this study provided some support for the efficacy of combining rational emotive imagery with hypnosis. Subjects in the rational emotive imagery plus hypnosis group evidenced significantly less anxiety than subjects in the rational emotive imagery and instructional control group on the two self-report measures. There were no significant differences as between subjects in the rational emotive imagery group and instructional control group or between subjects with high and low imaginative ability on post-treatment assessments. Subjects tended to have their highest pulse rates at the start of the speeches, their lowest pulse rate just after the speeches, and moderate pulse rates just before and during the speeches. "Factors contributing to these results and interpretations of the data were discussed. Suggestions regarding the direction of future research were offered" (p. 633- 634).

1984

Kearns, John S.; Zamansky, Harold S. (1984). Synthetic versus analytic imaging ability as correlates of hypnotizability. International Journal of Clinical and Experimental Hypnosis, 32, 41-50.

It was hypothesized that synthetic imaging ability, but not analytic imaging ability, is positively related to hypnotizability. The correlation of scores on a paired-associates task, used as a measure of synthetic imaging ability, with scores on the Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) of Weitzenhoffer and Hilgard (1962), indicated a statistically nonsignificant trend in the predicted direction. 2 measures of analytic imaging ability, as well as Sheehan's (1967) revision of the Betts (1909) Questionnaire Upon Mental Imagery, a measure of vividness of imagery, did not correlate significantly with SHSS:C. The results are discussed in terms of their relation to studies of creativity and goal-directed fantasy.

#### NOTES

The authors review the literature on imagery and hypnotizability and propose that an important variable in hypnosis is an ability to expand imaginatively upon a given verbal input (synthetic imaging ability), akin to Spanos' (1971) concept of goal-directed fantasy. They cite studies relating creativity ("essentially a synthetic process") to hypnotizability, and predict that skill in solving spatial relations problems (analytic imaging ability) is not correlated with hypnotizability because it involves "accurately scanning visual images and converging on solutions to specific problems," (p. 42) rather than creative fantasy characteristic of hypnotic behavior. Forty Subjects had two sessions each: imagery tests in #1 and SHSS:C in #2. Imagery tests included, in this order: 1. Paired Associates (Paivio, 1972; a test of synthetic imaging), in which paired words are learned and later recalled; Experimental Ss were to learn them by combining them into an image, while Control Ss were to simply try to learn them. The nouns differed in imagery strength (potential for stimulating images). 2. Nonsense Forms (a test of analytic imaging), in which Subjects trace with their fingers an irregularly shaped Masonite form, blindfolded, and then choose one of 5 drawings that best matches the form. 3. Cube Visualization (a test of analytic imaging), in which Ss imagine a 2" wooden cube painted red on all faces, that had been sawed into 1" cubes; they are to say how many of the smaller cubes would be red on 3 faces, 2 faces, one face, and none of the faces. 4. Betts QMI.

The Paired Associates (PA) scores were a ratio of high imagery words recalled to low imagery words recalled, intended to reflect the impact of imagery availability on memory. There was a trend for hypnotizability to correlate with PA ratio scores, regardless of whether intermediate or low imagery nouns were used as baseline ( $\rho = .37$  and  $.34$ ,  $p < .10$ ) in the experimental group ("Use imagery to learn."), a trend that was not found in the control group (no imagery instructions). Neither measure of analytic imaging ability (Nonsense Forms, Cube test) correlated with hypnotizability.

In their Discussion, the authors write, "The common factor in successful performance of both imagery-mediated paired associates learning tasks and hypnotic suggestions appears to be the ability to expand imaginatively upon a given verbal input" (p. 47). They cite the literature relating hypnotizable and creative performance (p. 47). "The present findings with the Nonsense Forms Test and the Cube Visualization Test, both of which failed to correlate significantly with SHSS:C, support the hypothesis that hypnotizability is not related to analytic, spatial-imagining skills" (p. 47). "The nonsignificant correlation between Betts QMI and SHSS:C adds to the growing body of inconsistent findings observed with Betts QMI" (p. 47).

"Given the complex nature of hypnotic susceptibility and of imagery (Monteiro et al., 1980), it is perhaps not surprising that studies attempting to relate the two variables directly frequently yield only modest relationships. Very likely, the inclusion of appropriate mediating variables would serve to clarify and, in particular instances, augment the relationships observed between hypnotic responsiveness and imaging ability. One such variable may be the capacity to become fully involved in everyday nonhypnotic experiences, commonly called absorption. This variable has been shown in numerous studies to be related to hypnotizability (e.g. Tellegen & Atkinson, 1974), as well as to creativity and vividness of imagery (P. Bowers, 1978, 1979; Monteiro et al., 1980). Even more relevant to the present study is the possible interaction between level of hypnotic susceptibility and the relationship between synthetic imaging ability and SHSS:C scores. It may be, for example, that the contribution of synthetic imaging ability becomes more critical in eliciting hypnotic behavior from Ss who are only moderately susceptible to hypnosis. Such an analysis was not possible in the present experiment, since the number of high, medium, and low susceptible Ss was approximately equal, and, therefore, the number of Ss at each level was insufficient for an adequate subgroup analysis. Clearly, however, future studies of the role of imaginal skills in hypnotic responsivity must move in directions such as these" (p. 48).

1983

Crawford, Helen J.; Allen, Steven N. (1983). Enhanced visual memory during hypnosis as mediated by hypnotic responsiveness and cognitive strategies. Journal of Experimental Psychology: General, 112 (4), 662-685.

To investigate the hypothesis that hypnosis has an enhancing effect on imagery processing, as mediated by hypnotic responsiveness and cognitive strategies, four experiments compared performance of low and high, or low, medium, and high hypnotically responsive subjects in waking and hypnosis conditions on a successive visual memory discrimination task that required detecting differences between successively presented picture pairs in which one member of the pair was slightly altered. Consistently, hypnotically responsive individuals showed enhanced mean number of correct performance during hypnosis, whereas nonresponsive ones did not. Hypnotic responsiveness correlated .52 ( $p < .001$ ) with enhanced performance

during hypnosis, but it was uncorrelated with waking performance (Experiment 3). Reaction time was not affected by hypnosis, although high hypnotizables were faster than lows in their responses (Experiments 1 and 2).

#### NOTES

Subjects reported enhanced imagery vividness on the self-report Vividness of Visual Imagery Questionnaire during hypnosis. The differential effect between lows and highs was in the anticipated direction but not significant (Experiments 1 and 2).

Two cognitive strategies appeared to mediate visual memory performance: (a) detail strategy (memorization and rehearsal of individual details) and (b) holistic strategy (looking at and remembering the whole picture with accompanying imagery). Both lows and highs reported predominantly detail-oriented strategies during waking; however the highs shifted to a more holistic strategy during hypnosis. It appears that high hypnotizables have a greater capacity than lows for cognitive flexibility (Battig, 1979).

Results are discussed in terms of Paivio's (1971) dual coding theory and Craik and Tulving's (1975) depth of processing theory. The authors also discuss whether hypnosis involves a shift in cerebral dominance, as reflected by the cognitive strategy changes and enhanced imagery processing.

Farthing, G. William; Venturino, Michael; Brown, Scott W. (1983). Relationship between two different types of imagery vividness questionnaire items and three hypnotic susceptibility scale factors: A brief communication. International Journal of Clinical and Experimental Hypnosis, 31, 8-13.

122 Ss were administered the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962), the Tellegen Absorption Scale (Tellegen & Atkinson, 1974), and 2 tape-recorded questionnaires on vividness of mental imagery. On 1 imagery questionnaire the items were impersonal, objective visual scenes (MIQ:VS), whereas on the other questionnaire the items involved discrete personal actions which elicited a combination of visual and kinesthetic imagery (MIQ:PA). Imagery vividness scores from both questionnaires correlated significantly with hypnotizability scores. MIQ:VS vividness scores were better than MIQ:PA vividness scores at predicting cognitive factor item scores of HGSHS:A, but not ideomotor or challenge factor items scores. Multiple correlations involving MIQ:VS vividness and the Tellegen predicted cognitive factor scores better than ideomotor or challenge factor scores.

#### 1982

Crawford, Helen J. (1982). Hypnotizability, daydreaming styles, imagery vividness, and absorption: A multidimensional study. Journal of Personality and Social Psychology, 42 (5), 915-926.

In 25 male and 31 female university student and staff volunteers, the interrelationships between the following measures were studied: hypnotic susceptibility (SHSS:A and C), imagery vividness (VVIQ), involvement in everyday

activities (TAS), and daydreaming styles (28 scales of Singer & Antrobus's Imaginal Processes Inventory). Factor analysis produced a factor characterized as a positively vivid and absorptive imagination style. Hypnotic susceptibility, VVIQ, TAS, and positive-affect daydreaming styles all loaded on this factor. Two other factors were a dysphoric daydreaming style and a lack-of-attentional-control style. Stepwise multiple regressions suggested that males and females, at least within this sample, exhibit different relationships between hypnotic susceptibility and predictor variables. Similar differences were found for the VVIQ and the TAS and their daydreaming-scale predictor variables.

Smigielski, Jeffrey Steven (1982). Imagery enhancement: An investigation of the effects of hypnosis and practice (Dissertation, University of South Dakota). Dissertation Abstracts International, 43 (n6-B), 2004. (Order No. DA 8226277)

A variety of psychotherapeutic techniques utilize imagery procedures. Many of these are considered to be dependent upon the participant's ability to produce clear, vivid, and manipulable imagery. Clinical procedures have been devised to attempt to enhance imagery ability, in order to obtain maximum therapy effectiveness. The present study was designed to assess the effectiveness of three variations of enhancement procedures. Eighty undergraduate student volunteers, paid for their participation, were selected on the basis of screening for level of hypnotic susceptibility. Ten high susceptibility and ten low susceptibility individuals were randomly assigned to each of 4 experimental conditions: (1) imagery practice only (PR), (2) hypnosis only (Hypnotic), (3) hypnosis plus practice (Help), and (4) inert treatment control (Can). Ss' self reports of imagery vividness and imagery control were obtained following administration of the experimental procedures. Three standard imagery questionnaires were used for this purpose: (1) Betts' (1909) Questionnaire Upon Mental Imagery (QMI), as revised by Sheehan (1967), (2) the Guy Emotional Imagery Scale (GEIS, Guy and McCarter, 1978), and (3) Gordon's (1949) Test of Visual Imagery Control (TVIC), as presented in Richardson (1979). Analyses of variance using the QMI and GEIS as dependent variables yielded no significant treatment effects. Significant differences were noted in analysis of TVIC scores. Post hoc analysis of differences indicated that low susceptibility individuals assigned to the Help condition reported significantly lower imaginal control in comparison with low susceptibility individuals in the PR and Hypnotic conditions, and with high susceptibility controls. They did not differ significantly from low susceptibility controls. Results were interpreted as failing to support the effectiveness of imagery enhancement procedures. Results were considered to be generally consistent with previous work. Suggestions for further research were discussed. Comparison of group versus individually administered enhancement procedures was considered likely to be especially important in future research" (p. 2004).

1981

Hilgard, Ernest R.; Sheehan, Peter W.; Monteiro, K. P.; Macdonald, Hugh (1981). Factorial structure of the Creative Imagination Scale as a measure of hypnotic

responsiveness: An international comparative study. International Journal of Clinical and Experimental Hypnosis, 29, 66-76.

The factor structure of the Creative Imagination Scale (CIS) of Wilson and Barber (1978) was investigated in two studies by correlating scores on it with scores on the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962), the Absorption scale of Tellegen and Atkinson (1974), and Sheehan's (1967) revision of Betts' (1909) imagery scale. One of the studies was conducted at the University of Queensland in Australia (N = 237), the other at Stanford University in California (N = 92). The major finding, consistent in both investigations, was that two factors accounted for the major portion of the variance, one factor designated as a Hypnotic Performance factor, the other designated as an Absorption/Imagination factor. The CIS was weighted highly on both factors, the data bearing on earlier claims that CIS represents a single-factor scale.

Singer, Jerome L.; Pope, Kenneth S. (1981). Daydreaming and imagery skills as predisposing capacities for self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 271-281.

A growing body of empirical literature suggests that daydreaming and related forms of waking reverie are natural-occurring, common experiences in normal individuals. Specific experiments relating daydreaming and the stream of ongoing thought as an alternative source of stimulation to external cues are described. It is proposed that everyday waking consciousness has many features of internal absorption in imagery and adaptive but non-sequential processes that resemble fantasy, hypnosis, and night dreaming. Experiments linking daydreaming, imagery vividness, and hypnosis are cited as suggesting that individuals may develop capacities for control over the stream of thought and that such capacities are closely similar to the skills needed for self-hypnosis.

1980

Coe, William C.; St. Jean, R. L.; Burger, J. M. (1980). Hypnosis and the enhancement of visual imagery. International Journal of Clinical and Experimental Hypnosis, 28, 225-234.

The enhancing effect of hypnosis on the vividness and the control of imagery was investigated. In 1 experiment, Ss who volunteered to be hypnotized were administered 2 measures of imagery, 1 under hypnotic conditions and 1 under imagination instructions while waking (counter-balanced). In another experiment, the imagery of 2 independent samples of Ss (waking or hypnotized) who volunteered for an imagery experiment was evaluated. Of the samples, hypnosis enhanced the vividness and control of imagery in only 1 -- the sample with Ss who volunteered for hypnosis and were first administered a test of imagination while awake. Between the 2 independent samples, control of imagery was reduced in the hypnotized sample. There were no differences in the findings on vividness and control of imagery across high, medium, and low susceptible Ss. Combining all Ss, the correlation between

vidness of visual imagery and hypnotic responsiveness was significant for males ( $r = .52$ ) and the total sample ( $r = .33$ ) but not for females ( $r = .15$ ). Similar correlations for the control of imagery were not significant for males or females alone, but they were for the total sample ( $r = .18$ ). The implications of the results are discussed in light of their relevance to theory, future research, and clinical practice.

Straus, R. A. (1980). A naturalistic experiment investigating the effects of hypnotic induction upon Creative Imagination Scale performance in a clinical setting. International Journal of Clinical and Experimental Hypnosis, 28 (3), 218-224.

A novel experimental design compared performances on the Creative Imagination Scale (CIS) of Wilson and Barber (1978) under hypnotic induction and control conditions. The Ss were 42 paying clients who participated in the study as an implicit part of their first clinical session. Results in this clinical context replicated previous laboratory studies which found that a conventional hypnotic induction procedure did not enhance scores on CIS. The present study suggests that the implicit clinical investigation, where appropriate, permits scientifically sound hypnosis research in natural field settings.

1979

Spanos, Nicholas P.; Ansari, Ferhana; Stam, Henderikus J. (1979). Hypnotic age regression and eidetic imagery: A failure to replicate. Journal of Abnormal Psychology, 88 (1), 88-91.

Walker, Garrett, & Wallace (1976) reported the restoration of eidetic imagery in hypnotically age-regressed subjects. In an attempted replication of that study, 60 subjects who previously scored high on hypnotic susceptibility were 'hypnotically regressed' to age 7. Before administration of the hypnotic procedures and again after age regression, subjects were tested for eidetic imagery using the random-dot stereograms employed by Walker et al. None of our subjects including those who were age regressed according to standard criteria and who reported having been eidetikers as children, were successful at the stereogram tasks. Although these results fail to replicate those of Walker et al., they are consistent with the available evidence concerning the performance of children on stereogram tasks. Contrary to the impression conveyed by Walker et al., children tested to date, including those classified as eidetikers by Haber and Haber's criteria, have been unsuccessful at stereogram tasks.

1978

Dyckman, John M.; Cowan, Philip A. (1978). Imaging vividness and the outcome of in vivo and imagined scene desensitization. Journal of Consulting and Clinical Psychology, 46 (5), 1155-1156.

This study reexamined the role of imaging vividness in desensitization success. Scores on the Betts Questionnaire on Mental Imagery were used to divide 48 snake-phobic subjects into high, medium, and low vivid groups, who were assigned to

imagined scene or in vivo desensitization treatments. Imaging vividness was assessed at scheduled points during therapy. Significant decreases in behavioral and self-reported fear were observed after both treatments, though in vivo desensitization produced significantly greater fear reduction. In therapy imaging vividness scores were significantly correlated with therapeutic success and were superior to pretherapy ratings as predictors of outcome.

Hiscock, Merrill (1978). Imagery assessment through self-report: What do imagery questionnaires measure?. Journal of Consulting and Clinical Psychology, 46, 223-229.

Four studies examined imagery questionnaires and addressed issues of reliability, agreement among different questionnaires, social desirability, and construct validity. The Betts, Paivio, and Gordon scales were examined. In two studies the Betts and Paivio correlated .45-.50, but correlations involving the Gordon were inconsistent from one study to the next. Imagery measures generally were not influenced by social desirability. Factor analysis indicated that subjective and objective measures of visualization are independent. Concludes that imagery is not a unitary construct and that criteria other than visuospatial tests may be appropriate for validating imagery questionnaires.

t'Hoen, P. (1978). Effects of hypnotizability and visualizing ability on imagery mediated learning. International Journal of Clinical and Experimental Hypnosis, 26, 45-54

The Ss selected for hypnotizability and visualizing ability were tested for their performance on an imagery-mediated, paired-associates task in which the stimulus materials were varied in imagery and concreteness. Imagery and concreteness showed significant main effects and an additive interaction facilitating learning. Neither hypnotizability nor visualizing ability showed main effects, thereby contradicting the conjecture that those 2 factors would facilitate imagery-mediated learning. However, high hypnotizable Ss learned more high imagery words than the low hypnotizables, and visualizing ability was shown to interact with word concreteness. It is concluded that the effects of hypnotizability and visualizing ability on verbal learning are, at least in part, a function of the content of the words to be learned.

1977

Buckner, Linda G.; Coe, William C. (1977). Imaginative skill, wording of suggestions and hypnotic-susceptibility. International Journal of Clinical and Experimental Hypnosis, 25, 27-36.

3 groups of 20 s based on preselected imaginative capacity were administered either a hypnotic susceptibility scale containing item wording that suggested a goal-directed fantasy or one that did not. Preselected imaginative ability did not predict hypnotic susceptibility or the production of goal-directed fantasies during hypnosis.

However, Ss who received the hypnotic scale containing item wording that suggested goal-directed fantasies reported more goal-directed fantasies than Ss who received the other scale. Limitations of the study are discussed and the causal role of goal-directed fantasy in hypnotic responsiveness is questioned.

1976

Slade, P. D. (1976). An investigation of psychological factors involved in the predisposition to auditory hallucinations. Psychological Medicine, 6 (1), 123-132.

Previous research by the author (Slade, 1972, 1973) and others has suggested that psychological stress plays an important role in triggering off the experience of auditory hallucinations. Clearly, however, predispositional factors are involved as well. The present study is an attempt to investigate some of the psychological factors which may predispose the individual to such experiences. A battery of tests involving cognitive, personality and mental imagery variables and the verbal transformation effect was administered to two small groups of psychotic patients differing only in respect of a history of auditory hallucinations and a normal control group. The main conclusion was that the results lend direct support to the proposition of Mintz & Alpert (1972) that a combination of vivid mental imagery and poor reality-testing in the auditory modality provides the basic predisposition for the experience of auditory hallucinations. 6458, Slade, 1976

1970

Davis, Daniel; McLemore, Clinton W.; London, Perry (1970). The role of visual imagery in desensitization. Behaviour Research and Therapy, 8 (1), 11-13.

#### NOTES

Summary: a measure of visual imagery ability was obtained for 33 females who and participated in desensitization therapy for snake phobia. Visual imagery was positively related to pretherapy performance (closeness of approach to a live snake), but not to improvement. On the basis of these results and the results of two other studies, it was hypothesized that the fear of good imagers tends to be based on imagination while that of poor imagers tends to be based on sensory experience.

Most psychologists now recognize behavior therapy as effective in alleviating a wide variety of fears, but the nature of the processes underlying the various methods remains an open issue. Imagery has been of particular interest as a possible common denominator among various desensitization techniques. Lazarus (1961), for example, asserts that a "prerequisite for effective application of desensitization is the ability to conjure up reasonably vivid images," and Wolpe (1961) claims, "it is essential for visualizing to be at least moderately clear." London suggests that theoretically opposed treatments such as reciprocal inhibition (Wolpe, 1958) and implosion (Stampfl and Levis, 1967) may both be facilitated by repeated imagery which "produces a discrimination set such that the patient learns to distinguish between the imaginative, cognitive, affective aspects of experience, and the sensory and overt muscular aspects" (1964, p. 130). However, no systematic studies linking

visual imagery to desensitization have been reported. This study examined the relationship between visual imagery and success in desensitization therapy

## IMAGINATION

2003

Holroyd, Jean (2003). The science of meditation and the state of hypnosis. American Journal of Clinical Hypnosis, 46 (2), 109-128.

Two aspects of Buddhist meditation -- concentration and mindfulness -- are discussed in relationship to hypnosis. Mindfulness training facilitates the investigation of subjective responses to hypnosis. Concentration practice leads to altered states similar to those in hypnosis, both phenomenologically and neurologically. The similarities and differences between hypnosis and meditation are used to shed light on perennial questions: (1) Does hypnosis involve an altered state of consciousness? (2) Does a hypnotic induction increase suggestibility? It is concluded that a model for hypnosis should include altered states as well as capacity for imaginative involvement and expectations.

Sapp, Marty; Hitchcock, Kim (2003). Creative imagination, absorption, and dissociation with African American college students. Sleep and Hypnosis, 5 (2), 95-104.

The purpose of this study was to assess creative imagination, absorption, and dissociation with African American college students. Two hundred thirty-six undergraduate African American students ranging between the ages of 18 to 22 participated in this study. Students were assigned to the following experimental manipulation: (a) Creative Imagination Scale (CIS), a cognitive-behavioral measure of hypnotizability; and (b) Dissociative Experiences Scale (DES), General Dissociation Scale (GDS), and Tellegen Absorption Scale (TAS) embedded within the CIS. Results indicated that dissociation and absorption were affected by the CIS. Finally, this sample was compared with the European American sample obtained by Barber and Wilson (1978) and Wilson and Barber (1978), and clearly the two samples differed on creative imagination,  $t(405)=7.00$ ,  $p<.005$ . The African American sample had a significantly lower mean CIS score than the European American sample.

Gibbons, Don E. (2001). Experience as an art form: Hypnosis, hyperempiria, and the Best Me technique. San Jose CA: Authors Choice Press. (([available online:] <http://www.iuniverse.com/bookstore/marketplace>))

### NOTES

The Best Me Technique is a procedure for constructing suggestions which incorporates many different dimensions of experience -- beliefs, emotions, sensations, thoughts, motives, and expectations -- for maximum involvement and effectiveness. Best Me suggestions may be used with either hyperempiria, an alert induction based on suggestions of mind expansion and increased alertness and sensitivity, or with more traditional forms of hypnotic induction.

Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)

This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; (3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain.

Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

Gibbons, Don (2000). Applied hypnosis and hyperempiria. New York NY: Plenum Press. ([available online:] <http://www.iuniverse.com/bookstore>)

The book features both traditional hypnotic procedures and hyperempiric inductions based on suggestions of increased awareness, mind expansion, and increased alertness and sensitivity. It contains sections on the use of suggestion as an instrument of personal growth in areas such as improving study skills, taking examinations, achievement motivation, artistic expression, emotional enrichment, aesthetic appreciation and enjoyment, interpersonal effectiveness, musical performance, problem solving, public speaking, salesmanship, sports performance, theatrical performance, and writing ability.

1999

Faymonville, M. E.; Meurisse, M.; Fissette, J. (1999). Hypnosedation: A valuable alternative to traditional anaesthetic techniques. Acta Chirurgica Belgica, 99 (4), 141-146.

Hypnosis has become routine practice in our plastic and endocrine surgery services. Revivication of pleasant life experiences has served as the hypnotic substratum in a series of over 1650 patients since 1992. In retrospective studies, followed by randomised prospective studies, we have confirmed the usefulness of hypnosedation (hypnosis in combination with conscious IV sedation) and local anaesthesia as a valuable alternative to traditional anaesthetic techniques. The credibility of hypnotic techniques and their acceptance by the scientific community will depend on independently-confirmed and reproducible criteria of assessing the hypnotic state. Based on the clinical success of this technique, we were interested in confirming this phenomenon in healthy volunteers. The revivication of pleasant life experiences thus served as the cornerstone of a basic research program developed to objectify the neurophysiological attributes of the hypnotic state. We compared hypnosis to normal alertness with similar thought content. In our experience, the activation profile obtained during the hypnotic state was completely different from simple re-memoration of the same subject matter during normal alertness. This represents an objective and independent criteria by which to assess the hypnotic state.

1998

Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..

NOTES

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful

and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

1995

Bryant, Richard A. (1995). Fantasy proneness, reported childhood abuse, and the relevance of reported abuse onset. International Journal of Clinical and Experimental Hypnosis, 43 (2), 184-193

This study investigated the relationship between fantasy proneness and the age at which reported childhood sexual abuse occurs. Seventeen adult females who reported having been sexually abused before the age of 7 years, 20 females who reported having been abused after the age of 7 years, and 20 females who reported having never been abused were administered two measures of imaginative involvement (Tellegen Absorption Scale [TAS] and Inventory of Childhood Memories and Imaginings [ICMI]). Participants who were reportedly abused early in childhood obtained higher scores on the TAS and ICMI than participants who were reportedly abused later in childhood, who in turn obtained higher scores than the control participants. Findings are discussed in terms of factors that mediate fantasy proneness and reports of childhood abuse.

Zamansky, Harold S.; Ruehle, Beth L. (1995). Making hypnosis happen: The involuntariness of the hypnotic experience. International Journal of Clinical and Experimental Hypnosis, 43 (4), 386-398.

The authors tested the hypothesis that hypnotized individuals do not truly experience their responses to suggestions as occurring involuntarily, but instead absorb themselves in imagery that is congruent with the suggestions while avoiding critical thoughts, or even simply comply with suggestions without genuinely experiencing their responses as nonvolitional. Participants were instructed to engage in thoughts and imagery that conflicted with the suggestions given, were urged to pay attention to their behavior, and were questioned regarding the perceived involuntariness of their responses. Simultaneously, electrodermal skin conductance responses provided a measure of the truthfulness of their reports. It was found that responses to all hypnotic suggestions were reported as being involuntary, in spite of the conflicting imagery and increased saliency, and that these reports were truthful. These findings provide disconfirming evidence for the sociocognitive theories of hypnosis.

Malinoski, Peter; Aronoff, Jodi; Lynn, Steven J.; Moretsky, Michael (1994, August). Hypnosis and early memories. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

#### NOTES

We studied autobiographical memory in the college population, as manifested in the therapy situation, as a way of investigating an individual difference variable. Most people do not have recall before age 3 or 4 (and probably infantile amnesia begins before age 2).

Administered Autobiographical Memory Scale (AMS), and later in context of a hypnosis scale. 247 students were in phase 1, conducted as two separate experiments so that Ss wouldn't link the AMS to measures used in the second study.

First study was presented as a study of personal memories. Asked Ss to distinguish first five birthdays, circumstances around loss of first tooth, first day of high school. Also, they were asked about their earliest memory events, rated according to 3 scales (detail, vividness, accuracy of recall). Authors summed Ss' responses on these 3 ratings for the 8 item scale.

Part II. Administered various scales: Life Experiences, Fantasy Proneness, Wilson & Barber's scale, Imagery Control Scale, Global Psychopathology, 25 item scale of physical and sexual abuse, Brier's list of symptoms of abuse, and DES (Dissociative Experiences Scale). Imbedded were 12 items to test carelessness in responding (e.g. "I have never said Hello to anyone who wore eyeglasses.")

#### RESULTS

Phase 1. Two people indicated they had memories dating to before their first birthday; an additional 5% of Ss gave memories between 12-24 months. This would probably be impossible. Another 14.4% described events between 24-36 months; 37.4% said their earliest memory was at age 3. Mean age for earliest memory was 3.4 years (which agrees with other surveys.) Only 1 subject stated his earliest memory was as late as the tenth year of life.

High intercorrelation was obtained, ranging .79 to .89, between ratings on any of the memory event ratings (as detailed, vivid, or accurate). There was a negative correlation of these ratings with age of recall. Ss who report more detail, vividness, and competence, were also likely to report earlier first memories.

Authors divided Ss into three groups based on age of first memory: 12 with first memory earlier than first year; those whose first memory was between 1-7 years; and those with a later first memory. The earlier memory group were more fantasy prone; and rated their memories as more reliable, vivid. This suggests there are persons who report memories that are covered by infantile amnesia, report them with greater detail, and are more fantasy prone than those who report memory events beginning later in life. This is consistent with Wilson & Barber's finding that fantasy prone people have vivid recall of early childhood events.

None of the memory reports correlated with psychopathology or dissociation. Dissociation (DES) was correlated with abuse indicators, however. Compared top and lowest 10% and middle range on DES on their memory scores and found no relationship. There was no support for the idea that report of early life events in dissociative people is compromised. Failure to recall early memories shouldn't suggest that people are dissociative (which some therapists tend to do).

All three memory measures were associated with Harvard Scale scores. The AMS was administered at the same time as the Harvard. Objective responding on the Harvard correlated with detail, vividness, and accuracy of recall. Also, involuntariness of response correlated with all 3 measures of the AMS. Finally, subjective involvement correlated with all three measures of AMS. At least when hypnosis is measured first, and explicit connection is suggested, there is a connection. Further research is needed to see if the relationship holds when measured in independent contexts. This may explain why High Hypnotizables are more prone to pseudo memories and leading questions. They may come to confuse them with historical reality.

The results suggest caution for early memory reports. They may be vulnerable to confusing fantasy and reality, as well as to biasing effects.

Smith, Julien T. (1994). Hypnosis and distraction in the relief of medical pains in an ethnically diverse population of young children (Dissertation, Washington State University, Pullman). Bulletin of Division 30, Psychological Hypnosis, APA, 4 (3), 11.

An ethnically diverse sample of children (N = 36) and their parents volunteered for the study and were trained, with the expectation of equal effects, to use both distraction and imaginative involvement to reduce pain and anxiety. Standardized measures of pain, anxiety and hypnotizability were obtained. Skin conductance response confirmed pain stimulation. Half the subjects used imaginative involvement first and the other half used distraction first. All procedures were video taped. Blind raters judged subjects' responses and subjects reported pain on a standardized scale. Data were collected at baseline, during two intervention sessions and at follow-up. Supporting Hilgard's neodissociation theory, hypnotizable subjects significantly reduced both subjective and objective pain and anxiety scores in response to hypnotic imagination involvement in contrast to low hypnotizable Ss.

No significant effects were found for the distraction condition. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1995, Vol. 4, No. 3.)

1992

Bowers, Kenneth S. (1992). Imagination and dissociation in hypnotic responding. International Journal of Clinical and Experimental Hypnosis, 40 (4), 253-275.

A neodissociative model of mind is better equipped than a social-psychological model to deal with the complexities of hypnosis, and of human behavior generally. It recognizes, as Coe's (1992) model does not, that behavior can be more automatically activated than strategically enacted. In particular, Coe's emphasis on human behavior as purposeful and goal directed does not distinguish between goal-directed behavior that serves a purpose, and goal-directed behavior that is performed on purpose. It is this distinction that permits goal-directed behavior to be dissociated from a person's conscious plans and intentions. In addition to offering a critique of Coe's "limited process" view of hypnosis, 4 main points are made in the interest of developing a slightly modified, neodissociation view of hypnosis. First, it is argued that goal-directed fantasies are more limited in their ability to mediate hypnotic responding than is commonly appreciated; as well, they do not seem to account for the nonvolitional quality of hypnotic responding. Second, it is argued that hypnotic ability is not unidimensional, with compliance and social influence more apt to account for the low than for the high hypnotizable's responsiveness to suggestion. Third, compared to low hypnotizables, the hypnotic responsiveness of high hypnotizables seems more likely to result from dissociated control. In other words, for high hypnotizables, hypnotic suggestions may often directly activate subsystems of cognitive control. Consequently, the need for executive initiative and effort to produce hypnotically suggested behavior is minimized, and such responses are therefore experienced as nonvolitional. Fourth and finally, while goal-directed fantasies typically accompany hypnotically suggested responses, they are in many cases more a marker of dissociated control than a mediator of suggested effects.

Kirmayer, Laurence J. (1992). Social constructions of hypnosis. International Journal of Clinical and Experimental Hypnosis, 40 (4), 276-300.

Both clinical and experimental views of hypnosis are social constructions that reflect the biases and interests of practitioners and scientists. Each perspective offers useful metaphors for hypnosis. Underlying clinical uses of the term hypnosis are states of mind associated with imaginative reverie and automatic behavior based on procedural knowledge. Social discourse and narratives shape hypnotic experience, but they are themselves influenced by mechanisms of attention and automaticity. Study of hypnosis must proceed on both social and psychological fronts to account for the experience and clinical efficacy of hypnosis. NOTES 1: "In accord with Coe, Sarbin, and other social-psychological theorists, I will argue that hypnosis, like all higher mental phenomena, is fundamentally social in nature. To accept this, however, does not obviate the role of distinctive processes of attention, imagery, and imagination. Hypnosis is a socially constructed context and ritual for evoking imaginative enactment and involuntary of "automatic" modes of experience and behavior. Contemporary social-psychological theorists have failed to

sufficiently explore the nature of enactment. A satisfactory account of hypnosis must go much deeper into the cognitive and social construction of experience; only then can involuntary behavior be properly distinguished from self-deception and self-authorship from cultural construction" (p. 277).

Lynn, Steven Jay; Sivec, Harry (1992). The hypnotizable subject as creative problem-solving agent. In Fromm, Erika; Nash, Michael R. (Ed.), Contemporary hypnosis research (pp. 292-333). Guilford Press.

## NOTES

These notes are taken only from the section of this chapter that deals with Hypnotic Responding, Imaginative Activity, and Expectancies, and they treat of the concept of nonvoluntary responding (pp 315-316). Other topics covered in the chapter include: Imagination, Fantasy, and Hypnosis Theories; The Hypnotizable Subject as Creative Problem-Solving Agent; Hypnosis and Subjects' Capability for Imaginative Activity; Goal-Directed Fantasy: Patterns of Imaginative Activity during Hypnosis; Hypnosis and Creativity; and a Conclusion.

Several studies manipulated expectancies re the relationship between imagination and involuntariness. When Ss were told that "good" hypnotic subjects could (or could not) resist suggestions, "this information affected their ability to resist the hypnotist and tended to affect subjects' report of suggestion-related involuntariness ... [Lynn, Nash, Rhue, Frauman, & Sweeney, 1984]. Furthermore, subjects who successfully resisted suggestions and subjects who failed to do so reported comparable levels of hypnotic depth and imaginative involvement in suggestions.

"Spanos, Cobb, and Gorassini (1985) conducted a similar experiment in which they found that hypnotizable subjects who were instructed that they could become deeply involved in suggestions and yet resist them successfully resisted 95% of the suggestions and rated themselves as maintaining voluntary control over their behavior. Thus, subjects are able to resist nearly all of the suggestions when resistance is facilitated by situational demands. It is worth noting that subjects in this research who resisted hypnotic suggestions rated themselves as just as deeply involved in the suggestions as Ss who failed to resist suggestions after being informed that deeply hypnotized subjects were incapable of resisting suggestions" (pp. 315-316).

Lynn, Snodgrass, et al. (1987). showed that hypnotizable Ss who were just "imagining" along with suggestions but instructed to resist responding to motoric suggestions acted the way hypnotized Ss did in their earlier countersuggestion research: imagining subjects tended to move in response to suggestion (that "good" Ss responded in certain ways), despite being instructed to resist. In this study, with instructions designed to increase the use of goal directed fantasies (GDFs), low and high hypnotizable subjects reported equivalent GDF absorption and frequency of GDFs. However, highs responded more and reported greater involuntariness than lows, even when their GDFs were equivalent.

"A number of other studies have examined the effects of expectancies on imaginings and hypnotic behavior. Spanos, Weekes, and de Groh (1984) informed subjects that deeply hypnotized individuals could imagine an arm movement in one direction

while their unconscious caused the arm to move in the opposite direction. Even though subjects so informed moved in the opposite direction, they imagined suggested effects and described their countersuggestion behavior as involuntary" (p. 317).

Spanos, Nicholas P.; Brice, Peter; Gabora, Natalie J. (1992). Suggested imagery and salivation in hypnotic and non-hypnotic subjects. Contemporary Hypnosis, 9, 105-111.

Salivation was measured in 100 subjects on both a baseline and post-test trial. Subjects in hypnotic, relaxation, and suggestion alone treatments were asked to imagine tasting a lemon during the post-test trial. Subjects in the suggestion alone and relaxation treatments exhibited significant baseline to post-test increments in salivation and, on the post-test trial suggestion alone subjects exhibited greater salivation than either hypnotic subjects or no treatment controls. Neither hypnotizability nor imagery vividness correlated significantly with suggestion-induced increments in salivation.

#### NOTES

"Our findings, like those of numerous earlier studies (reviewed by White, 1978) indicate that instruction to imagine food substances enhance salivation. The fact that imagery-alone instructions were more effective in this regard than hypnotic imagery instructions was unexpected, but this finding is certainly consistent with the large body of evidence which indicates that hypnotic procedures are no more effective than non-hypnotic procedures at enhancing responsiveness to suggestions. Moreover, the present findings, along with those concerning wart regression (Spanos et al., 1988), contradict the hypothesis that hypnotic procedures are particularly effective at enhancing responsiveness to suggestion when the target response is not under direct voluntary control.

"The reasons for the superiority of the imagery-alone treatment to the hypnotic treatment at inducing saliva production remain unclear. Subjects in the three treated groups reported equivalent levels of suggested imagery vividness and, therefore, differences on that variable could not have mediated treatment differences in the amount salivated. On the post-test trial the two treatments that received relaxation instructions (hypnosis and relaxation groups) failed to differ significantly from controls in amount salivated, whereas imagery alone subjects did differ from controls in this respect. Perhaps high levels of relaxation produce a slight inhibition of salivation which at least partly offsets the enhancement produced by suggested imagery. This hypothesis is, of course, highly tentative, and the finding of somewhat less salivation in groups administered relaxation instructions requires replication before further speculation is warranted.

"The finding that controls exhibited a significant decrease in salivation was also unexpected, and the reason for this finding remains unclear.

"Neither the Betts QMI nor any of the hypnotizability indexes correlated significantly with the suggestion induced increments in salivation. On the one hand, these findings are consistent with those of previous studies, which reported no relationship between imagery and/or hypnotizability and suggestion-induced

changes in target responses that were not under subjects' direct control (e.g. Surman et al., 1973; Swirsky-Sacchetti & Margolis, 1986; Spanos et al., 1988). On the other hand, our results failed to replicate White's (1978) finding of a significant correlation between suggestion-induced salivation and Betts QMI scores. Our study differed from that of White (1978) in several important respects. White asked subjects to imagine several foods which they preferred to differing degrees. Significant differences in salivation for subjects classified as high, medium or low on the QMI were found only when subjects imagined preferred foods. Furthermore, subjects classified as high and medium on the QMI tended to salivate to similar degrees when imagining preferred foods, but salivated more under these conditions than low QMI scorers. In the present study all subjects imagined the same food stimulus regardless of preference, and subjects were not selected for extreme scores on the QMI. These differences between our study and that of White (1978) may account for our failure to obtain a significant relationship between QMI scores and imagery-induced salivation" (p. 109).

1991

Crowson, J. Jeffrey, Jr.; Conroy Aileen M.; Chester, Traci D. (1991). Hypnotizability as related to visually induced affective reactivity: A brief communication. International Journal of Clinical and Experimental Hypnosis, 39 (3), 140-144.

Numerous studies have explored the relationship between hypnotizability and individual differences in imaginative involvement and creativity. Most have assessed imaginative or affective involvement by involving Ss in a variety of imaging tasks. Unlike these earlier studies, however, the present study made no attempt to actively involve Ss in the film viewing task. Rather, individuals assessed as high, medium, or low in hypnotizability were exposed to either a violent film, a neutral film, or no film. Results provided tentative evidence to indicate that the level of negative affect reported was significantly greater for highly hypnotizable Ss. Results were discussed in terms of the limitations of the present study and implications for future studies.

Glicksohn, Joseph; Mourad, Boaz; Pavell, Eyal (1991-92). Imagination, absorption and subjective time estimation. Imagination, Cognition and Personality, 167-176.

We report an exploratory study that investigated the interaction of trait and task in determining duration judgment. High and low absorption subjects (determined by median split along the Absorption Scale) viewed a series of paired slides, and were required to relate to each pair in one of two tasks: A metaphor-production task, and a story-production one. These tasks were carried out for an objective interval of fifteen minutes, following which the subject was required to verbally estimate this duration, retrospectively. In addition, from the individual protocols we measured the average time till response and the average time of response. A significant interaction between absorption and task was obtained for the latter two variables. In addition, a main effect for task was found for the duration estimation. These and other results are assessed in terms of both a cognitive-timer model for time

estimation and a contextualistic approach to temporal processing.

#### NOTES

The authors used a model for subjective time estimation (STE) that involves a cognitive timer (or internal clock) that encodes temporal information. STE purportedly may be correlated with the amount of attention directed at the passage of time, and negatively correlated with attention paid to other kinds of tasks.

They used tasks that aroused Subjects' imagination--a series of pairs of slides. One group was to produce a metaphor relating the two slides, while the other group was to produce a short story relating the two--theoretically an easier task.

The authors hypothesized that high absorption Ss would be more engrossed in the task than low absorption Ss, and therefore would underestimate the amount of time used for the task irrespective of task difficulty. For the low absorption Ss they predicted that time estimates for the more difficult metaphor task should be longer, because the task itself demanded more attention than the other task. (High absorption Ss would not exhibit such a difference.)

As another measure, Subjects were required to produce four short time intervals (4, 8, 16, and 32 seconds) to assess whether there might be a different rate of the cognitive timer for the two types of Ss, irrespective of nontemporal task involvement.

26 Ss were randomly allocated to one of two conditions (metaphor task or story task). Since this number of Ss is too small for an adequate evaluation of the interaction effect (absorption x task) of particular interest, the authors regard the experiment as exploratory only.

The results suggest that high absorption Ss view the tasks as easy and pleasant relative to the lows, and have larger STE values. Shorter time estimates are associated with the metaphor task than the story task, for both highs and lows--an unexpected finding. While highs take the same amount of time for metaphor production as for story production, lows take longer to produce a metaphor than a story (and of course, the metaphor is shorter in length!)

The high absorption Ss provided larger estimations of time for the task in which they produced a required number of seconds (4, 8, etc.), indicating a slower baseline rate of functioning of the cognitive timer.

The authors in their discussion find the results supportive of the cognitive timer model. They cite the finding that duration estimate was predicted from STE, task, and interaction of absorption with average time to response. (1) remembered duration was positively correlated with baseline functioning of the cognitive timer (STE) (2) remembered duration was negatively correlated with task difficulty (3) remembered duration was an interactive function of absorption and average time to response.

Rhue, Judith W.; Lynn, Steven Jay (1991). Storytelling, hypnosis and the treatment of sexually abused children. International Journal of Clinical and Experimental Hypnosis, 39 (4), 198-214.

The present article describes an assessment and therapy program for sexually abused children using hypnotherapeutic techniques which center on storytelling. Storytelling presents the therapist with an opportunity to use comforting suggestions, symbolism, and metaphor to provide the emotional distance necessary to deal with the trauma of abuse. Hypnotherapy proceeds in a stepwise fashion from the building of a sense of safety and security; to imaginative sharing; to the introduction of reality events; to the final step of addressing complex emotional issues of loss, trust, love, and guilt brought about by the abuse.

Ross, Colin A.; Joshi, S.; Currie, R. (1991). Dissociative experiences in the general population: A factor analysis. Hospital and Community Psychiatry, 42, 297-301.

The 28-item Dissociative Experiences Scale was administered to a stratified cluster sample of 1055 respondents in a general population of Winnipeg. Dissociative experiences were common in the sample and were not related to socioeconomic status, sex, education, religion, or place of birth, although they declined with age in both sexes. A principal components analysis identified three factors accounting for 47.1% of the combined variance of scores. The first factor, absorption-imaginative involvement, is composed of common, benign experiences such as missing part of a conversation, being able to ignore pain, staring into space, absorption in a television program or movie, not being sure if you did something or only thought about it, and remembering things so vividly one seems to be reliving it. The other two factors, activities of dissociated states and depersonalization-derealization, composed of less common experiences such as not recognizing friends or family members and not recognizing one's own reflection in a mirror, may be powerful predictors of DSM-III-R dissociative disorders.

Strauss, Billie S. (1991). The use of a multimodal image, the apple technique, to facilitate clinical hypnosis: A brief communication. International Journal of Clinical and Experimental Hypnosis, 39, 1-5.

A 1- to 3-minute exercise involving imagination (of an apple) and ideomotor ideation (hand levitation) is a simple, benign technique that is useful for illustrating to patients the nature of imagery and hypnosis. It avoids power struggles and allows a reasonable approximation of the patient's capacity for imagery and hypnotic responsiveness, without emphasizing the use of a hypnotic procedure. When administered to 35 college students, the hand levitation component of this exercise correlated with the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & E. R. Hilgard, 1963) ( $r = .66, p < .001$ ) and with the Stanford Hypnotic Clinical Scale: Adult (Morgan & J. R. Hilgard, 1975, 1978/79) ( $r = .60, p < .001$ ). NOTES 1: NOTES: Hypnosis is explained as involving imagination and concentration. Then the patient is asked to participate as the clinician checks their imagination. The patient is asked to close their eyes and hold out their hand, after which the clinician says "I'm going to put an apple in your hand; describe the apple to me." The patient is prompted to report multiple sensory modalities with questions Like, "Does the apple have weight? Does it have a smell? Would you Like to take a bite out of the

apple? How does it sound as you chew it?" The clinician can obtain useful information about the patient's preferred sensory modalities, the amount of structure required to engage in imaginal activities, etc.

If the patient becomes very involved with the image and would like to continue the experience on into hypnosis, the clinician can ask them to concentrate on the apple's weight, then tell the patient that s/he will take the apple from the patient's hand and the patient will notice that the hand feels light. As this imagery progresses, the clinician can move into suggesting a sense of lightness, and ultimately an arm levitation procedure like that of Chiasson, i.e. that "when the hand reaches the patient's face, the patient will find himself or herself in a comfortable state of hypnosis" (p. 2).

"At any point where the patient does not appear to respond to suggestions or remain involved with the imagery, techniques are shifted. For example, if the patient indicates that the apple does not appear to have weight or the hand does not feel light, I suggest simply that the patient continue to listen to my voice, to breathe deeply, and to continue to enjoy this comfortable state, perhaps using imagery commensurate with the skills shown by the patient when he or she first imagined the apple. Finally, patients are roused, with posthypnotic suggestions for alertness, comfort, and control" (p. 2).

The author administered this Apple Technique to 12 patients, following the administration with an interview to learn about their subjective responses. Of the 12, 6 showed at least some hand levitation and scored 3-5 on SHCS:A; 6 had no levitation and scored 0-1 on SHCS:A. When administered to 35 college students, only 3 did not experience a sensation of weight when imagining an apple in their hand. A three-point rating (1 = no hand movement; 2 = some hand movement, but not to the face; 3 = hand movement to the face) correlated .66 with SHSS:C and .60 with SHCS:A.

The author has found that good Ss can go into hypnosis within 2-3 minutes using the Apple Technique, while poor Ss conversely may reveal limited imaginative involvement or ideomotor skill within the same amount of time.

**Drake, Stephen D.; Nash, Michael R.; Cawood, Glenn N. (1990-91). Imaginative involvement and hypnotic susceptibility: A re-examination of the relationship. *Imagination, Cognition and Personality*, 10, 141-155.**

Several researchers have reported that significant correlations between hypnotic susceptibility and absorption result from the reactive effects of administering scales immediately before measurement of hypnotizability. The present study was conducted to determine whether interview measures of imaginative involvement are similarly reactive. Three groups of 48, 43, and 43 Ss each were first administered 3 scales of absorption/imaginativeness. This was followed by administration of a hypnotizability scale. Ss in Group 1 who were administered the 3 scales immediately prior to hypnosis evidenced the usual significant positive correlation between each of the 3 scales and hypnotizability. Ss in Groups 2 and 3 were administered the 3 scales 24 to 36 hours prior to hypnosis. Group 2 Ss were informed that administration of these scales was part of a hypnosis experiment. Group 3 Ss were

not aware that the scales were part of a hypnosis experiment. No significant correlation between hypnotizability and the 3 measures of imagination/absorption was evidenced for either Group 2 or Group 3. Our findings suggest that any relationship between these two constructs may be quite dependent on how and when the measures are administered.

Fellows, Brian J. (1990). Current theories of hypnosis: A critical overview. British Journal of Experimental and Clinical Hypnosis, 7, 81-92.

The present state of theory in hypnosis is reviewed and observations are made concerning future prospects. The state- non-state issue continues to dominate theoretical debate, although no satisfactory reply has yet been made to T. X. Barber's criticisms of the 'hypnotic trance' concept. The impact of social-psychological theory has been considerable and the results of Spanos's hypnotic training programme could have significant implications for our understanding of hypnosis. Future theorizing should see a move towards a more integrated sociocognitive approach. Neodissociation theory has generally not fulfilled its early promise and is encumbered with the 'hidden observer' concept. The role of imaginative processes continues to be a dominant theme in hypnosis theory, although the relatively small correlation between imaginative and hypnotic abilities remains a problem. The links between hypnosis, sleep and relaxation deserve further research, although, as theories of hypnosis, their scope seems limited. Suggestibility and role enactment theories have shown few signs of development in recent years. Theoretical problems over the interpretation of hypnosis need to be more widely recognized and the use of question-begging terminology curtailed. One advantage of the imagination hypothesis is that it provides a bridge, or a point of convergence, between state and non-state approaches (Spanos & Barber, 1974). It also handles certain hypnotic phenomena very well. For example, the known facts of age regression can be readily interpreted, together with the oddities of age progression and past life regression, as imaginative reconstructions (Barber, 1979). However, other phenomena, such as amnesia and analgesia, are less easily explained.

Stewart, Malcolm W.; Marks, David F. (1990). Actual and expected hypnotizability in hypnotic analgesia. British Journal of Experimental and Clinical Hypnosis, 7, 47-56.

The effects of actual hypnotizability, assessed by the Creative Imagination Scale (CIS), and expected hypnotizability on hypnotic analgesia were assessed in a design in which a high hypnotizability group and a low hypnotizability group were given incorrect information about their true levels of hypnotizability whilst other groups of highs and lows were correctly informed. Both actual and expected hypnotizability significantly affected self-reports of cold-pressor pain. Post hoc testing showed that the high CIS/high expectancy group reported significantly less pain than the other three groups and, in fact, was the only group to show significant analgesia. The research shows expected hypnotic ability to be an important factor in hypnotic

analgesia. Direct verbal suggestion about a subject's hypnotizability prior to the hypnotic induction significantly enhances reported hypnotic analgesia. This finding could have important clinical applications and indicates the special role of favourable expectancies in hypnotic phenomena. N

#### NOTES

The authors provide a good description of analgesia testing that could be used in training patients to control pain.

**Pain rating:** the subject used a 10-point numerical pain rating scale (as used by Spanos et al., 1979) where 0 was described as 'no pain,' 5 as 'moderate pain' and 10 as 'excruciating pain.'

**Apparatus:** plastic tank with crushed ice and water to depth of 11 cm; digital thermometer to record hand temperature when Subject clasped it tightly; digital stop watch; tape recorder to present instructions; cassette tape recorder to record Subjects' pain ratings.

**Procedure for pain tests:** After recording skin temperature, the Subject was told to put right hand in the water and leave it there until either 90 seconds elapsed or they felt pain was no longer tolerable; Subject was asked to call out each level of pain as it was reached. After removing arm from tank and sitting quietly for 5 minutes, Subject read a letter informing them about their level of hypnotizability. Then they were hypnotized with tape recorded induction (approximately 8 1/2 minutes long), followed by an analgesic suggestion. "Just relax and breathe deeply. You become more and more sleepy, more and more drowsy, deeper and deeper asleep. Deeper and deeper asleep. You are feeling very, very relaxed. This time when your hand is in the water ... it will continue to become more and more numb, insensitive and unfeeling. Just relax and breathe deeply, you will become more and more sleepy, more and more drowsy, deeper and deeper asleep, deeper and deeper asleep, you are feeling very, very relaxed. Now open your eyes. This time when your hand is in the water ... it will continue to become more and more numb, insensitive and unfeeling. This time when your hand is in the water ... it will become more and more numb, insensitive and unfeeling." Then the Subject was instructed to do the cold water immersion (using the other hand this time). Finally, Subjects completed a post-experiment questionnaire.

#### 1989

Snodgrass, M.; Lynn, Steven Jay (1989). Music absorption and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 37, 41-54.

The present study investigated differences between high (N = 15), medium (N = 20), and low (N = 16) hypnotizable Ss' involvement in imaginative versus nonimaginative music. Ss were first screened for hypnotizability with the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962). In a second session presented as a study of music appreciation, Ss listened to classical music of high- and low-rated music imaginativeness. Ss' involvement was indexed by absorption, imagery elaboration reported in open-ended essays, and reaction time to a pure tone. High hypnotizable Ss reported more absorption than low hypnotizable Ss,

regardless of the imaginativeness level of the music. Ss reported more imagery elaboration in the imaginative than in the low-imaginative passages. High hypnotizable Ss tended to differ in their imagery elaboration in response to the imaginative passages but not in response to the nonimaginative passages. Reaction time results were nonsignificant. No sex differences were found. Medium hypnotizable Ss were indistinguishable from both high- and low-hypnotizable Ss. The findings are generally compatible with J. R. Hilgard's (1970, 1974) construct of imaginative involvement.

Spanos, Nicholas P.; Flynn, Deborah M. (1989). Compliance, imaginal correlates and skill training. [Comment/Discussion] .

#### NOTES

The authors defend the Carlton skill training program against accusation that the trained Ss are simply complying in the context of social pressure. They also discuss characteristics of high hypnotizables (absorption and imagery), noting that the majority of lows do not have low absorption/imagery scores (citing de Groh, 1988, and noting the research on context dependency for absorption).

"Despite all of this, it is worth noting that the results of our modification studies are not inconsistent with the hypothesis that high hypnotizability requires imaginative skills that some subjects do not possess in sufficient degrees. For example, two recent studies (Spanos et al., 1987; Cross and Spanos, 1988) found that the extent to which low hypnotizables showed gains following administration of the CSTP was predicted by their pre-tested levels of imagery vividness. Lows with good imagery benefitted substantially more from the CSTP than did lows with poor imagery ability. When it is kept in mind that most low hypnotizables do not score low on measures of imagery/absorption (de Groh, 1988), then the findings that substantial numbers of low hypnotizables can be taught to attain high hypnotizability is not at all inconsistent with the notion that high hypnotizability requires at least moderate levels of imagery/absorption ability" (p. 14).

de Groh, Margaret (1989). Correlates of hypnotic susceptibility. In Spanos, Nicholas P.; Chaves, John F. (Ed.), Hypnosis: The cognitive-behavioral perspective (pp. 32-63). Buffalo, NY: Prometheus Books.

#### NOTES

The author describes a non-linear relationship between imagery and hypnotizability and between absorption and hypnotizability. People good at imagery may be high or low on hypnotizability scales; the same is true for people high on absorption trait. However, people low on those traits generally are low on measured hypnotizability.

Council, James R.; Greyson, Bruce; Huff, Kenneth D. (1988, November). Reports of paranormal experiences as a function of imaginative and hypnotic ability.

[Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

Wilson and Barber (1983) have suggested that some excellent hypnotic subjects ("fantasy prone" persons) may be more likely to report paranormal experiences than the rest of the population. Council and Greyson (1985), studying a sample of subjects who had reported near-death experiences (NDEs), found a significant relationship between fantasy-proneness and NDEs, and a much stronger relationship between fantasy-proneness and reports of paranormal experiences in general. This paper presents new data from the study of NDE reporters and a replication and extension of those findings with a sample not selected for NDEs. These data indicate a strong association between fantasy-proneness and reports of paranormal experiences. Hypnotic susceptibility bears a weaker relationship with such reports that appears dependent upon variance shared with measures of fantasy-proneness. Other data from these studies suggests that both imaginative ability and reports of paranormal experiences may be related to a history of stressful or traumatic childhood experiences.

#### NOTES

This article is cited by Spanos & Flynn (1989) as indicating that high hypnotizability requires imaginative skills that some people do not possess in sufficient degrees.

Gorassini, Donald R.; Hooper, Cynthia L.; Kitching, Kathleen J. (1988). The active participation of highly susceptible hypnotic subjects in generating their hypnotic experiences. Imagination, Cognition and Personality, 7 (3), 215-226.

Hypnotized individuals have traditionally been considered to be detached from the control of their own suggested behavior. We tested this and the alternative notion that hypnotized subjects attempt to self-generate the experiences (i.e., mainly of involuntariness) as well as produce the behaviors thought to be prototypical of high hypnotic ability. In an experimental investigation, highly susceptible hypnotic subjects were found to engage in the kind of imaginative activity that would be expected of individuals who were attempting deliberately to generate their experiences of involuntariness; they engaged as actively in imagery-generation as did subjects who were specifically instructed to imagine during suggested responding, and they experienced as much involuntariness as subjects in whom suggested movements were produced by an external physical force. The implications of these findings for the neodissociation and social psychological theories of hypnotic responding are discussed.

LeBaron, Samuel; Zeltzer, Lonnie K. (1988). Imaginative involvement and hypnotizability in childhood. International Journal of Clinical and Experimental Hypnosis, 36, 284-295.

2 pilot studies assessed the relationship between hypnotizability in children and extent of involvement in fantasy-related activities during early childhood. The

Stanford Hypnotic Clinical Scale for Children and a structured interview questionnaire regarding fantasy activities based on previous work by Singer (1973) were given to 30 medical patients aged 6-18 years in the first study and to 37 healthy children aged 6-12 years from a school population in the second study. In both studies, hypnotizability correlated moderately (.42 and .39, respectively) with extent of involvement in fantasy-related activities. Results support Hilgard's (1979) findings that hypnotizability is related in part to the development of imaginative involvement in childhood.

Lynn, Steven Jay; Rhue, Judith W. (1988). Fantasy proneness: Hypnosis, developmental antecedents, and psychopathology. American Psychologist, 43 (1), 35-44.

Lynn, Steven Jay; Rhue, Judith W. (1988). Fantasy proneness: Hypnosis, developmental antecedents, and psychopathology. American Psychologist, 43 (1), 35-44.

This article presents a summary of the findings of our ongoing research program on the fantasy-prone person. In seven studies, nearly 6,000 college students were screened in order to obtain five samples of 156 fantasy-prone subjects. Fantasy-prone subjects (fantasizers) were selected from the upper 2%-4% of the college population on a measure of imaginative involvement and contrasted with nonfantasizers (lower 2%-4%), and medium fantasy-prone subjects (middle range). General support was secured for Wilson and Barber's construct of fantasy proneness: Fantasizers were found to differ from nonfantasizers, and in many cases also from medium-range subjects, on measures of hypnotizability, imagination, waking suggestibility, hallucinatory ability, creativity, psychopathology, and childhood experiences. Differences in hypnotizability were most reliable when subjects participated in a multisession study and were screened not only with the screening inventory, but also with an interview that substantiated their fantasy-prone status. However, our findings indicated that less correspondence between fantasy proneness and hypnotizability exists than Wilson and Barber suggested. Hypnotic responsiveness is possible even in the absence of well-developed imaginative abilities, and not all fantasizers were highly hypnotizable. Fantasizers recollected being physically abused and punished to a greater degree than other

subjects did and reported experiencing greater loneliness and isolation as children. Many fantasizers appeared to be relatively well-adjusted; however, a subset of fantasizers were clearly maladjusted based on self-report, Minnesota Multiphasic Personality Inventory (MMPI), and Rorschach test data. Because of the diversity inherent in the fantasy-prone population, it is misleading to think of individuals at the extreme end of the fantasy-proneness continuum as conforming to a unitary personality type.

Ross, Colin A.; Norton, G. R.; Anderson, Geri (1988). The dissociative experiences scale: A replication study. Dissociation, 1 (3), 21-22.

The authors administered the Dissociative Experiences Scale to medical student controls and patients with multiple, personality disorder, schizophrenia panic disorder, and chemical dependency. Patients with multiple personality disorder scored significantly better than the other clinical groups and the medical student controls.

Spanos, Nicholas P.; Stenstrom, Robert J.; Johnston, Joseph C. (1988). Hypnosis, placebo, and suggestion in the treatment of warts. Psychosomatic Medicine, 50, 245-260.

Two experiments assessed the effects of psychological variables on wart regression. In Experiment 1, subjects given hypnotic suggestion exhibited more wart regression than those given either a placebo treatment or no treatment. In Experiment 2, hypnotic and nonhypnotic subjects given the same suggestions were equally likely to exhibit wart regression and more likely to show this effect than no treatment controls. In both experiments, treated subjects who lost warts reported more vivid suggested imagery than treated subjects who did not lose warts. However, hypnotizability and attribute measures of imagery propensity were unrelated to wart loss. Subjects given the suggestion that they would lose warts on only one side of the body did not show evidence of a side-specific treatment effect.

Van Der Hart, O. (1988). An imaginary leave-taking ritual in mourning therapy. International Journal of Clinical and Experimental Hypnosis, 36 (2), 63-69.

One form of mourning therapy is the therapeutic leave-taking ritual, the essence of which is that by parting with symbols connected with the deceased, patients take their leave of the deceased and can start a new life of their own. In the case described in the present paper, the patient performed such a ritual in her imagination while under hypnosis. Her extreme grief response is explained in terms of Janet's theory of emotions. It is emphasized that successfully performing the ritual necessarily involved a change in attitude towards the deceased, and it is argued that the specific characteristics of hypnosis--involuntariness and effortlessness--add an extra dimension to guided imagery approaches to unresolved mourning.

1987

Crist, Dwayne Anderson (1987). The effect of suggestibility on the efficacy of relaxation training instruction: A multisession evaluation (Dissertation, University of Alabama). Dissertation Abstracts International, 47 (n9-B), 3950.

Progressive relaxation is a well established procedure used in the treatment of anxiety related disorders. Research has suggested that the muscle tension-release component of progressive relaxation is the critical variable in producing relaxation effects. However, other techniques which do not employ muscle-tension release have proven effective. It has been suggested that treatment type may interact with personality characteristics to produce greater effects. Suggestibility was selected as a personality characteristic that may facilitate or inhibit relaxation effects. Fifty high and 50 low suggestible individuals were selected to participate based on scores from the Creative Imagination Scale. Half of each group as randomly assigned to either a progressive relaxation or imagery relaxation treatment. Subjects received four weekly sessions of relaxation training. The Relaxation Scale was administered before and after each session to assess effects of training. The results indicated that high suggestible individuals had significantly greater increases in relaxation within session on each of the three scales of the Relaxation Scale, but this appeared to be a result of lower pre-test scores. Only the Physical Assessment scale also demonstrated higher post-test scores for the high suggestible participants. A ceiling effect appeared to be operating for both the Physiological Tension and Cognitive Tension scales. There were no significant differences between the progressive relaxation and imagery relaxation treatments. It appears that muscle tension release may not be a critical variable in relaxation effects" (p. ).

Lynn, Steven Jay; Rhue, Judith W. (1987). Hypnosis, imagination, and fantasy. Journal of Mental Imagery, 11, 101-112.

Considers three questions pertaining to the relationship between hypnotic responsiveness and imaginative processes: Are subjects' nonhypnotic imaginative involvements related to hypnotic susceptibility? Do some fantasy prone subjects share a unique constellation of personality attributes and experiences, including an ability to respond to hypnotic suggestions? What are the childhood developmental antecedents of persons who score at the extremes of hypnotic ability and measures of fantasy and imagination? Reviews literature.

Makarec, K.; Persinger, M. A. (1987). Electroencephalographic correlates of temporal lobe signs and imaginings. Perceptual and Motor Skills, 64, 1124-1126.

Significant correlations (0.50) were observed between scores for the Wilson-Barber Inventory of Childhood Memories and Imaginings and the experiences that are indicative of temporal lobe lability. In addition, positive correlations (0.42) occurred between temporal lobe EEG measures (scalp electrodes) and numbers of temporal lobe signs. The numbers of alpha seconds per minute from the occipital lobes were correlated (0.57) with the Wilson-Barber cluster that indicated interests in 'altered

states'. Scores on the childhood imaginings section of the Wilson-Barber Inventory were correlated (0.44) with the numbers of spikes per minute over the temporal lobes when the eyes were closed.

Persinger and DeSano (1986) found that people who display temporal lobe signs were also more likely to have more imaginings (as defined by Wilson and Barber's (1983) Inventory of Childhood Memories and Imaginings) and to be more suggestible as indicated by Spiegel's Hypnosis Induction Profile" (p. 1124).

Subjects in this investigation were 12 male and 18 female students, ages 18-39 (M = 25 years) Bipolar measures were taken from just above the ears (approximately T3-T4) and the occipital lobe (01-02). Number of alpha seconds per minute and number of spikes per minute from each lobe was taken for 10 minutes (5 successive pairs of 1 minute eyes- open, 1 minute eyes-closed).

"The total Wilson-Barber score was significantly ( $p < .01$ ) correlated ... with the major (0.46) and minor (0.50) temporal lobe clusters but not with two clusters of control items: normal psychological experiences (0.21) and mundane proprioceptive experiences (0.29). These correlations are similar to those in the Persinger and DeSano study (0.60, 0.50, 0.13, and 0.14, respectively). Like the first study (0.53), the items that were most associated with dissociation (depersonalization) were best correlated with the Wilson- Barber scores (0.60). The Wilson-Barber subcluster: adults' extreme experiences (Items 44 through 52, that indicate physiological changes associated with thinking) was again most strongly correlated with the major (0.55) and minor (0.65) temporal lobe clusters; these values were 0.42 and 0.52 in the first study" (p. 1125).

"The only statistically significant ( $p < .01$ ) correlations between the Wilson-Barber scales and the EEG measures were between the number of alpha seconds from the occipital lobe (with the eyes closed) and the [Wilson-Barber] 'altered state' cluster ( $r = 0.57$ ; Items 33, 41, 42, 43). A weaker correlation (0.36) occurred between the number of alpha seconds per min. (eyes closed condition) and childhood vestibular experiences (items 1, 2, 3, 10, 24)" (p. 1126).

Siuta, J. (1987). Normative and psychometric characteristics of a Polish version of the Creative Imagination Scale. International Journal of Clinical and Experimental Hypnosis, 35 (1), 51-58.

111 Polish undergraduate students participated in a study designed to provide psychometric characteristics of the Creative Imagination Scale (CIS). These results were compared to those from American (Wilson & Barber, 1978) and Australian (Sheehan, McConkey, & Law, 1978) norm studies which also used CIS. The total scale score means of the three samples differed no more than .20 scale points; these differences were not statistically significant. This finding, together with a high consistency in item difficulty level among the three samples which were compared, indicates that cultural differences do not influence the major pattern of findings obtained with CIS. It was also found that CIS possesses high test-retest reliability ( $r = .79$ ) and moderate split-half reliability ( $r = .50$ ). Factor analysis yielded only one

significant factor; this is congruent with results obtained by Wilson and Barber (1978).

**1986**

Lynn, Steven Jay; Rhue, Judith W. (1986). The fantasy-prone person: Hypnosis, imagination, and creativity. Journal of Personality and Social Psychology, 51, 404-408.

Experimenters selected subjects who ranged along the continuum of fantasy proneness and assessed hypnotizability, absorption, vividness of mental imagery (QMI; Sheehan, 1967), response to waking suggestion (Creative Imagination Scale), creativity, and social desirability (Crowne & Marlowe). Fantasy-proneness was evaluated with the Inventory of Childhood Memories and Imaginings (Wilson & Barber, 1981). Strong support was secured for J. R. Hilgard's construct of imaginative involvement and Wilson and Barber's contention that fantasy prone persons can be distinguished from others in terms of fantasy and related cognitive processes. Fantasizers were found to outscore subjects in both comparison groups on all of the measures of fantasy, imagination, and creativity, with social desirability used as a covariate. Low fantasy-prone subjects were no less creative or less responsive to hypnosis than their medium fantasy-prone counterparts.

**1985**

Levitan, Alexander A. (1985). Hypnotic death rehearsal. American Journal of Clinical Hypnosis, 27 (4), 211-215.

Death rehearsal is a technique developed to help terminally ill patients and their families deal with anxieties about death. It has proven useful in demystifying the dying process by answering the question "What is it like to die?" Patients, who are able to hypnotically experience the death process, learn to deal with both grief and anxiety with the help of the hypnotherapist. - Author's abstract

Neufeld, Victor; Lynn, Steven Jay; Jacquith, Leah; Weekes, John (1985, November). Fantasy style, imagination, and hypnotizability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

## **NOTES**

Authors discuss three fantasy styles: 1. Positive constructive daydreaming 2. Guilt / fear of failure 3. Poor attentional control. Fantasy style has been related to many personality variables, usually based on questionnaires.

They examined subjects in hypnosis and waking states using hypnotic dreams, Short Imaginal Processes Inventory, Tellegen Absorption, Betts QMI Imagery Vividness, Hypnosis (HGSHS and suggested dream) involvement, Wilson and Barber ICI, Nonvoluntary experience, Fantasy Proneness, Content of fantasies.

137 student volunteers participated in the study. 82 had HGSHS-A and hypnotic dream, and gave involuntariness ratings. Ss self-rated pleasant and unpleasant for hypnotic dreams. Experimenter rated dream for 1) positive emotion, 2) negative

emotion, and 3) anxiety. Correlations were significant for female Ss, but not for male Ss.

**RESULTS.** Fantasy-style, at least of negative affect, was consistent for waking and hypnotic states. Positive constructive fantasy correlated to HGSHS but the other two fantasy styles did not. [Other results reported are not included in this brief summary.]

**Nogrady, Heather; McConkey, Kevin M.; Perry, Campbell (1985).** Enhancing visual memory: Trying hypnosis, trying imagination, and trying again. Journal of Abnormal Psychology, 94 (2), 195-204.

Tested visual recall memory of high (n = 24) and low (n = 24) hypnotizable undergraduates (screened under the Harvard Group Scale of Hypnotic Susceptibility and the Stanford Hypnotic Susceptibility Scale) for black and white line drawings of common objects in either hypnosis, imagination, or control conditions. Memory performance in terms of both correct and incorrect items increased appreciably across the recall tests. Neither hypnosis nor imagination enhanced recall beyond that of normal repeated testing. Hypnotizability was not related to the amount of correct material recalled but was related to the amount of incorrect material reported. High hypnotizable Ss in the hypnosis condition were more likely than other Ss to confidently rate the incorrect material as correct. Findings are discussed in terms of the impact of hypnosis on and the relevance of hypnotizability to enhancing visual memory.

**Spanos, Nicholas P.; de Groot, Hans P.; Tiller, Dale K.; Weekes, John R.; Bertrand, Lorne D. (1985).** 'Trance logic,' duality, and hidden observer responding in hypnotic, imagination control, and simulating subjects: A social psychological analysis. Journal of Abnormal Psychology, 94 (4), 611-623.

Tested the hypothesis that a tolerance for logical incongruity characterizes hypnotic responding and is related to reports of duality experiences during age regression and hidden-observer responding during suggested analgesia. 30 undergraduates (the "reals") with high scores on a responsiveness-to-suggestion scale were randomly assigned to hypnotic or imagination control treatments, while 15 undergraduates with low scores were assigned to a simulation treatment in which they were instructed to fake hypnosis. Ss were assessed on 6 indicators of logical incongruity, given age-regression suggestions and perception tasks, administered a suggestion for analgesia and hidden observer instructions, and interviewed. Results do not support the hypothesis. The differences in responding that did emerge between reals and simulators were accounted for by the different task demands to which Ss were exposed. These behavioral differences, which have been previously interpreted in terms of intrinsic characteristics of hypnosis, may instead reflect a combination of between-treatments differences in demands and between- Ss differences in the interpretation of those demands and in the ability to fulfill them.

Barabasz, Arreed F. (1984). Antarctic isolation and imaginative involvement - preliminary findings: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32 (3), 296-300.

Group 1 Ss (N = 9) were interviewed in Antarctica prior to and following 1 year of Antarctic isolation. Group 2 Ss (N = 7) were exposed to 3 weeks of Antarctic field-site isolation and were interviewed upon return to the United States. A control group of 10 Ss was also interviewed on 2 occasions, paralleling Group 1. Group 1 showed a significant increase in imaginative involvement from pre- to post-Antarctic isolation. Group 2 showed a significantly greater level of imaginative involvement than the control Ss. The possibility that Antarctic living may have revived the mental processes available to these Ss as children is considered within both regression and learning explanations.

Billotti, Thomas J. (1984, August). The effects of rational emotive imagery and rational emotive imagery plus hypnosis in reduced public speaking anxiety (Dissertation). Dissertation Abstracts International, 46 (2), 633-634-B.

Previous investigations have demonstrated the effectiveness of rational emotive therapy in reducing public speaking anxiety and the increased benefit derived by combining rational emotive procedures with hypnosis. The present study examined the effectiveness of rational emotive imagery and rational emotive imagery plus hypnosis in reducing public speaking anxiety in subjects with high and low levels of imaginative ability. The dependent measures employed included self report, behavioral and physiological measures of anxiety. "47 undergraduate students who reported anxiety while speaking in public served as subjects in the study. The subjects were divided into high and low levels of imaginative ability and randomly assigned to one of three experimental groups as follows: rational emotive imagery, rational emotive imagery plus hypnosis, and an instructional control group. It was hypothesized that subjects in the rational emotive imagery plus hypnosis group would evidence significantly less anxiety than subjects in the rational emotive imagery and instructional control group, and that subjects with high pre-treatment levels of imaginative ability would evidence significantly less anxiety than subjects with low pre- treatment levels of imaginative ability. "The results of this study provided some support for the efficacy of combining rational emotive imagery with hypnosis. Subjects in the rational emotive imagery plus hypnosis group evidenced significantly less anxiety than subjects in the rational emotive imagery and instructional control group on the two self-report measures. There were no significant differences as between subjects in the rational emotive imagery group and instructional control group or between subjects with high and low imaginative ability on post-treatment assessments. Subjects tended to have their highest pulse rates at the start of the speeches, their lowest pulse rate just after the speeches, and moderate pulse rates just before and during the speeches. "Factors contributing to these results and interpretations of the data were discussed. Suggestions regarding the direction of future research were offered" (p. 633- 634).

Kearns, John S.; Zamansky, Harold S. (1984). Synthetic versus analytic imaging ability as correlates of hypnotizability. International Journal of Clinical and Experimental Hypnosis, 32, 41-50.

It was hypothesized that synthetic imaging ability, but not analytic imaging ability, is positively related to hypnotizability. The correlation of scores on a paired-associates task, used as a measure of synthetic imaging ability, with scores on the Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) of Weitzenhoffer and Hilgard (1962), indicated a statistically nonsignificant trend in the predicted direction. 2 measures of analytic imaging ability, as well as Sheehan's (1967) revision of the Betts (1909) Questionnaire Upon Mental Imagery, a measure of vividness of imagery, did not correlate significantly with SHSS:C. The results are discussed in terms of their relation to studies of creativity and goal-directed fantasy.

#### NOTES

The authors review the literature on imagery and hypnotizability and propose that an important variable in hypnosis is an ability to expand imaginatively upon a given verbal input (synthetic imaging ability), akin to Spanos' (1971) concept of goal-directed fantasy. They cite studies relating creativity ("essentially a synthetic process") to hypnotizability, and predict that skill in solving spatial relations problems (analytic imaging ability) is not correlated with hypnotizability because it involves "accurately scanning visual images and converging on solutions to specific problems," (p. 42) rather than creative fantasy characteristic of hypnotic behavior.

Forty Subjects had two sessions each: imagery tests in #1 and SHSS:C in #2. Imagery tests included, in this order: 1. Paired Associates (Paivio, 1972; a test of synthetic imaging), in which paired words are learned and later recalled; Experimental Ss were to learn them by combining them into an image, while Control Ss were to simply try to learn them. The nouns differed in imagery strength (potential for stimulating images). 2. Nonsense Forms (a test of analytic imaging), in which Subjects trace with their fingers an irregularly shaped Masonite form, blindfolded, and then choose one of 5 drawings that best matches the form. 3. Cube Visualization (a test of analytic imaging), in which Ss imagine a 2" wooden cube painted red on all faces, that had been sawed into 1" cubes; they are to say how many of the smaller cubes would be red on 3 faces, 2 faces, one face, and none of the faces. 4. Betts QMI.

The Paired Associates (PA) scores were a ratio of high imagery words recalled to low imagery words recalled, intended to reflect the impact of imagery availability on memory. There was a trend for hypnotizability to correlate with PA ratio scores, regardless of whether intermediate or low imagery nouns were used as baseline ( $\rho = .37$  and  $.34$ ,  $p < .10$ ) in the experimental group ("Use imagery to learn."), a trend that was not found in the control group (no imagery instructions). Neither measure of analytic imaging ability (Nonsense Forms, Cube test) correlated with hypnotizability.

In their Discussion, the authors write, "The common factor in successful performance of both imagery-mediated paired associates learning tasks and hypnotic suggestions appears to be the ability to expand imaginatively upon a given

verbal input" (p. 47). They cite the literature relating hypnotizable and creative performance (p. 47). "The present findings with the Nonsense Forms Test and the Cube Visualization Test, both of which failed to correlate significantly with SHSS:C, support the hypothesis that hypnotizability is not related to analytic, spatial-imagining skills" (p. 47). "The nonsignificant correlation between Betts QMI and SHSS:C adds to the growing body of inconsistent findings observed with Betts QMI" (p. 47).

"Given the complex nature of hypnotic susceptibility and of imagery (Monteiro et al., 1980), it is perhaps not surprising that studies attempting to relate the two variables directly frequently yield only modest relationships. Very likely, the inclusion of appropriate mediating variables would serve to clarify and, in particular instances, augment the relationships observed between hypnotic responsiveness and imaging ability. One such variable may be the capacity to become fully involved in everyday nonhypnotic experiences, commonly called absorption. This variable has been shown in numerous studies to be related to hypnotizability (e.g. Tellegen & Atkinson, 1974), as well as to creativity and vividness of imagery (P. Bowers, 1978, 1979; Monteiro et al., 1980). Even more relevant to the present study is the possible interaction between level of hypnotic susceptibility and the relationship between synthetic imaging ability and SHSS:C scores. It may be, for example, that the contribution of synthetic imaging ability becomes more critical in eliciting hypnotic behavior from Ss who are only moderately susceptible to hypnosis. Such an analysis was not possible in the present experiment, since the number of high, medium, and low susceptible Ss was approximately equal, and, therefore, the number of Ss at each level was insufficient for an adequate subgroup analysis. Clearly, however, future studies of the role of imaginal skills in hypnotic responsivity must move in directions such as these" (p. 48).

Lynn, Steven Jay; Nash, Michael R.; Rhue, Judith W., Frauman, David C.; Sweeney, Carol A. (1984). Nonvolition, expectancies, and hypnotic rapport. Journal of Abnormal Psychology, 93 (3), 295-303.

Prior to hypnosis, subjects were informed either that hypnotizable subjects can resist motoric suggestions or that such control does not characterize good hypnotic subjects. During hypnosis, susceptible and simulating subjects received countering suggestions involving inhibiting suggestion-related movements. Susceptible subjects' responses were found to be sensitive to prehypnotic normative information. There was a corresponding tendency for reports of involuntariness to be sensitive to the expectancy manipulation. Furthermore, subjects were able to feel deeply hypnotized and to rate themselves as good subjects yet concomitantly experience themselves as in control over their actions when normative information supported this attribution. Reports of suggestion-related sensations but not imaginative involvement were associated with movements in response to countersuggestion. Simulators were unable to fake susceptibles' reports of sensations and involuntariness. However, for all subjects, movements paralleled expectancies about appropriate response, supporting the hypothesis that involuntary experiences are sensitive to the broad

expectational context and are mediated by active cognitive processes. Also, rapport with the hypnotist was found to be a factor. Susceptible subjects with highly positive rapport resolved hypnotic conflict, in part, by achieving a compromise between meeting normative expectations and complying with the hypnotist's counterdemand.

Tilton, P. (1984). The hypnotic hero: A technique for hypnosis with children. International Journal of Clinical and Experimental Hypnosis, 32 (4), 366-375.

A technique for the use of hypnosis with children is described in detail. The method of using this technique to create a new source of ego strength and a secure reality for rapid symptom reduction is discussed. Cases are presented to give the reader examples of the various ways of utilizing this technique.

1983

Eisen, Marlene R.; Fromm, Erika (1983). The clinical use of self-hypnosis in hypnotherapy: Tapping the functions of imagery and adaptive regression. International Journal of Clinical and Experimental Hypnosis, 31 (4), 243-255.

The authors present a new method of interweaving hetero-hypnotic psychotherapy and self-hypnosis. In the hetero-hypnotic sessions, the hypnotherapist acts as a dependable parent figure who is supporting and available when that is desirable, but who also encourages and fosters the patient's efforts to develop his/her inner resources and ability to function autonomously. Self-hypnosis is utilized for its rich idiosyncratic imagery. The hypnotherapist uses and elaborates on this rich, affect-loaded imagery. At other times the therapist takes a guiding role in producing therapeutic metaphors of positive valence. The patient uses and enlarges on these during self-hypnosis between the weekly therapeutic hours. In addition, the hypnotist may counteract any negative strong self-hypnotic images during hetero-hypnosis. Self-directed self-hypnosis allows patients to experience openness and receptivity to internal and unconscious processes against which they may defend themselves in the dyadic relationship with the therapist. For patients struggling with issues of control and for patients fighting their own regressive pull towards dependency, this mode of therapy appears to be particularly effective. The emphasis in this paper is on imagery and on the inter-twining of the two modalities, hetero-hypnosis and self-hypnosis.

Myers, S. A. (1983). The Creative Imagination Scale: Group norms for children and adolescents. International Journal of Clinical and Experimental Hypnosis, 31 (1), 28-36.

This study presented the responsiveness of 1302 children and adolescents (ages 8-17) to the Creative Imagination Scale (CIS) of Wilson and Barber (1978) and Barber and Wilson (1978/79). The normative features of CIS were highlighted in the data analysis. Since items on CIS have been found to be related, a MANOVA was used for the analysis. There were significant differences in both sex and age. Females at each age level, 8 through 17, scored higher on CIS than males of the same age. Ss of

ages 9, 10, and 11 obtained the highest scores, but only differed significantly from the scores for 15-year-old Ss. The other age groups did not differ significantly from each other. In addition, the stability of CIS was confirmed. The author would recommend CIS for Ss 9 years old through adult years, however, CIS should be administered individually to Ss 12 and 15 years old, due to peer pressure.

Sheehan, Peter W. (1982). Imagery and hypnosis--forging a link, at least in part. Research Communications in Psychology, Psychiatry and Behavior, 7 (2), 257-272.

The role of imagery as one aspect of the processes of imagination at work is viewed in relation to ease of responsiveness in hypnosis. Focus is placed on the issue of imagery enhancement in hypnosis and on the relevance of imagery as a correlate of hypnotic susceptibility. Evidence suggests that imagery is positively related to hypnotizability but no clear support has been provided for the enhancement hypothesis. The nature of the association being examined needs to be clarified by closer scrutiny both of the measures used for assessing imagery and hypnosis, and of the test conditions under which the association is studied. Experience-based modes of assessment may help considerably in that pursuit.

Spanos, Nicholas P.; Bridgeman, M.; Stam, H. J.; Gwynn, M. I.; Saad, C. I. (1982-83). When seeing is not believing: The effects of contextual variables on the reports of hypnotic hallucinations. Imagination, Cognition and Personality, 2, 195-209.

When administered a hallucination suggestion most high susceptible hypnotic and task-motivated subjects reported that they "saw" the suggested object. When asked what they meant by "saw," however, almost all indicated that they had imagined the object but did not believe that it had actually been present. On the other hand, simulating subjects maintained that the suggested object had been "really there." Simulators were also more likely than non-simulators to provide "life-like" descriptions of the suggested object (e.g., solid rather than transparent, colored, highly vivid). These findings are consistent with the view that hypnotic hallucinations are context-generated imaginings. They also indicate that unique or unusual psychological processes like "trance logic" need not be posited to account for the descriptions of "hallucinatory" experiences proffered by hypnotic subjects.

#### NOTES

It was observed that hypnotized Ss reported more vivid (and longer sustained) imagery than task motivated Subjects. Hypnotized Ss did not differ from high susceptible simulators on vividness of imagery or how long they experienced the imagery, but did report shorter and less vivid imagery than simulators who were low hypnotizables.

1981

Hilgard, Ernest R.; Sheehan, Peter W.; Monteiro, K. P.; Macdonald, Hugh (1981). Factorial structure of the Creative Imagination Scale as a measure of hypnotic

responsiveness: An international comparative study. International Journal of Clinical and Experimental Hypnosis, 29, 66-76.

The factor structure of the Creative Imagination Scale (CIS) of Wilson and Barber (1978) was investigated in two studies by correlating scores on it with scores on the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962), the Absorption scale of Tellegen and Atkinson (1974), and Sheehan's (1967) revision of Betts' (1909) imagery scale. One of the studies was conducted at the University of Queensland in Australia (N = 237), the other at Stanford University in California (N = 92). The major finding, consistent in both investigations, was that two factors accounted for the major portion of the variance, one factor designated as a Hypnotic Performance factor, the other designated as an Absorption/Imagination factor. The CIS was weighted highly on both factors, the data bearing on earlier claims that CIS represents a single-factor scale.

Singer, Jerome L.; Pope, Kenneth S. (1981). Daydreaming and imagery skills as predisposing capacities for self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 271-281.

A growing body of empirical literature suggests that daydreaming and related forms of waking reverie are natural-occurring, common experiences in normal individuals. Specific experiments relating daydreaming and the stream of ongoing thought as an alternative source of stimulation to external cues are described. It is proposed that everyday waking consciousness has many features of internal absorption in imagery and adaptive but non-sequential processes that resemble fantasy, hypnosis, and night dreaming. Experiments linking daydreaming, imagery vividness, and hypnosis are cited as suggesting that individuals may develop capacities for control over the stream of thought and that such capacities are closely similar to the skills needed for self-hypnosis.

Spanos, Nicholas P.; Brown, Jude M.; Jones, Bill; Horner, Donna (1981). Cognitive activity and suggestions for analgesia in the reduction of reported pain. Journal of Abnormal Psychology, 90, 554-556.

Assessed 38 undergraduates' pain magnitude and pain tolerance for arm immersion in ice water during a baseline and posttest session. Before the posttest, half the Ss received an analgesia suggestion. On the basis of their written testimony, Ss were classified as having either predominately coped (e.g., imagined event inconsistent with pain or made positive self-statements) or predominantly exaggerated (e.g., worried about and exaggerated the noxious aspects of the situation) during each immersion. On both immersions, copers reported less pain and exhibited higher pain tolerance than exaggerators. Moreover, the suggestion was associated with reductions in reported pain only when it transformed baseline exaggerators into posttest copers.

1980

Pereira, M. J.; Austrin, H. R. (1980). Locus of control and status of the experimenter as predictors of suggestibility. International Journal of Clinical and Experimental Hypnosis, 28 (4), 367-374.

The present study investigated locus of control and manipulated status of the experimenter as predictors of suggestibility. Rotter's (1966) Internal-External Locus of Control Scale was used as the paper-pencil measure of locus of control, and the Barber (1965) Suggestibility Scale was used as the measure of suggestibility. We predicted two main effects on suggestibility; one for high externality, and one for high status. In addition, we predicted an interaction between locus of control and status of experimenter. A main effect for locus of control was not found, but one for status was significant, with externals significantly more suggestible than internals in the high status experimenter condition and significantly less suggestible in the low status condition. This interaction effect was viewed as the most significant finding, and implications for prediction were discussed.

Spanos, Nicholas P.; Pawlak, Anne E.; Mah, Christopher D.; D'Eon, Joyce L. (1980). Lateral eye movements, hypnotic susceptibility and imaginal ability in right-handers. Perceptual and Motor Skills, 50, 287-294.

A total of 46 male and 36 female right-handers were assessed on three measures of left-moving, as well as on hypnotic susceptibility, and several measures of imaginal ability. The three left-moving indices intercorrelated significantly. However, none of these indices correlated significantly with hypnotic susceptibility or imaginal ability variables in either sex.

Straus, R. A. (1980). A naturalistic experiment investigating the effects of hypnotic induction upon Creative Imagination Scale performance in a clinical setting. International Journal of Clinical and Experimental Hypnosis, 28 (3), 218-224.

A novel experimental design compared performances on the Creative Imagination Scale (CIS) of Wilson and Barber (1978) under hypnotic induction and control conditions. The Ss were 42 paying clients who participated in the study as an implicit part of their first clinical session. Results in this clinical context replicated previous laboratory studies which found that a conventional hypnotic induction procedure did not enhance scores on CIS. The present study suggests that the implicit clinical investigation, where appropriate, permits scientifically sound hypnosis research in natural field settings

Wallace, Benjamin (1980). Autokinetic movement of an imagined and an hypnotically hallucinated stimulus. International Journal of Clinical and Experimental Hypnosis, 28 (4), 386-393.

Autokinetic movement (AKM) of an imagined or an hallucinated stimulus was assessed as a function of hypnotic susceptibility level. 3 groups of Ss were asked to produce an image of a small, pinpoint spot of light and to monitor any activity of the stimulus. The stimulus was produced by imagination for a group of Ss judged high

in hypnotic susceptibility and for a second group of Ss judged low in hypnotic susceptibility. A third group of Ss, highly susceptible to hypnosis, was asked to hallucinate the pinpoint spot stimulus with the aid of instructions administered by E. Instructions by which movement reports were elicited were kept equal and open-ended for all 3 groups of Ss. Results indicated that form of the stimulus (imagined or hallucinated) did not affect reports of AKM. Hypnotic susceptibility level, however, was a major factor in influencing resultant reports. The Ss judged high in hypnotic susceptibility reported a significantly greater number of direction changes of AKM than Ss low in hypnotic susceptibility. The data are interpreted in terms of the possible differences in stimulus monitoring ability as a function of hypnotic susceptibility level

1979

McConkey, Kevin M.; Sheehan, Peter W.; White, K. D. (1979). Comparison of the Creative Imagination Scale and the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 27 (3), 265-277.

237 Ss were administered both the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962), and the Creative Imagination Scale (CIS) of Barber and Wilson (1977) and Wilson and Barber (1978) in separate testing sessions. Results were analyzed to assess the extent of relationships between the 2 scales and particular attention was paid to the question of whether, or not, CIS can be said to be an index of hypnotizability as traditionally measured by HGSHS:A. Data indicated that performance on CIS relates positively ( $r = .28$ ) to success on HGSHS:A, but the 2 tests are independent in their underlying dimensions. The CIS appears to tap primarily the processes of imagery and imagination which are only partly related to performance on the more complex scales which measure hypnosis as generally conceptualized.

Connors, J. R.; Sheehan, P. W. (1978). The influence of control comparison tasks and between-versus within-subjects effects in hypnotic responsivity. International Journal of Clinical and Experimental Hypnosis, 26, 104-122.

Type of experimental design (between- versus within-subjects) and type of control task were examined for their differential effects on the magnitude of objective and state report test scores associated with response to items on the Stanford Hypnotic Scale of Susceptibility, Form C (Weitzenhoffer & Hilgard, 1962). In an integrated program of work exploring design effects in hypnotic research, Ss in each of 7 comparison conditions that involved hypnosis and 4 separate comparison conditions that did not involve hypnosis were tested twice on successive occasions. Three of the control tasks used (waking, imagination, and imagination [alert] instruction) were counterbalanced with hypnosis to analyze possible order effects associated with hypnotic test conditions. Data indexed the patterns of between- versus within-subjects effects associated with standard control tasks and also highlighted the

order effects that accompanied them. Imagination instructions, in particular, pose specific difficulties that require attention when Ss are tested as their own controls.

1978

Sanders, Shirley (1978). Creative problem-solving and psychotherapy. International Journal of Clinical and Experimental Hypnosis, 26, 15-21.

The techniques described comprise a creative problem-solving approach to short-term individual psychotherapy which appears effective in conjunction with hypnosis. The techniques include describing and visualizing the client's problem, imagining alternative reactions, dreaming about new solutions, and trying the solutions in real life. The method is illustrated by 2 clinical examples. The discussion focuses on a comparison of the techniques used with individuals versus with small groups, the fostering of regression in the service of the ego, and the redirection of attention from the physically out of control to the recognition of the possibility of obtaining control. This shift of attention fosters active coping on the part of the client.

1977

Buckner, Linda G.; Coe, William C. (1977). Imaginative skill, wording of suggestions and hypnotic-susceptibility. International Journal of Clinical and Experimental Hypnosis, 25, 27-36.

3 groups of 20 s based on preselected imaginative capacity were administered either a hypnotic susceptibility scale containing item wording that suggested a goal-directed fantasy or one that did not. Preselected imaginative ability did not predict hypnotic susceptibility or the production of goal-directed fantasies during hypnosis. However, Ss who received the hypnotic scale containing item wording that suggested goal-directed fantasies reported more goal-directed fantasies than Ss who received the other scale. Limitations of the study are discussed and the causal role of goal-directed fantasy in hypnotic responsiveness is questioned.

1976

Gur, R. C.; Reyher, J. (1976). Enhancement of creativity via free-imagery and hypnosis. American Journal of Clinical Hypnosis, 18, 237-249.

Thirty-six male, highly susceptible subjects, divided into hypnosis, simulation and waking groups, were given the Torrance Test of Creativity with modified instructions requiring them to wait passively for visual images in response to the test stimuli. Twelve waking subjects received the same test under standard instructions. The hypnotized group scored higher than all control groups on over-all creativity and on Figural creativity, but not on Verbal creativity. The results seem to support the application of the ego-analytic concept of 'adaptive regression' to both hypnosis and creativity. They also seem to confirm the association found between hypnosis and the activation of the non-verbal cerebral hemisphere.

**Raikov, V. L. (1976). The possibility of creativity in the active stage of hypnosis. International Journal of Clinical and Experimental Hypnosis, 24, 258-268.**

Creative capacity was studied by means of suggestions given to Ss under the condition of active hypnosis. In deep hypnosis it was suggested to S that he was a famous person with a specific talent. In a series of experiments Ss performed under active hypnosis such tasks as drawing, playing musical instruments, and playing chess. The results illustrated that creative processes can be facilitated in Ss capable of deep hypnosis and there is a carry-over of the creative achievements from hypnosis to the waking state. Low hypnotic Ss and control groups did not show improvements in the tasks. A particular significant increase in creativity was observed when Ss capable of deep hypnosis performed several successive creative tasks while hypnotized. The theoretical and experimental definitions of several new approaches to active hypnosis are also discussed.

**Slade, P. D. (1976). An investigation of psychological factors involved in the predisposition to auditory hallucinations. Psychological Medicine, 6 (1), 123-132.**

Previous research by the author (Slade, 1972, 1973) and others has suggested that psychological stress plays an important role in triggering off the experience of auditory hallucinations. Clearly, however, predispositional factors are involved as well. The present study is an attempt to investigate some of the psychological factors which may predispose the individual to such experiences. A battery of tests involving cognitive, personality and mental imagery variables and the verbal transformation effect was administered to two small groups of psychotic patients differing only in respect of a history of auditory hallucinations and a normal control group. The main conclusion was that the results lend direct support to the proposition of Mintz & Alpert (1972) that a combination of vivid mental imagery and poor reality-testing in the auditory modality provides the basic predisposition for the experience of auditory hallucinations. 6458, Slade, 1976

1975

**Barber, Theodore Xenophon (1975). Responding to 'hypnotic' suggestions: An introspective report. American Journal of Clinical Hypnosis, 18 (1), 6-22.**

The author first presents an introspective report which describes some of his attitudes, motivations, and expectancies and ongoing thought processes while he is responding to 'hypnotic' suggestions. The introspective report indicates that (a) suggested effects are experienced when a person thinks with and imaginatively focuses on those things that are suggested and (b) a person imaginatively focuses on the suggestions when he sees the test situation as useful and worthwhile and when he wants to and expects to experience those things that are suggested. It is then argued that the responsive subject in a hypnotic situation differs in every important respect from the sleepwalker and closely resembles the person who is involved in reading an interesting novel or in observing an interesting motion picture. Finally, the author

outlines a course, now being developed, that aims to teach individuals how to respond to suggestions.

#### **NOTES**

**Imagination refers to (1) forming mental pictures (imaging) and creative innovating. The authors focus on "the more literal meaning of imagining, that is, 'having mental pictures,' for [they] believe that a clarification of that concept is basic to any further discussion of the psychology of the imagination.**

**"Before continuing, let us establish some reference cases for what a psychologist would call instances of imaging or imagining.**

**1. In a psychophysical experiment, a subject declares that he hears an auditory signal when no signal is presented. The experimenter scores the response as a 'false alarm.'**

**2. A patient in a mental hospital reports seeing the Mother of God. The psychiatrist classifies the report as a hallucination.**

**3. A novelist describes his work habits as involving conversations with imaginary characters. The critic calls this creative work.**

**4. A three-year-old child engages in play with a fictitious invisible rabbit. She is said to have an imaginary playmate" (p. 54).**

**Sutcliffe, J. P.; Perry, Campbell; Sheehan, Peter W. (1970). The relation of some aspects of imagery and fantasy to hypnotizability. Journal of Abnormal Psychology, 76, 279-287.**

**Studied relations between hypnotic susceptibility and some aspects of imagery and fantasy in a normal population of 95 undergraduates. Vividness of imagery was assessed by a reliable questionnaire adapted from procedures 1st devised by G. H. Betts; dreams were collected by a diary method which studied the incidence of distortion in dream content; and hypnotizability was assessed by the Stanford Hypnotic Susceptibility scale (Form C), a standardized scale devised by the authors, and a rating procedure based on both scales. Results show a positive, curvilinear relationship between vividness of imagery and hypnotic susceptibility, but no significant relationship for fantasy. Evidence suggests that both imagery and fantasy, considered conjointly, lead to a more accurate prediction of deep susceptibility than the imagery variable alone. (34 ref.) **Nowlis, D. P. (1969). The child-rearing antecedents of hypnotic susceptibility and of naturally occurring hypnotic-like experience. International Journal of Clinical and Experimental Hypnosis, 17, 109-120.**

Data pertaining to early and mid-childhood socialization experiences available from a sample of children and their mothers as studied earlier by R. R. Sears, E. E. Maccoby, H. Levin, and others were related to hypnotizability scores and scores of susceptibility to naturally occurring hypnotic-like experiences for a part of the same sample when the children reached late adolescence. As hypothesized by J. R. Hilgard and E. R. Hilgard (see 37:3) after retrospective interviewing with college-age hypnotic Ss, the present study, using a longitudinal method of investigation, indicated some relationship between firm parental discipline in childhood and subsequent susceptibility to hypnosis and hypnotic-like experiences in adolescence. Correlations, however, were low and the overall yield of significant data was judged to be meager. This was particularly true of hypnotizability scores in relation to the other variables available for analysis. Barber, Theodore Xenophon; Calverley, David S. (1968). Toward a theory of 'hypnotic' behavior: Replication and extension of experiments by Barber and co-workers (1962-65) and Hilgard and Tart (1966). International Journal of Clinical and Experimental Hypnosis, 16, 179-195.

RESPONSES TO TEST SUGGESTIONS (E.G., HALLUCINATION AND AMNESIA) WERE ASSESSED UNDER THE FOLLOWING TREATMENTS: MOTIVATIONAL INSTRUCTIONS ALONE, HYPNOTIC PROCEDURE WITH MOTIVATIONAL INSTRUCTIONS, AND IMAGINATION-CONTROL. COMPARISONS WERE MADE ACROSS INDEPENDENT GROUPS, EACH TESTED UNDER 1 TREATMENT, AND ALSO WITHIN THE SAME SS TESTED TWICE UNDER VARIOUS COMBINATIONS OF THE TREATMENTS. ALTHOUGH SS WERE SUGGESTIBLE UNDER THE IMAGINATION-CONTROL TREATMENT, BOTH THE MOTIVATIONAL INSTRUCTIONS ALONE AND THE HYPNOTIC PROCEDURE GIVEN TOGETHER WITH THE MOTIVATIONAL INSTRUCTIONS RAISED SUGGESTIBILITY ABOVE THE CONTROL LEVEL. THE HYPNOTIC-MOTIVATIONAL TREATMENT TENDED TO PRODUCE AN INCREMENT IN SUGGESTIBILITY WHICH WENT SLIGHTLY BEYOND THAT ATTRIBUTABLE TO THE MOTIVATIONAL INSTRUCTIONS. THE LATTER INCREMENT IS INTERPRETED AS DUE TO THE SLIGHTLY GREATER EFFECTIVENESS OF THE HYPNOTIC PROCEDURE IN DEFINING THE SITUATION AS ONE IN WHICH UNUSUAL MANIFESTATIONS, SUCH AS HALLUCINATION AND AMNESIA, ARE WITHIN SS' CAPABILITIES AND DEFINITELY EXPECTED BY E. **Schneck, Jerome M. (1955). Hypnotic interviews with the therapist in fantasy. Journal of Clinical and Experimental Hypnosis, 3 (2), 109-116. (Abstracted in Psychological Abstracts, 56: 1126)**

#### **NOTES**

**" Summary. This report furnishes illustrations from two patients of the technique consisting of hypnosis interviews conducted by the patients with the therapist in fantasy. This method emerged from previous work with visual imagery in the form of scene visualization and some of its derivatives. The writer believes that further work with the technique presented now may prove to be beneficial in psychotherapy. At the same time it offers an opportunity for further study of personality functioning in general and certain aspects of psychodynamics. The patients manipulate the session in a way which furthers a duality in their functioning as a result of which they attempt to probe and contend with contradictory tensions in their unconscious. The image of the therapist undergoes certain distortions demonstrating dynamisms such as projection and identification as utilized by the patient. The therapist is in a position to view all of this and to discern elements in his relationship with the patient which may otherwise have escaped him. Countertransference issues may be clarified in this way. The technique may assist at points where the therapist seems to be functioning too blindly and where the patient may more pointedly show the way by guiding the therapist while relating to a mental image of him. There is a possibility that some aspects of this approach in treatment may prove of value in psychotherapy which does not**

incorporate hypnosis. This may be of assistance to workers who have not been trained in hypnotherapy" (pp. 115-116).

1953

Israeli, Nathan (1953). Experimental study of projection in time: I. Outlook upon the remote future--extending through the quintillionth year. Journal of Clinical and Experimental Hypnosis, 1 (2), 49-60.

#### Author's Summary

This report on research now under progress is concerned with time projection and with hypnotic imagination and dreams of projection into varying remote future periods extending to the very distant quintillionth year. The work proceeded in stages including (a) orientation to the general procedure, (b) hypnotic future autobiographic material (age progression), (c) going successively from one future period to another from the end of the 21st century through the quintillionth year -- devoting usually one experimental session to any future period. This paper reports on the self-ratings for hypnosis depth reached by the subjects, their description of life, things, and events, in connection with each projection into a future period, and their visual or nonvisual imagery.

1. Self-ratings for hypnosis depth show with one insignificant exceptional instance that all subjects were always at least at the trance-level or in a deeper hypnotic stage. Individual differences in level reached were indicated with a general trend towards more profound trance in later sessions. The deeper levels on the scale used were not described by the experimenter. Each subject gave those levels his own interpretation in setting up his own scale.

2. The time projections are to be explained in terms of changing space-time framework, social topographic reorientation, recentering, and non-conventional time centering.

3. Hypnotic suggestion to imagine and dream about being suddenly transported and projected into a specified future period is followed by rapid recentering as the subjects follow out the suggestions.

4. Although no specific instructions or sets of suggestions were included about the nature of their anticipations, the description of life, things, and events of any future period was on a predominant impersonal level, with the personal aspects in the background. Nonetheless, the suggestion of transportation and projection into a future period leads to various changes in one's present-situation perceptions, imagery, space-time framework, and system of concepts and beliefs. With a change in time reference, the description of life, things, and events is adjusted to the era or epoch specified. This involves description of technological, biological, psychological, and anthropological changes. The extinction of mankind is anticipated in the very remote future by some subjects. The earth and the moon are expected to disappear by collision or otherwise.

5. Individual analysis shows that the descriptions of the different future periods approximately fit into patterns and are not discontinuous. An individual subject's descriptions beginning with the first future period and taking in all the other periods show constructive or catastrophic trends or cyclical variation between both

extremes. Descriptions of life, things, and events of each future period in the main change in a constructive or in a catastrophic direction. They are continuous but with certain discontinuities and incoherence.

6. A geocentric orientation and a heliocentric preoccupation are invariant and predominant. The subjects are unable to abandon their basic planetary orientation or schemata.

7. Colored imagery includes mainly the primary colors. They comprise both expanse colors and surface colors. Auditory imagery is quite frequent. There are also references to olfactory, tactile, and kinesthetic imagery. Thermic imagery becomes increasingly prominent in the more remote future periods when the sun's heat is described as more intense. Imagery changes with the outlook patterns and appears to have personal, structural, and social determinants. One subject's imagery was macropic.

## IMMUNOLOGY

2003

Wood, Gary J.; Bughi, Stefan; Morrison, John; Tanavoli, Sara; Tanavoli, Sohrab; Zadeh, Homayoun H. (2003). Hypnosis, differential expression of cytokines by T-cell subsets, and the hypothalamo-pituitary-adrenal axis. *American Journal of Clinical Hypnosis*, 45 (3), 179-196.

Tested the hypothesis that hypnosis can differentially modulate T-cell subsets, and that this effect is mediated by changes in hypothalamo-pituitary-adrenal (HPA) mediators. Seven healthy, highly hypnotizable volunteers (aged 24-42 yrs) participated in 3 1-day sessions, a baseline and 2 intervention sessions. Hypnosis intervention entailed a standardized induction, suggestions for ego strengthening and optimally balanced functioning of the immune and neuroendocrine systems, and post-hypnotic suggestions for stress management and continued optimal balance of bodily systems. Blood samples were analyzed for T-cell activation and intracellular cytokine expression (Interferon [IFN]-gamma, Interleukin-2 [IL-2], Interleukin-4,) and HPA axis mediators (ACTH, cortisol, and beta-endorphin). The proportion of T-cells expressing IFN-gamma and IL-2 were lower after hypnosis. T-cell activation response to polyclonal stimulation was positively correlated with ACTH and beta-endorphin, while IFN-gamma expression was correlated with levels of cortisol. Further controlled studies utilizing hypnosis with patients in treatment are warranted in order to examine whether an altered T-cell response can be replicated in the presence of disease. 2002

Hammond, D. C. (2002). Treatment of chronic fatigue with neurofeedback and self-hypnosis.. *NeuroRehabilitation*, 16, 1-6..

A 21 year old patient reported a relatively rapid onset of serious chronic fatigue syndrome (CFS), with her worst symptoms being cognitive impairments. Congruent

with research on rapid onset CFS, she had no psychiatric history and specialized testing did not suggest that somatization was likely. Neuroimaging and EEG research has documented brain dysfunction in cases of CFS. Therefore, a quantitative EEG was done, comparing her to a normative data base. This revealed excessive left frontal theta brainwave activity in an area previously implicated in SPECT research. Therefore, a novel treatment approach was utilized consisting of a combination of EEG neurofeedback and self-hypnosis training, both of which seemed very beneficial. She experienced considerable improvement in fatigue, vigor, and confusion as measured pre-post with the Profile of Mood States and through collaborative interviews with both parents. Most of the changes were maintained at 5, 7, and 9 month follow-up testing.

Kiecolt-Glaser, Janice K.; Marucha, Phillip T.; Atkinson, Cathie; Glaser, Ronald (2001). Hypnosis as a modulator of cellular immune dysregulation during acute stress. Journal of Consulting and Clinical Psychology, 69 (4), 674-682.

To assess the influence of a hypnotic intervention on cellular immune function during a commonplace stressful event, the authors selected 33 medical and dental students on the basis of hypnotic susceptibility. Initial blood samples were obtained during a lower stress period, and a second sample was drawn 3 days before the first major exam of the term. Half of the participants were randomly assigned to hypnotic-relaxation training in the interval between samples. Participants in the hypnotic group were, on average, protected from the stress-related decrements that were observed in control participants' proliferative responses to 2 mitogens, percentages of CD3-super(+) and CD4-super(+) T-lymphocytes, and interleukin 1 production by peripheral blood leukocytes. More frequent hypnotic-relaxation practice was associated with higher percentages of CD3-super(+) and CD4-super(+) T-lymphocytes. These data provide encouraging evidence that interventions may reduce the immunological dysregulation associated with acute stressors. Rossi, Ernest L. (2000). In search of a deep psychobiology of hypnosis: Visionary hypotheses for a new millennium. American Journal of Clinical Hypnosis, 42 (3/4), 178-207.

This search for the deep psychobiological foundations of hypnosis begins with a review of some of the paradoxes of historical hypnosis and the impasse of current theory. It is proposed that further progress requires a deeper investigation of how psychosocial cues can modulate the mechanisms of healing at the CNS, autonomic, neuroendocrine and cellular-genetic levels. The dynamics of hypnotic communication and healing from the cognitive-behavior level to the cellular-genetic are outlined in 4 stages: (1) information transduction between the experiences of consciousness and the limbic-hypothalamic-pituitary system; (2) the psychosomatic network of messenger molecules and their receptors; (3) the immediate early gene

protein cascade; and (4) state dependent memory, learning and behavior. Neuroscience research is outlined for its contributions to a mathematical model of how a psychobiological approach to the therapeutic applications of hypnosis and the placebo response could facilitate neurogenesis in the human hippocampus and healing at the cellular-genetic-protein level throughout the body. A series of 10 hypotheses is proposed as a guide for theory and research in therapeutic hypnosis. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1997

Schafer D. W. (1997). Hypnosis and the treatment of ulcerative colitis and Crohn's disease. American Journal of Clinical Hypnosis, 40 (2), 111-117.

Ulcerative colitis and Crohn's Disease can be cured if they are treated as autoimmune diseases with a special understanding of the personality conflicts in the patient. The author hypothesizes that all autoimmune diseases are characterized by a high normal amount of the aggressive instinctual drives and ambivalence about their realization. Each patient's personality causes the ambivalence to be somaticized into specific autoimmune bodies that aggressively are overproduced and then attack specific tissues. Hypnosis helps in gaining insight, reinforcing interpretations, handling stress, visualizing normal intestinal areas, and controlling of the autoimmune antibodies to the normal level. This paper deals specifically with these 2 diseases.

Hall, Howard; Papas, Angela; Tosi, Michael; Olness, Karen N. (1996). Directional changes in neutrophil adherence following passive resting versus active imagery. International Journal of Neuroscience, 85, 185-194.

This study was designed to determine whether increases or decreases in neutrophil adherence could be achieved following a self-regulation (relaxation/imagery) intervention. Fifteen subjects were randomly assigned to one of three conditions. Two experimental groups employed imagery focused on either increasing or decreasing neutrophil adherence. Subjects had two weeks of self-regulation practice (4 total training sessions) prior to blood drawings. A third group of control subjects had the same number of resting sessions without imagery training. All subjects had blood samples collected before and after either 30 minutes of self-regulation or resting practice for two sessions. Pulse and peripheral finger temperature measures were taken before and after the blood samples. Both experimental groups demonstrated decreases in neutrophil adherence, and the control group showed a tendency toward increases in this measure. The psychophysiologic data for the control group was suggestive of a relaxation response. The experimental group that attempted to increase neutrophil adherence demonstrated psychophysiologic responses that were contrary to relaxation. We concluded that an active cognitive exercise or process is associated with decreases in neutrophil adherence irrespective of the intent of the exercise. In contrast, relaxation without an active imagery exercise was associated with increases in neutrophil adherence. The results of this

study are discussed in terms of behavioral engineering of directional immune changes.

**NOTES**

**1:**

Historically, hypnosis has been associated with mental healing (e.g. Mesmer's salon), and clinical literature has been well reviewed by T. X. Barber (1984); Di Piano & Salzberg (1979); E. Hilgard & J. Hilgard (1975); Mott (1979); Paul (1963); and Perry, Gelfand, & Marcovitch (1979). Recently psychoneuroimmunology research has provided some support for the clinical evidence of healing. Research in this area should provide for determining whether the results are due to relaxation, to suggestion (waking or hypnotic), to personality (high hypnotizability), and should lead to an understanding of the basic physiological processes.

Clinical studies are sometimes given more credence by basic laboratory studies in a closely related area. For example, irritable bowel syndrome responded better to hypnosis with direct suggestions than to a combination of psychotherapy and a placebo pill (Whorwell, Prior, and Faragher, 1984). In the laboratory, Klein and Spiegel (1989) showed that secretion of stomach acid could be controlled by hypnosis and suggestion. Chapman, Goodell, & Wolff (1959) demonstrated that hypnotic suggestions could not only decrease but could increase the inflammatory response to burns, and that the response probably was mediated by a histamine-type substance.

Warts have been removed not only by hypnotic suggestion but by waking suggestion (Spanos, Stenstrom, & Johnston, 1988; Spanos, Williams, & Gwynn, 1990), and the hypnosis was more effective than potent placebo comparison treatment conditions. The elimination of warts may be related to control of blood flow or to a change in the immunological response. Chaves, Whilden, & Roller, 1979 (and Chaves, 1980) showed that dental patients could reduce the blood loss associated with dental surgery, using hypnosis and imagery suggestions. Bennett, Benson, & Kuiken (1986) helped back surgery patients to reduce blood loss using waking suggestions. The

immune response also can be modified using hypnotic suggestion (Zachariae, Bjerring, & Arendt-Nielsen, 1989).

In the research on mind-body healing, the following considerations also apply: 1. People's psychosomatic reactivity may affect the results obtained with hypnosis. Research on the immune response has sometimes used patients with psychosomatic disorders as the research subjects, to assure reactive physiological systems. 2. Severity of the disease may affect outcome (e.g. in the Spanos studies, those with the most warts responded best to the hypnosis intervention). 3. Hypnotizability sometimes relates to outcome and sometimes does not, in these investigations. In general, among very highly hypnotizable people, some can perform one hypnotic task such as develop amnesia while others can perform other, different hypnotic tasks.

In summary, there is an extensive clinical literature on hypnosis and healing, and experimental laboratory studies can offer support and some understanding of hypnosis effects on blood flow, histamine release, acid release, immune cell function, etc. In order to establish the effect of hypnosis one needs to start with the best chances for finding an effect: use high hypnotizable subjects. But later you either need to see if results correlate with general hypnotizability or with some other ability or experience, and often waking suggestion is sufficient.

Zachariae, Robert; Locke, Steven E. (1994, October). Effects of hypnotic suggestions on immune and inflammatory processes--experimental studies 1962-1994. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

## NOTES

1:

We reviewed studies of the effects of hypnotic suggestion to enhance or suppress immediate type hypersensitivity (ITH) or delayed type hypersensitivity (DTH) skin responses (investigations between 1960-1994). In the early 60's most of the studies occurred in England with Black and colleagues. In Black's studies there weren't many subjects.

In most studies the stimulus was an allergen to the patient, or histamine injections that mimic immediate type hypersensitivity response. In one study we have used ultraviolet stimulation. Most studies involve decreasing the response, but a few studies used both increasing and decreasing the response.

Measures include the wheal response (local) and erythema (mediated by the nervous system). Most studies find a reduction in both types of response, but in some of our later studies and also the study by Beahrs, Harris, & Hilgard (1970) they didn't find a wheal response but did find erythema reduction. In the ultraviolet response we didn't get a reduction in erythema but did in blood flow.

Studies in delayed type hypersensitivity usually measure induration and erythema; 3 used tuberculin, 3 used varicella zoster, 1 used multiple antigens, 1 used mumps. Antigen in mumps is latent in the body so the immune response will be different. Most studies tried to increase and decrease the response; two tried just to increase, one just to depress it. Some tried to increase the response in one arm and suppress it in the other arm. In ours we separated the two conditions by a week.

## **RESULTS.**

**ITH in general can be suppressed, both the wheal and flare response. Erythema was altered in six studies, unchanged in three; wheal response was altered in [missed number] and unchanged in four. Some studies used allergic patients or those with a psychosomatic history; others screened them out.**

**DTH results are inconclusive for erythema and induration. All studies using PPD as the antigen were positive; one study using DCP and DNCB was positive. Negative results are found in three studies using Varicella Zoster; 1 study using the Multitest, and 1 study using mumps as antigen.**

**One could think the reasons for positive vs. negative results relate to the antigens used, and also the dosages given. Some studies use very small doses; one of ours uses such a large dose it is actually felt and sensed. Health status of Ss also could make a difference: a healthy immune response would resist modification if it's not needed. Timing between stimulus and measurement also varies. Suggestions and rapport may affect results, and also the presentation of suggestions. (Some studies taped the suggestions, some use scripts, but using tapes or scripts may lessen rapport with the Subjects.) Measurements differ, e.g. from area tested, diameter of measurement, type of measurement (ultrasound to measure skin thickness, caliper measurement of skin thickness). In measuring hypnotizability and selecting only high hypnotizables, you may eliminate people who can modify their physiological processes. Ss differ with degree of prior training (those with training are more able to effect responses than on the first time). Operator differences between hypnotists may have some effect.**

**Mechanisms of the process being studied are at issue: Are we dealing with immune or non-immune processes. Changes in skin temperature and blood flow suggest the latter (vaso dilation and vaso constriction), because of lack of changes seen in lymphocytes etc, although two studies found some kind of changes.**

**Damage to cutaneous sensory nerves has produced clearing of psoriasis.**

### **COMMENTS FROM THE AUDIENCE:**

**H. Bennett: How about hypnotizability of the Subjects? Also, T. X. Barber indicated in a long review article that local vascular response accounts for all of this.**

**Response: Just testing for hypnotizability isn't enough. Local response may be important; immunologists say this isn't immunology because you are affecting nonimmune responses.**

**1993**

**Covino, Nicholas A.; Frankel, F. M. (1993). Hypnosis and relaxation in the medically ill. Psychotherapy and Psychosomatics, 60, 75-90.**

**Interest in the application of hypnotic techniques for patients with medical disorders seems to rise and fall over the years. Enthusiasm for this work comes both from patients and from clinicians. Often, however, these techniques are offered without regard to the psychological theories that should inform their operation and the limits that clinical and experimental research suggest. This article offers a brief description of the elements of hypnosis and a review of the history of the use of**

hypnotic techniques with a variety of medical problems, including asthma, habits, pain, cardiology, surgical preparation, irritable bowel syndrome, persistent nausea and vomiting, trichotillomania, and infection and immunity. Special attention is placed on the psychological and physiological principles that help to establish the valid use of hypnotherapy.

Don, Norman S. (1993, October). Trance surgery in Brazil. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

**NOTES**

**1:**

Showed a videotape of a Brazilian trance surgeon, who cuts without analgesia or asepsis. Patients later report no pain, infections, etc. The healer/surgeon is believed by everyone to be in a trance state, and the body is believed to be taken over by a spiritual doctor. The people involved deny that the patient is in trance.

Hall, Howard; Minnes, Luke; Olness, Karen (1993). The psychophysiology of voluntary immunomodulation. International Journal of Neuroscience, 69, 221-234.

In twenty-two studies of intentional efforts of humans to change immune measures, only four monitored psychophysiologic parameters. One study reported physiologic alterations associated with immune changes. In this current study we examined changes in pulse rate and peripheral temperature associated with intentional changes in neutrophil adherence. Subjects had blood, pulse and temperature recordings collected before and after either a rest condition (Group A), or a self-regulation exercise (Groups B and C) for two sessions. Group C had four prior training sessions before participating in the experimental sessions. This study found no association between psychophysiologic alterations and neutrophil changes. the control group (A) demonstrated no significant neutrophil changes but showed physiologic alterations, whereas, the experimental group (C) that showed increases in neutrophil adherence demonstrated no significant physiologic changes. It was speculated that intentional changes on neutrophil adherence and the pattern of the psychophysiologic measures were associated with and reflective of cognitive activity.

Hall, Howard R.; Papas, Angela; Tosi, Michael; Olness, Karen (1993, October). Bi-directional changes in neutrophil adherence following hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

**NOTES**

**1:**

At the last time that I presented a paper, I talked about the neutrophil. The neutrophil is a model of convenience because it responds quickly to psychological interventions, it is important in upper respiratory infections, and it can be measured reliably in vitro.

We had found that Ss with two weeks of relaxation/imagery training showed an increase in stickiness of neutrophils. We wanted to replicate and extend that study.

We wanted one group to increase, another group to decrease, stickiness in neutrophils. There were a total of three groups, including a resting control group. The model of investigation involves two weeks of training in self hypnosis or simply resting.

Session 1

1 week of practice

Session 2

**Results.** The Control group increased adherence in neutrophils. The imagery-increase group and imagery-decrease group both decreased adherence. (In the first study the controls had no previous experience in relaxation. Also, the experimental group that was tested showed a decrease in first week and increased in the second week.)

Imagery is work, and that may result in less adherence. Pulse rate increased for the group trying to increase stickiness, in Session 1--implying less relaxation for them.

Hypnotizability (measured with the Pennsylvania State University Scale) was not correlated with increase in neutrophil adherence.

#### NOTES

Bill Moyers' TV show on public television, Healing and the Mind, was seen by 15 million when first shown, and the book became a Book of the Month selection. Consumer Reports published Mind-Body Medicine. A TV program, Heart of Healing, sponsored by Noetic Sciences, will be shown; their teaching guides refer to the Society for Clinical and Experimental Hypnosis (SCEH).

The federal government's NIH Office of Alternative Medicine (OAM) now has grants providing up to \$30,000; in first year they received 800 letters of intent, ultimately 500 applications. In Nursing Research they also have sponsored research with OAM. OAM and the Cancer Institute are evaluating studies on using visual imagery with cancer patients. July of this year there was a 3-day working conference, with 80 scientists--1/2 of them from NIH--; David Spiegel and Karen Olness were there. Forty draft RIA's will be coming out. She will give us a draft of the RIA's.

Fetzer Institute of Michigan has been involved, with Robert Lehman--new director--who vows to make it the leading institute for research on the mind. They funded the NIH Conference, but don't give direct research support to investigators.

Marketing information on science and clinical medicine is not an interest for me, but Fetzer's marketing effort has resulted in research support that previously we would not have had. We do not have enough research on the value (cost vs benefits) of hypnotherapy.

Jacknow & Associates looked at nausea in children; hypnotized patients had less nausea than the control group. Syrjala's study (Pain, 1992) and this one did not have a cost benefit component.

A medical student and I learned that even HMOs don't know the average costs for various treatments for migraine headaches. There are only 3 controlled studies on child migraine that compare drugs to placebos! 5-7% of children in U.S. have migraines; 18% of men and 22% of women also have migraines.

We need more studies of how hypnotic ability can be modified, to increase beneficial outcomes.

We are forming a pediatric multi-site group to study Tourette's Syndrome and warts. A Wart Sensor is being developed to measure what is going away and in what order; by Case Western Reserve.

There should be increased funds available in the next 5-7 years. The magazine Scientific American, Sept 24 1993, predicts more support for the behavioral sciences.

It's time to explain the mechanisms of what happens in hypnosis.

Olness, Karen N. (1993, October). Intentional immunomodulation - does it exist?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

## NOTES

1:

Robert Ader coined the term psychoneuroimmunology. The immune system is modulated by feedback mechanisms mediated via neural and endocrine processes, and by feedforward mechanisms, as well (see the second edition of Ader's book).

Ader, Grotta, and Cohen have shown that the immune system of animals also can influence behavior (e.g. genetic influences on preference for chocolate). She thinks this should be considered in designing controlled studies.

In her review of studies, some investigators request Ss to focus on changing an immune parameter; others to "relax." There is evidence for intentional influence on the immune response. Black in England and Good in the U.S. presented studies (Manteaux, histamine sensitivity, etc.) and all were laboratory studies.

Olness (1986) worked with children: they were given self hypnosis practice with instructions to "increase the immune stuff in your spit." This suggestion or request resulted in an increase in saliva IgA. [N.B. In giving suggestions to children, don't use the words "I want you to ..." because that phrasing may arouse resistance.]

The area of hypnosis and suggestion curing warts has a lot of research papers. We are doing a consortium study on treatment of warts with hypnosis and found that basic agreement on methods, such as "how you define a wart," don't exist.

Schoen, Marc (1993). Resistance to health: When the mind interferes with the desire to become well. American Journal of Clinical Hypnosis, 36, 47-54.

Secondary gain has long been viewed as a variable that can significantly affect a patient's recovery from such conditions as chronic pain disorders, factitious and somataform disorders, and other psychological disorders. Secondary gain has not been evaluated in terms of its impact on major illnesses such as cancer or autoimmune disorders. In this paper I discuss how secondary gain can be present in such illnesses and how it results in a resistance to health. This resistance to health can lead not only to medical noncompliance, but can also ultimately affect the progression and recovery from the illness. I describe how hypnosis can be used to

ferret out this resistance to health and how patients in a hypnotic state will indicate or express their resistance to becoming healthy. The advantage of this approach is that it enables the clinician to deal directly with the patient's unconscious resistance to health.

Walker, Leslie G.; Johnson, Vanessa C.; Eremin, Oleg (1993). Modulation of the immune response to stress by hypnosis and relaxation training in healthy volunteers: A critical review. Contemporary Hypnosis, 10, 19-27.

#### NOTES

1:

They review literature on modulation of the immune response to stress with relaxation and/or hypnosis, and raise the following questions and conclusions: 1. It is not clear which dependent variables should be studied. 2. There is a need to clarify which independent variables are responsible for particular effects. 3. There is the question of moderator variables. 4. There is room for many more case studies, including single case research (given the uncertainties discussed and the costs of controlled studies). 5. There is evidence that pathways exist whereby the brain could alter or modulate aspects of immune reactivity. [They describe assigning 20 healthy volunteers randomly to experimental or control group. The experimental group received 3 weeks progressive relaxation and cue-controlled relaxation training, with hypnosis before exposure to an experimental stressor--video recording and playback of a doctor-patient role play. They evaluated not only the biochemical and immunological effects of relaxation training but also the effect in modulating the biological responses to stress.] 6. They concentrated on studies with healthy volunteers because there are already known immunological changes in patients who have tumors. However people with a healthy immune system may have a natural limit in how much they can improve their immune response with interventions like hypnosis.

Zachariae, Robert; Bjerring, P. (1993). Increase and decrease of delayed cutaneous reactions obtained by hypnotic suggestions during sensitization. Studies on dinitrochlorobenzene and diphenylcyclopropanone. Allergy, 48, 6-11.

Cutaneous reactivity to challenge with dinitrochlorobenzene (DNCB) and diphenylcyclopropanone (DCP) was studied in 16 subjects following hypnotic suggestions to increase and to decrease response during sensitization. The immunoreactivity to DNCB and DCP was modulated by direct suggestions and guided imagery under hypnosis. Subjects were high in hypnotizability as measured by the Harvard Group Scale of Hypnotic Susceptibility. Measurement of skin reactions to the challenge one month after sensitization was performed double blindly. Results showed a significant (.01) difference in visually scored reactions to DCP and DNCB between the group instructed to increase reaction to DCP and decrease reaction to DNCB and the group given the opposite instructions. A nonsignificant difference (.055) in skin thickness measured by ultrasound was found between the two groups. The study supports previous reports of experimental modulation of immunoreactivity and indicates that the specific immunological

processes involved in the development of all allergic reactions may be susceptible to psychological factors.

1992

Ewin, Dabney M. (1992). Hypnotherapy for warts (*verruca vulgaris*): 41 consecutive cases with 33 cures. American Journal of Clinical Hypnosis, 35, 1-10.

Published, controlled studies of the use of hypnosis to cure warts are confined to using direct suggestion in hypnosis (DSIH), with cure rates of 27% to 55%. Prepubertal children respond to DSIH almost without exception, but adults often do not. Clinically, many adults who fail to respond to DSIH will heal with individual hypnoanalytic techniques that cannot be tested against controls. By using hypnoanalysis on those who failed to respond to DSIH, 33 of 41 (80%) consecutive patients were cured, two were lost to follow-up, and six did not respond to treatment. Self-hypnosis was not used. Several illustrative cases are presented.

#### NOTES

I do not consider self-hypnosis necessary, and I believe it may be contraindicated. Once the change in sensation has been acknowledged by an ideomotor signal, I suggest that the subconscious will take care of healing the warts and that the patient should ignore them and get interested in other things. Self-hypnosis would require regularly giving attention to the warts, and a high rate of cure is obtained without it. In their controlled study using DSIH with adults, Johnson and Barber (1978) included daily self-hypnosis and got cures in only 3 of 11 (27%) of the hypnotic group. This is the poorest result in the published literature. Their control group of 11 patients was given waking suggestions to 'practice imagining that the specified wart(s) were tingling for a few minutes each day until they were gone' and got no change in 3 months. Hellier (1951) got remission in 27 of 74 (36%) patients just using sham x-ray, (waking suggestion without any self-hypnosis). Spanos et al. (1988) instructed their hypnotic group to 'count their warts every day, and after each counting to close their eyes and spend 3 to 4 minutes imagining the warts on their target hand disappearing.' Only 2 of 8 patients (25%) with a single wart cleared, while 9 of 14 (69%) with multiple warts lost one or more warts at 6- weeks' follow-up. My impression is that conscious daily attention to the lesion is contrary to normal body healing of injuries such as cuts, burns, sprains, in which healing progresses best when ignored while undue attention increases suffering" (pp. 3-4). All Ss were private patients referred for hypnotherapy; most were diagnosed clinically.

"...I found that there were sexual implications in 7 of the 16 miscellaneous warts in patients over 13, so I separated the cases into pre- and postpuberty to evaluate the results" (p. 4).

"An early success was with a medical student (Case 28) with whom I used suggestions of warmth, with the blood vessels dilating and bringing in antibodies, leukocytes, opsonins, etc. Changes were visible in 3 days. This biased me toward using 'warm,' but two of the children (Cases 6 and 9) got no result until I gave them a choice. Using ideomotor signals they chose cold. Only two healed with 'warm,'

while five did with 'cold.' All of them had either had the warts cauterized or frozen previously and had a personal feeling about heat and cold. I've learned to give the patient a choice on the first visit" (p. 5).

"Three... were first treated using DSIH without result and later responded to hypnoanalysis. After obtaining an ideomotor signal that there was no more subconscious value to the warts, the suggestion was given that the body's healing processes would take over without any more conscious attention by the patient. No self-hypnosis was prescribed" (pp 7-8).

Gildston, Phyllis; Gildston, Harold (1992). Hypnotherapeutic intervention for voice disorders related to recurring juvenile laryngeal papillomatosis. International Journal of Clinical and Experimental Hypnosis, 40 (2), 74-87.

Recurring juvenile laryngeal papillomatosis is resistant to cure, and thus usually requires multiple operations which may lead to the extensive proliferation of vocal fold scar tissue. Severe hoarseness, sharply lower pitch, and weak loudness levels are common sequelae. Adjunctive hypnotherapy can increase motivation for change, speed up the acquisition of vocal skills, and possibly even facilitate or sustain remission of growths in selected patients. An 8-year-old girl with severe active eruptions went into remission after 16 sessions, and a 12-year-old boy, already in remission at the beginning of the intervention period, remained free of neoplasms throughout the regimen. Whether or not hypnosis contributed significantly to the sanguine results, it is probable that, at the least, the hypnotic intervention facilitated the achievement of certain technical objectives in voice therapy.

Includes a review of relevant studies of physiologic changes induced by hypnosis.

Hall, Howard R. (1992, October). Voluntary immunomodulation in adolescents: A cyberphysiologic approach. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

NOTES

1:

He is working with a normal population studying neutrophils.

Gave Ss 30 minutes of an imagery exercise to increase neutrophil adherence when compared with controls; e.g., imagery could be ping pong balls in the blood stream, clumping together with honey.

Phase 1: blood sample; strategy or rest; blood sample  
practice for 1 week at home

blood sample; strategy; blood sample Hypothesis 2 Healthy adolescents who practice cyberphysiologic (imagery) strategies for 2 weeks will increase neutrophil adherence compared with controls.

Phase 2:

2 week training in cyberphysiologic technique

Session 1 and Session 2 same as in first study. (Thus, these Ss had practiced the technique already.)

Results were analyzed with ANOVA. Only one factor was significant: neutrophil adherence, the one they were studying.

The experimental group with no prior training showed less adherence than controls, as did the trained group in session 1; but the trained group in session 2 showed a large increase over session 1.

Does this reflect relaxation or an active cognitive process? The group that showed the most change did not show relaxation effect of lowered pulse and finger temperature, though the other two groups lowered pulse rate some. Therefore, it is not relaxation.

There was no association of hypnotizability to the increase in neutrophils, using the Penn State Group Hypnotizability Scale, which correlates with the Stanford Scale.

In future the author will look at whether Ss can increase and decrease neutrophil adherence.

Hall, Howard; Minnes, Luke; Tosi, Michael; Olness, Karen (1992). Voluntary modulation of neutrophil adhesiveness using a cyberphysiologic strategy. International Journal of Neuroscience, 63, 287-297.

In a study of voluntary immunomodulation, 45 subjects were assigned either to a control group or one of two experimental groups. All groups had blood and saliva samples collected before and after either a 30 minute rest condition (Control group) or a 30 minute cyberphysiologic strategy (Experimental groups) to increase neutrophil adherence. These samples were analyzed on a range of immunologic measurements including neutrophil adherence. The second experimental group practiced a cyberphysiologic strategy two weeks prior to the experimental session. Subjects in each group returned to repeat their exercise in a second session the following week. Analysis of all immune measurements revealed statistical significance for changes in neutrophil adherence. These studies suggest that such strategies may be used to effect changes in immune cell functions. Analysis further revealed that those subjects with prior cyberphysiologic training were able, by the second session, to induce a significant increase in neutrophil adherence.

Hall, Howard R.; Mumma, Gregory H.; Longo, Santo; Dixon, Richard (1992). Voluntary immunomodulation: A preliminary study. International Journal of Neuroscience, 63 (3-4), 275-285.

This study explored the effects of relaxation and imagery procedures on the voluntary self-regulation of immune responses. Immune studies of 19 adults were made before and after a 45 minute intervention consisting of relaxation with imagery aimed at enhancing immune activity. A self-report measure of psychological distress was completed before each blood sample. Results indicate that the seven blood measures of immune functioning were measured with adequate reliability and consisted of two sets of immune parameters. A statistically significant increase in one of the mitogen measures and a marginally significant increase in one of the blood count measures was found following the relaxation/imagery procedure. Age, hypnotizability, and their interaction significantly predicted change on the set

of blood count measures but not on the set of mitogen measures. As expected, level of subjective psychological distress generally decreased following the intervention. The methodological limitations of this study included limited sample size and absence of a control group.

Holroyd, Jean (1992). Hypnosis as a methodology in psychological research. In Contemporary hypnosis research (pp. 201-226). New York: Guilford Press.

## NOTES

1:

This chapter deals with how the changes brought about by hypnosis (in cognition, behavior, motivation, etc.) may be used in research in other areas of psychology. "The distinction between experimental effects attributable to a personality trait (i.e. hypnotizability), hypnosis context (i.e. an induction), and interaction between the two is particularly important in using hypnosis as a research strategy.

The author discusses suggestibility, imagery enhancement, and changes in the mind-body relationship (immunology, pain, cognitive neuropsychology, attention, learning and memory, and awareness) as they might be employed in social psychology or psychophysiology research. She reviews problems inherent in using hypnosis as part of the research methodology, while noting that hypnosis nevertheless offers new information when introduced into traditional content areas. "For example, in cognitive psychology it has re-introduced the importance of studying experiential aspects of cognition, i.e. I think, I remember, or self reference (Kihlstrom, 1987)" (p. 223).

She concludes, "Hypnosis as a research method will continue to benefit from contributions of radically different theoretical views of hypnotic phenomena. Social-cognitive psychologists have contributed significantly toward unifying the fields of hypnosis research and general experimental psychology. At the same time, advances in neurophysiology and psychosomatic medicine employing hypnosis indicate that there is a role for hypnosis as a research strategy, solely because of its altered-state characteristics. If theoretical physics can reconcile both wave and particle theories of light, it is conceivable that psychology can accommodate both behavioral and state theories of hypnosis" (p. 224).

Isenberg, S. A.; Lehrer, P. M.; Hochran, S. (1992). The effects of suggestions and emotional arousal on pulmonary functions in asthma: A review and a hypothesis regarding verbal mediation. Psychosomatic Medicine, 54, 192-216.

This paper reviews the empirical literature on the relation between asthma, suggestion, and emotion, and proposes the hypothesis that these effects are mediated parasympathetically. The literature indicates that, among asthmatics, suggestion can produce both bronchoconstriction and bronchodilation, and that stress can produce bronchoconstriction. The proportion of asthmatic subjects showing bronchoconstriction to both suggestion and stress averages 35%-40% across studies, but, because of methodological considerations, might be conservatively estimated as closer to 20%. The effect is smaller for suggestion of bronchodilation, and is very short-lived among nonasthmatics. No clear connection has been found between these

responses and such subject variables as age, gender, asthma severity, atopy, or method of pulmonary assessment, although some nonsignificant tendencies appear. Most studies in this literature used small n's and did not systematically examine various somatic, environmental, and demographic factors that could influence results. A hypothesis is presented regarding vagal mediation of psychological effects on the airways, as well as possible alternative mechanisms, and recommendations for future research to evaluate these hypotheses.

Isenberg, S. A.; Lehrer, P. M.; Hochron, S. (1992). The effects of suggestion on airways of asthmatic subjects breathing room air as a suggested bronchoconstrictor and bronchodilator. Journal of Psychosomatic Research, 36, 769-776.

Thirty-three asthmatic subjects were told they were receiving, alternately, an inhaled bronchoconstrictor and inhaled bronchodilator, although they actually were only breathing room air. No subjects showed suggestion-produced effects on FEV1, although two (of the 19 on whom FEF50 was measured) showed effects of greater than 20% on measures of maximal midexpiratory flow. The incidence of the effect is smaller than reported previously, possibly because some subjects in previous studies inhaled saline, a mild bronchoconstrictor, and reversal of effect was not required for classification as a reactor. Higher percentages of subjects in this study showed decreased MMEF in response to the "bronchoconstrictor", but this appeared to reflect fatigue rather than suggestion effects. However, the fact that the effect occurred in a relatively non-effort-dependent measure suggests that real changes occurred in bronchial caliber, not just in test effort. Suggestion had a significant effect on perception of bronchial changes, but the correlation between actual and perceived changes was minimal. There was an increase in FVC prior to administration of the "bronchoconstrictor", possibly reflecting a preparatory response to the expected drug. Correlations among self-report variables suggested the existence of three personality dimensions among our population related to suggestion and asthma: cognitive susceptibility to suggestion of bronchial change; feeling of physical vulnerability; and anxiety. However, there was no significant relationship between airway response to suggested changes and hypnotic susceptibility, as measured by the Harvard Group Scale of Hypnotic Susceptibility

Ruzyla-Smith, Patricia; Barabasz, Arreed; Barabasz, Marianne (1992, October). Effects of hypnosis and restricted environmental stimulation therapy on the immune response: B- and T-cells, helper and suppresser cells. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

1:

This research extends Robert Hall's work with B-cells and T-cells, adding helper cells and suppressor cells to the dependent measures also.

Random assignment of high hypnotizable people and low hypnotizable people to 3 groups resulted in 6 groups: Hypnosis High Hypnotizables (10) Hypnosis Low

Hypnotizables (11) REST High Hypnotizables (13) REST Low Hypnotizables (11)  
Control High Hypnotizables (10) Control Low Hypnotizables (10)

The Research Procedure entailed: Orientation to hypnosis, plateauing hypnosis response through repeated inductions Assigned participants randomly by hypnotizability to above groups Orientation to immune response measurement Administration of the Symptom Check List - 90, Revised Skin conductance response (taken during blood draws to measure anxiety) Pretreatment blood draw Audiotaped hypnotic induction Self hypnosis instructions Posttreatment 1 blood draw One week Treatment 2 Induction Posttreatment 2 Blood draw Post Experimental inquiry

Prior to first session Ss in Group 1 received orientation to flotation tank Pretreatment blood draw One hour REST session [with no suggestions to alter the immune response] Posttreatment 1 blood draw One week Treatment 2 REST session Posttreatment 2 Blood draw Post experimental inquiry

Waiting list controls experienced: First blood draw Second blood draw after 1 hour One week follow up Third Blood draw Post experimental inquiry  
(N.B. SCL-90 apparently was being taken on each experimental visit.)

## RESULTS

The analysis used covariate of pretreatment measurements. Immune response measured was a standard procedure, e.g. % B-Cells by FACS (the dot measure of immune response). Post Treatment 1 showed high and low hypnotizables increasing their B-cells in the hypnosis condition; also H-cells increased. Highs in hypnosis had higher T-cells when compared with highs in REST but not in other treatment and control groups.

No significant changes were observed in T suppressor cells, though high hypnotizables in the hypnotized condition seemed to have increase in suppressor cells. Maybe it was the way the suggestion was given; perhaps we should say they would not only increase their helper cells but would decrease their suppressor cells. The author viewed the results as supporting Hilgard's neodissociation theory.

Spiegel, David (1992, October). Hypnotizability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

## NOTES

1:

Dr. Spiegel announced that this was a last minute substitution for Fred Frankel's presentation on Hypnotizability.

We have ongoing a major replication of the study that we published on group therapy with terminally ill breast cancer patients. The matched control patients get educational materials but not psychotherapy. We are looking at NKC cytotoxicity and delayed hypersensitivity.

Tasks: spend 15 minutes discussing list of problems; 15 minutes discussing things like, "What is your spouse doing that doesn't help; what can we do to help it?" We get drop in NKC cytotoxicity immediately afterward, returning after 24 hrs to usual levels. Controls don't drop in NKC cytotoxicity. This measure of stress may be a predictor of survival time.

In Fawzy's study of group therapy with melanoma patients, they noted a significant difference at 6 months in interferon augmented activity of NK, which didn't hold up at a year. But at 6 years there were 10 of 40 deaths in control group vs 3 of 40 deaths in treated group. This is a vigorous effect.

Cohen's study of colds in New England J. of Med is another good clinical study.

There are two broad areas of relevance of hypnotizability to healing: 1. Hypnotizability as a trait: do highs differ in way they regulate body or mind? 2. Is there something you do when in hypnotized state that is different? Studies of treatment of warts with hypnosis are important 3. Transition between states, e.g. circadian rhythms; is there a shift in wakefulness between trance and nontrance states that affects health?

Psychiatric Diagnosis and self regulation. High hypnotizability is associated with certain psychiatric disorders (dissociative reaction, PTSD, MPD, etc.). Schizophrenics score much lower than normals (av. = 4 vs 7; replicated with the Hypnotic Induction Profile (HIP). Stanford Hypnotizability Scales show no difference in means, but do show a difference in range). I don't know what this means. But schizophrenics can falsely pass some Stanford Scale items, e.g. amnesia which they don't however reverse; so schizophrenics' hypnotizability scores may be inflated on Stanford scales. We don't see extremely high scores in schizophrenics.

Psychoactive medication doesn't affect scores of schizophrenics, but improves scores of anxiety neurotics (by reducing anxiety). Frischholz has an article coming out in a psychiatry journal that confirms this.

There is a lot of evidence that patients with dissociative disorders are more hypnotizable than other groups. Frischholz et al couldn't replicate Frankel's finding of higher scores in phobics. Pettinati et al found higher scores in bulimia and I haven't seen anything to counter that. Another idea is that high hypnotizables are very good at internal regulation

Spiegel & Ken Kline selected Ss who could regulate gastric activity. They got an 80% increase in gastric acid output while imagining eating; got 40% decrease in output when imagining something pleasant that wasn't imagining eating. Injected with pentagastrin, which induces gastric output, they still got a decrease in gastric acid output in the relaxation condition.

This suggests that hypnotizability should be a selection criterion for some research. See also Katz et al. 1974 (?) with acupuncture; and McGlashan, Evans & Orne on the placebo response.

Herbert Spiegel found that 2/3 of highs but 1/3 of lows were cured of phobia. Eye roll sign on the HIP, living with spouse/lover, rating self as hypnotizable, and giving a postcard follow-up response at one week post treatment were associated with 89% rate abstinence at 2 years follow-up, when only 23% overall of 223 were abstinent. Absence of those positive predictors was associated with only a 4% rate of abstinence.

Walker, Leslie G. (1992). Hypnosis with cancer patients. American Journal of Preventative Psychiatry & Neurology, 3, 42-49.

Overviews the uses of hypnosis with cancer, for example to ameliorate side effects of treatment, help patients adjust to having cancer and its symptoms, reduce the distress caused by painful procedures, and to attempt to alter mechanisms of immunity with a view to improving prognosis. Studies in these areas are reviewed.

Zachariae, Robert; Petersen, Kirstan S.; Simonsen, Carsten; Thestrup-Pederson, Kristian (1992, October). Effects of guided imagery and relaxation on natural killer cell activity in high and low hypnotizable subjects. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

## NOTES

1:

Author describes work done in Denmark with immediate and delayed hypersensitivity; hypnotically induced emotions and effect on [missed words] chemocytotoxicity (?). Now we are studying cancer patients, because it is popular to believe you can cure yourself with guided imagery and hypnosis.

First study used healthy subjects and was directed at several questions: 1. Do results in previous studies result from immune specific suggestions or from a general effect on homeostasis (like one gets with relaxation)? 2. Few studies consider hypnotizability or use highly hypnotizable Ss. Is hypnotizability a factor? 3. What changes can we expect? 4. To what extent can we determine what a healthy immune response is?

There were 120 undergraduate psychology students (81 female, 39 male), measured with Harvard Scale of hypnotizability. We selected 30 for 3 groups with 5 highs (9-12) and 5 lows (0-6) in each group. The Ss were randomized into 3 groups:

Guided imagery group: Ss were instructed in how guided imagery might affect the immune system. They experienced live, direct intervention with music, and with instruction to imagine the cells of the immune system becoming increasingly effective. Ss were given an audiotape to use 3 times/wk for 2 weeks.

Relaxation group: Ss were not given instructions re the immune system. Control group: Ss were sitting, reading newspaper, magazines. All groups came in on days 1, 8, 15 and 36 (the last time after a 3 week separation). Ss provided 3 blood samples each session.

Music was composed to go along with the imagery (when the suggestions said that cells were active, the music was active). Relaxation imagery was of their own choosing, with instructions to go to some place in nature and relax.

The fourth session was changed so that the relaxation group was given "an intelligence test," which was a stressor. (They were told that anyone could do it, which wasn't true.) The Control group listened to what the investigators felt was neutral music.

Results showed no difference in percentage of K cells between the three groups. There are differences within each day. The only difference was in the Relaxation group on the fourth day; with the stress test there was a slight increase.

We also looked at the percentage of increase or decrease. There was tendency for highly hypnotizables to show larger increases and decreases. In the Control group, highs and lows were opposite in this reaction: lows showed large decreases, but highs showed no decreases and no or small increases.

After the stress test the lows had an increase in NKCA; they are the ones responsible for the change seen in the stress condition.

We did another similar study, with 30 Ss but only 2 blood samples each day. We studied the response to PHA, measuring cpm 10 - 3. Controls don't change, but the two other groups do. So we observed different lymphocyte proliferative response with different agents. Also, the control group that knows it is a control doesn't show changes at the beginning.

**CONCLUSIONS.** 1. Effects may vary with the immune parameter measured. 2. The effects of immune specific imagery and relaxation are similar. 3. Changes may be due to a non-specific effect on general homeostasis.

Though costly and time consuming, further studies with a larger number of Ss are needed.

**COMMENTS FROM THE AUDIENCE:**

Karen Olness: We found a difference between hypnosis and nonspecific relaxation with children. Research in this area is very expensive, however.

1991

Hajek, P. R.; Radil, T.; Jakoubek, B. (1991). Hypnotic skin analgesia in healthy individuals and patients with atopic eczema. Homeostasis in Health and Disease, 33, 156-157.

**NOTES**

The cutaneous pain threshold was measured before, during, and after 10 sessions of hypnosis in 14 healthy and 13 atopic eczema patients. A control group of 10 healthy subjects who were not hypnotized was also evaluated. Cutaneous pain threshold increase was correlated with improvement of eczema and was correlated with hypnotizability.

Madrid, Antonio D.; Barnes, Susan v.d.H. (1991). A hypnotic protocol for eliciting physical changes through suggestions of biochemical responses. American Journal of Clinical Hypnosis, 122-128.

We employed brief hypnotherapy to effect physical changes in patients suffering from medical disorders including allergies, rectal bleeding, systemic lupus, hyperemesis, headache, asthma, and chronic pain. We present, in language appropriate to the individual patient, considerations and suggestions to effect the release of healing biochemicals. Ideomotor signals indicated the patient's awareness of the healing. We hypothesize that the technique triggered novel state-dependent memory, learning, and behavior.

**NOTES 1:** NOTES: They hypothesize that the technique they use triggers novel state-dependent memory, learning, and behavior (See for example Rossi, 1987, and Rossi & Cheek, 1988).

Hypnotic Protocol: "1. Tell the patient that he can heal himself by allowing his body to supply its own biochemicals needed to make him well. If a specific biochemical is known, such as cortisone or endorphins, name it. "2. Hypnotize the patient. Resistant or hard to hypnotize patients need not be deeply hypnotized because the

patients, using this protocol, will automatically go into trance while accomplishing the next task of accessing and using ideomotor signals (Erickson, 1980; Rossi & Cheek, 1988). "3. Tell the patient that his index finger will automatically and involuntarily twitch and float when his body releases the biochemicals he needs. This ideomotor response (Rossi & Cheek, 1988) is the sole physical response required of the patient. Rossi hypothesizes that the ideomotor response correlates with biochemical changes (Rossi & Cheek, 1988). "4. Next, ask the patient to consider some things (as described below). Present the considerations one after another until one of them triggers the ideomotor response. "5. In some instances, ask the patient to practice on his own. Many patients who have dramatic emotional reactions during or at the completion of the task may not need to practice on their own" (p. 123).

They present several 'considerations' to the patient, one after the other, tailored to the patient's specific case, until his finger twitches or floats, indicating a biochemical response. For example, the following 'considerations' have been used: "1. Psychodynamic: 'Consider that you are not blamed for anything; that you are in fact perfect just the way you are; that you are loved by those you care about.' 'Consider that you can forgive whoever needs forgiving for hurting you.' 'Consider that there are no longer any threats; everything is better; everything is as it used to be.' "2. Autosuggestion: 'Tell your body to heal. It knows what to do; so ask it to do it.' 'Tell your adrenal glands to produce the steroids that your body needs.' 'Allow a glowing light to permeate that injured back, filling it with healing energy.' "3. Incompatible responses: 'Cover yourself with a cool breeze, cooling the injured leg.' 'Imagine your back getting slack and limp and relaxed.' 'Imagine your stomach lining becoming smooth and moving with easy, ocean-like waves.' "4. Emotion calling: 'Consider yourself feeling very happy with everything, for no reason at all.' 'Consider yourself getting angry at someone--your mother, your wife (husband), your boss, your lawyer.' "5. Bargaining: 'Tell yourself that you will heal if you agree to stay away from that job.' 'Tell yourself you will heal by allowing your right arm to begin to hurt when you are over- exerting yourself.' 'Tell yourself that you will heal in exchange for something else, not so serious, to replace this disease and to serve the same function'" (pp. 123-124).

They present seven cases involving, respectively, allergies, rectal bleeding, systemic lupus, hyperemesis of pregnancy, adult onset asthma, chronic pain, and cluster headaches. Two cases were particularly interesting because they represented patients who did not respond initially.

Their procedure involves reframing the state or emotion originally associated with the onset of disease using considerations, and then giving a suggestion that it is within the power of the person, rather than factors outside, to heal the body. First they instruct the patient that the body can heal itself; then they give the list of suggestions for the patient to consider, persisting with different considerations until they get an ideomotor response. Incorporation of the patient's psychodynamic issues appears to be very important.

The authors regard it as unimportant if the patient cannot be hypnotized; "As Cheek (Cheek & LeCron, 1968; Rossi & Cheek, 1988) points out, the patient's inability to be hypnotized may be synonymous with his disease. It is actually

beneficial if the patient cannot achieve ideomotor responses at first because both he and the therapist then trust the validity of the response when it does occur after the appropriate consideration" (p. 127).

#### NOTES

1:

This book discusses suggestibility in relation to mental illness (e.g., MPD, anorexia nervosa), advertising, education, self-deception, forensics, political persuasion, and the biological aspects of the suggestion process (e.g., the effects of suggestion on the immune system).

Van Der Kolk, Bessel; Van Der Hart, O. (1991). The intrusive past: The flexibility of memory and the engraving of trauma. American Imago, 48, 425-454.

Describes the work of Janet concerning narrative versus traumatic memory, dissociation, and subconscious fixed ideas. Janet (1904) believed PTSD patients suffer from a phobia for the traumatic memory. Repression and dissociation are distinguished. Contemporary concepts of memory processing and the concept of schemas are then reviewed. Finally, a model is presented about how the mind freezes some memories. Evidence for the involvement of autonomic hyperarousal, triggering, and state dependent learning in PTSD is reviewed. They conclude that helplessness and the inability of the PTSD victim to take action (psychological and physical immobilization) facilitates dissociation. Includes practical ideas for the working through of trauma.

#### NOTES

p. 443 "Traumatic memories are triggered by autonomic arousal ... and are thought to be mediated via hyper-potentiated noradrenergic pathways originating in the locus coeruleus of the brain... The locus coeruleus is the 'alarm bell' of the central nervous system, which properly goes off only under situations of threat, but which, in traumatized people, is liable to respond to any number of triggering conditions akin to the saliva in Pavlov's dogs. When the locus coeruleus alarm gets activated, it secretes noradrenaline, and, if rung repeatedly, endogenous opioids. These, in turn, dampen perception of pain, physical as well as psychological (van der Kolk et al. 1989). These neurotransmitters which are activated by alarm affect the hippocampus, the amygdala and the frontal lobes, where stress-induced neurochemical alterations affect the interpretation of incoming stimuli further in the direction of 'emergency' and fight/flight responses" (p. 443).

#### NOTES

(From the SUMMARY)

**"Without attempting to cover all the literature, we have used stress effects and conditioning phenomena as illustrations to point out that behavior can influence immune function. We have also described data indicating that the immune system can receive and respond to neural and endocrine signals. Conversely, behavioral, neural, and endocrine responses seem to be influenced by an activated immune system. Thus, a traditional view of immune function that is confined to cellular interactions occurring within lymphoid tissues is insufficient to account for changes in immunity observed in subhuman animals and man under real world conditions.**

**"These data question seriously the notion of an autonomous immune system. ... The immune system is, indeed, capable of considerable self-regulation, and immune responses can be made to take place in vitro. The functions of that component of adaptive processes known as the immune system that are of ultimate concern, however, are those that take place in vivo. There are now compelling reasons to believe that in vivo immunoregulatory processes influence and are influenced by the neuroendocrine environment in which such processes actually take place ... . The immune system appears to be modulated, not only by feedback mechanisms mediated through neural and endocrine processes, but by feedforward mechanisms as well. The immunologic effects of learning, an essential feedforward mechanism, suggest that, like direct neural and endocrine processes, behavior can, under appropriate circumstances, serve an immunoregulatory function in vivo. Conceptually, the capacity to suppress or enhance immune responses by conditioning has raised innumerable questions about the normal operation and modifiability of the immune system via neural and endocrine processes.**

**"We do not yet know the nature of all the channels of communication between the brain and the immune system or the functional significance of the neural and endocrine interrelationships that have been established....**

**"This integrated circuitry has extensive ascending and descending connections among the regions cited. These regions also share many similarities. They are sites intimately involved in visceral, autonomic, and neuroendocrine regulation. The cortical and limbic forebrain regions mediate both affective and cognitive processes and may be involved in the response to stressors, in affective states and disorders such as depression, in aversive conditioning, and in the emotional context of sensory inputs from the outside as well as the inside world. From an immunologic perspective, these regions are the sites in which lesions result in altered responses of cells of the immune system; they are the regions that respond to immunization or cytokines by altered neuronal activity or altered monoamine metabolism; and they are the regions that possess the highest concentration of glucocorticoid receptors and link some endocrine systems with neuronal outflow to the autonomic and neuroendocrine systems. Thus, this circuitry is the major system of the CNS suspected to play a key role in responding to immune signals and regulating CNS outflow to the immune system" (pp. 587-589).**

**Andrews, Vivian H.; Hall, Howard R. (1990). The effects of relaxation/imagery training on recurrent aphthous stomatitis: A preliminary study. Psychosomatic Medicine, 52, 526-535.**

Recurrent aphthous stomatitis (RAS) is one of the most common diseases of the oral mucosa. Although etiology remains unknown, immunological and emotional disturbances have been implicated in the pathogenesis of RAS. No consistently effective therapeutic regimen has been found. The present study investigates the voluntary modulation of RAS employing hypnosis-like relaxation/imagery training procedures. A multiple baseline design was used to evaluate change in frequency of ulcer recurrence. The role of psychological distress, ratings of perceived pain, and hypnotizability in the treatment of RAS were also examined. Results suggest that the relaxation/imagery treatment program was associated with a significant decrease in the frequency of ulcer recurrence for all subjects. Psychological distress was examined for relationship to ulcer recurrence and symptomatic changes with treatment, but no pattern was found. Finally, little support was found for the role of high hypnotic ability in the treatment of RAS.

Hajek, P.; Jakoubek, B.; Radil, T. (1990). Gradual increase in cutaneous threshold induced by repeated hypnosis of healthy individuals and patients with atopic eczema. Perceptual and Motor Skills, 70, 549-550.

Gradual increase in cutaneous pain threshold was found in healthy subjects and patients with atopic eczema during repeated hypnotic sessions with specific suggestions. This increase was less in the former than in the latter group. Repeated threshold measurements did not influence the threshold. The analgesic effect outlasted the hypnotic sessions by several months. It could be, however, suddenly reduced by appropriate hypnotic suggestion.

#### NOTES

Cutaneous pain threshold was measured in "time in seconds from onset of heat source of defined size, distance from skin, and temperature, to subjective threshold percept of pain" (p. 549). Used two symmetrical locations on both forearms, at healthy areas of the skin. Ten hypnotic sessions were induced in each S three times weekly, each lasting one hour.

Suggestions were the following type: "The "conduction of switch to the brain is interrupted." Your "immunologic system will digest the damaged skin cells like a shark."

Subjects were 14 healthy subjects and 13 patients with atopic eczema treated for years with the usual medications, unsuccessfully or with complications.

There was gradual increase in cutaneous pain threshold across the 10 sessions, especially for the patient group. Control experiments with repeated threshold measurements in repeated sessions without hypnosis showed no changes.

"Time of increases in cutaneous pain threshold was associated with improvement of atopic eczema. Both effects correlated significantly ( $r = 0.8$ ) with hypnotizability as measured by the Stanford scale" (pp. 549-550).

"In 9 patients without further hypnotic sessions a slow spontaneous decay of the cutaneous pain threshold was observed during a 17-mo. period. Special experiments performed with six repeatedly hypnotized healthy subjects showing increased thresholds did prove, however, that the cumulative analgesic effect could be reduced

to control values immediately by using the hypnotic suggestion that the 'skin sensitivity returns to normal values.'

"These results suggest a close association between hypnosis and activation and/or deactivation of endogenous analgesic systems (irrespectively whether they are of opioid or nonopioid nature)" (p.550)

Spanos, Nicholas P.; Williams, Victoria; Gwynn, Maxwell I. (1990). Effects of hypnotic, placebo, and salicylic acid treatments on wart regression. Psychosomatic Medicine, 52, 109-114.

Subjects with warts on their hands and/or feet were randomly assigned to a hypnotic suggestion, topical salicylic acid, placebo, or no treatment control condition. Subjects in the three treated groups developed equivalent expectations of treatment success. Nevertheless, at the six-week follow-up interval only the hypnotic subjects had lost significantly more warts than the no treatment controls. Theoretical implications are discussed.

#### NOTES

Study involved 15 females, 25 males (18-35 yrs old) with warts on at least one hand or foot, recruited through posters and newspaper ads; N = 10 in each condition. Hypnotic treatment consisted of 10 minute induction (modified from T. X. Barber's 1969 book) and a suggestion for wart regression that was 2 minutes in duration (the skin around warts was 'beginning to tingle and grow warm'; 'vividly imagine the warts shrinking and dissolving away'; 30 second break; repeated the suggestions). For Ss with warts on more than one limb the complete suggestion procedure was repeated for each wart-infected limb.

Results indicate psychological factors can influence course of some virally produced disorders; that self-medicating with over-the-counter products doesn't explain suggestion-induced wart regression; that expectation of treatment success is the most important variable in psychologically induced wart regression. "Hypnotic subjects attained significantly higher CURSS:S scores than did control subjects. Nevertheless, it is unlikely that between group differences in hypnotizability accounted for the group differences in wart regression. Two previous experiments (3) that used the CURSS found that hypnotizability failed to predict wart loss in either hypnotic suggestion, nonhypnotic suggestion, or placebo treatments, and even in the present study the hypnotic treatment failed to differ from either the real or placebo treatment on CURSS:S scores, and none of the treatments differed significantly on the CURSS:O scores. Our finding and earlier findings that hypnotic subjects reported more intense suggested sensations than placebo subjects is consistent with the hypothesis that vivid suggested imagery facilitates wart loss (7, 8)

"An alternative hypothesis emphasizes that only our hypnotic suggestion treatment encouraged subjects to see themselves as developing cognitive control over their own wart regression. This hypothesis suggests that subjects' subjective sense of cognitive involvement in and control over treatment outcome (as opposed to the vividness of their suggested imagery) may have been the important psychological factor in wart

regression. It would be of interest in a future study to manipulate subjects' sense of cognitive involvement in their treatment independently of suggested imagery in order to assess the relative contributions of these variables to wart regression" (pp. 113-114).

Abelson, James L.; Curtis, George C. (1989). Cardiac and neuroendocrine responses to exposure therapy in height phobics: Desynchrony within the 'physiological response system'. Behaviour Research and Therapy, 27 (5), 561-567.

Monitored subjective, behavioral, cardiovascular and neuroendocrine responses in 2 men (aged 19 and 34 yrs) with height phobias over a full course of exposure therapy and at 6 and 8 month follow-up. Both Ss showed rising cortisol responses and stable, nonextinguishing norepinephrine responses to height exposure over the course of treatment, while improvement occurred in subjective and behavioral response systems. They had differing heart rate responses. Despite desynchrony among anxiety response systems and within the physiological system at treatment conclusion, Ss had successful outcomes with general measures of change (phobia rating scales, the Fear Survey Schedule, and the SCL-90) showing substantial improvement for both Ss. These outcomes were preserved at follow-up.

Hall, Howard R. (1989). Research in the area of voluntary immunomodulation: Complexities, consistencies, and future research considerations. International Journal of Neuroscience, 47, 81-89.

NOTES

It is speculated that the successful voluntary alteration of one's immune functioning is a complex phenomenon associated with a number of possible factors. Evidence suggests the importance of prior experience in self-regulation and the role of practice, the ability of subjects to become relaxed and reduce sympathetic arousal, the importance of the nature and content of images, the complex role of hypnosis and hypnotizability, the importance of individual differences, and the choice of immune measures. Conclusions are drawn about the need for more experimental attention to these variables and future research with both experienced and inexperienced subjects.

Reid, S. (1989). Recalcitrant warts: Case report. British Journal of Experimental and Clinical Hypnosis, 6, 187-189.

NOTES

Recalcitrant warts which persisted for 5 years despite treatment cleared in 51 days with hypnotherapy. A cause/effect relationship between hypnotherapy and resolution was shown by at first excluding and then including the left hand from the suggestions given.

Spiegel, David; Bloom, J. R.; Kraemer, H. C.; Gottheil, E. (1989, October 14). The beneficial effect of psychosocial treatment on survival of metastatic breast cancer patients: A randomized prospective outcome study. Lancet, 888-891.

The effect of psychosocial intervention on time of survival of 86 metastatic breast cancer patients was studied using randomized prospective design. The one-year treatment consisted of weekly supportive group therapy with training in self-hypnosis for pain management, and resulted in significant reductions in mood disturbance and pain. Both the treatment and control groups had routine oncologic care. At ten-year follow-up, only three of the original 86 patients were still alive, and death records were obtained for the other 83. Survival from the time of randomization and onset of intervention was 36.6 (sd = 37.6) months for the treatment group, compared with 18.9 (sd = 10.8) months for the control group, and this difference was highly significant ( $Z = 3.94$ ,  $p < .0001$ ) using the Cox life table regression model. Kaplan-Meier survival analysis indicated that the divergence in survival began at 20 months after entry into the study, or 8 months after the treatment intervention ended. These unexpected findings suggest that intensive psychosocial support affects the course of the illness, although the mechanism by which it does so is not clear.

Zachariae, Robert; Bjerring, P.; Arendt-Nielsen, L. (1989). Modulation of type I mediated and type IV delayed immunoreactivity using direct suggestion and guided imagery during hypnosis. Allergy, 44 (8), 537-542.

Cutaneous reactivity against histamine skin prick test (Type I) and purified tuberculin protein derivative (Mantoux reaction, Type IV) was studied in eight volunteers under hypnosis. Types I and IV immunoreactivity were modulated by direct suggestion (Type I) and guided imagery (Type IV). When the highly susceptible volunteers underwent hypnotic suggestion to decrease the cutaneous reaction to histamine prick test, a significant ( $P$  less than 0.02) reduction of the flare reaction (area of erythema) was observed compared with control histamine skin tests. The wheal reaction did not respond to hypnotic suggestion. Neither wheal nor flare reaction could be increased in size by hypnotic suggestion compared with control histamine skin-prick tests. A hypnotic suggestion of increasing the Type IV reaction on one arm and decreasing the reaction on the other revealed a significant difference in both erythema size ( $P$  less than 0.02) and palpable induration ( $P$  less than 0.01). In two cases the reactions were monitored by laser doppler blood flowmetry and skin thickness measurement by ultrasound. The difference between the suggested increased and decreased reaction was 19% for the laser doppler bloodflow (in favor of the augmented side), and 44% for the dermal infiltrate thickness. This study objectively supports the numerous uncontrolled case reports of modulation of immunoreactivity in allergic diseases involving both Type I and Type IV skin reactions following hypnotic suggestions.

1988

Colgan, S. M.; Faragher, E. B.; Whorwell, P. J. (1988, June 11). Controlled trial of hypnotherapy in relapse prevention of duodenal ulceration. Lancet, 1299-1300.

**30 patients with rapidly relapsing duodenal ulceration were studied to assess the possible benefit of hypnotherapy in relapse prevention. After the ulcer had healed on treatment with ranitidine, the drug was continued for a further 10 weeks during which time patients received either hypnotherapy or no hypnotherapy. The two randomly selected groups were comparable in terms of age, sex, smoking habits, and alcohol consumption. Follow-up of both groups of patients was continued for 12 months after the cessation of ranitidine. After 1 year, 8 (53%) of the hypnotherapy patients and 15 (100%) of the control subjects had relapsed. The results of this study suggest that hypnotherapy may be a useful therapeutic adjunct for some patients with chronic recurrent duodenal ulceration.**

#### **NOTES**

**The aetiology of duodenal ulceration is poorly understood but it is probably multifactorial. ... Stress, both psychological and physical, has since been shown to affect gastric emptying and the secretion of acid and pepsin, but attempts to causally link stress and peptic ulcer disease have produced conflicting results.**

**"Hypnotherapy can modify the response to betazole-stimulated gastric acid secretion, although the mechanism by which this is mediated remains unclear" (p. 1299).**

**"The active [treatment] group received 7 sessions of hypnotherapy and were given an audio tape for daily autohypnosis; the other group were seen as often, but did not receive any hypnotherapy. The ranitidine was then stopped and both groups were reviewed every 3 months for a further year, with the active group receiving hypnotherapy at their follow-up visits. All subjects had an endoscopy at the end of the study, or sooner if a symptomatic relapse occurred.**

**"Hypnosis was induced as previously described, with attention focused on the abdomen by the use of the patient's hand. They were asked to imagine warmth beneath the hand and to relate this to the control of gastric secretion. Reinforcement by visualization was used if the patient had this ability" (p. 1299).**

**At the end of a year, on follow up, the patient relapse rate was 53% and controls relapse was 100%, a difference significant at  $p = 0.01$ .**

**In their Discussion, the authors state, "This study shows that hypnotherapy is helpful in maintaining remission in those patients with duodenal ulceration who are particularly prone to relapse. ... In this model, hypnotherapy might operate at a variety of levels in the disease process: it could act in a nonspecific psychotherapeutic sense increasing 'coping' capacities and decreasing perceived stress. Alternatively, hypnotically induced relaxation may affect gastric acid secretion, and there is some experimental evidence for this.**

**"The early relapse rate in the hypnotherapy subjects was similar to that of controls, but subsequently the curves showed a much greater separation. This finding could indicate that there is a subgroup of subjects who are particularly response to therapy. However, a detailed review of psychological and clinical parameters did not reveal any specific feature that could be used to predict a response to this form of treatment" (pp. 1299-1300).**

## NOTES

2:

Current etiology of duodenal ulcers includes the presence of bacteria *Helicobacter pylori* which is important in relapse. In order to compare treatments we must know what is the status of each group regarding the presence of this bacteria. Current treatment of duodenal ulcer includes metronidazole, amoxicillin and tetracycline to kill it. [Editor's Note: This appears to be a critique of the research methodology rather than notes on the article itself.]

1987

Bongartz, Walter (1987, October). Influence of hypnosis on white blood cell count and urinary level of vanillyl mandelic acid. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Los Angeles.

## NOTES

They hypothesized that hypnosis benefits to immunology are due to alterations in white blood cell counts (WBC). Found that (1) blood samples before and after hypnosis with relaxation scenes led to significant decrease in WBCs compared to watching film of Mesmer or doing mental arithmetic, and (2) Vanillyl Mandelic Acid also was reduced.

After physical exercise, video game, or reading, within 20', the WBCs return to pre-relaxation levels, i.e. they hadn't left the bloodstream. Key to understanding this result: only 50% of WBCs are in circulation, and others adhere to vessel walls; the experience of hypnotic relaxation leads to less sympathetic nervous activation and less epinephrine or hormonal response. WBCs also increased over a day period with mental arithmetic, but remained the same with hypnosis.

This research is only preliminary and exploratory.

Locke, Steven E.; Ransil, Bernard J.; Covino, Nicholas A.; Toczydlowski, Janice; Lohse, Christopher M.; Dvorak, Harold F.; Arndt, Kenneth A.; Frankel, Fred H. (1987). Failure of hypnotic suggestion to alter immune response to delayed-type hypersensitivity antigens. Annals of the New York Academy of Sciences, 496, 745-749.

The ability to alter delayed-type hypersensitivity via hypnotic suggestion was tested in 12 highly hypnotizable, untrained subjects and 30 non-hypnotized controls. Subjects were skin tested bilaterally with a standardized panel of delayed hypersensitivity antigens and instructed either to enhance or suppress the skin test response (STR) unilaterally. Compared to controls, STR's showed no effect of hypnotic suggestion with regard to either the area of induration or the degree of inflammation assessed histologically.

1986

Crawford, Jeffrey Cleon (1986, February). The effects of hypnosis and imagery on immunity (Dissertation, University of Texas Health Science Center at Dallas). Dissertation Abstracts International, 46, 2800-B.

"The present study explored the effects of hypnosis and imagery on Total T-Lymphocytes, T-Helper, T-Suppressor, Natural Killer Lymphocytes and level of Salivary IgA. Twenty-four volunteers (15 females and 9 males) between the ages of 23 and 41, with a mean age of 30, were assigned to an experimental or no-treatment control group in a modified random sequence. Participation was limited to individuals who were clinically free of disease, not using medication known to influence immunity, and scored above the mean on self-report pencil and paper measures of life stress (Life Experiences Survey and Stress Coping Rating Scale). Blood and saliva samples were obtained one day before, immediately before, one hour after, and eight days after a one hour hypnotic session. A relaxation induction, a variation of [H. R.] Hall's method, was utilized to induce hypnosis, and its effect measured by the Long Stanford Scale. The subjects were encouraged to imagine the cells of their immune systems multiplying and destroying pathogens. An adaptation of the IMAGE-CA was used to assess the effectiveness of the imagery. Finally, the experimental subjects were instructed in and asked to practice self-hypnosis and imagery twice daily for a week. The data were analyzed in six two-factor repeated measure analyses of variance, and Newman-Keuls tests were utilized to make multiple comparisons between the levels of Group and Time. The analyses produced no evidence for the confirmation of the overall hypothesis that the experimental group would increase in percent of T-Lymphocytes, percent of T-Helper cells, percent of Natural Killer cells and level of Salivary IgA, and decrease in percent of T-Suppressor lymphocytes. Post-hoc analyses revealed correlations that served as a basis for interesting speculation, but there was no revision in the overall conclusion that there was not evidence that hypnosis and imagery, as employed in this study, influenced in the selected measures of immunity. These results extend, but are not analogous, to the results of previously published studies using "fractional" measures of immunity" (pp. 3055-3056).

Olness, Karen N. (1986, March). Hypnotherapy in children: New approach to solving common pediatric problems. Postgraduate Medicine, 79 (4), 95-105.

Hypnotherapy, once thought of as magical and mysterious, is rapidly becoming accepted as an appropriate form of treatment for a wide range of disorders. Some primary care physicians are beginning to discover the value of hypnotherapy in controlling chronic disease and pain, in changing negative behavior, and in facilitating self-regulation of autonomic responses. Dr. Olness explores such use of hypnotherapy in children, the age-group that most readily acquires self-hypnosis skills and in which this technique has had dramatic results.

Rogers, Malcolm; Reich, Peter (1986). Psychological intervention with surgical patients: Evaluation outcome. Advances in Psychosomatic Medicine, 15, 23-50.

## NOTES

The Notes are a direct quotation of the authors' Conclusions. "There is well documented evidence that psychological and behavioral preparation prior to surgery can effect post-operative recovery. In almost all instances, except when patients are characterized by avoidance or denial defenses predominantly, the outcome results have been positive. The effect of interventions have been most consistently positive in reducing length of hospitalization and post-operative pain,

but a variety of other improvements in affect and physiologic stability have been shown. As others such as Auerbach have pointed out [76], in all but a handful of studies different intervention approaches have been combined, making it impossible to sort out the specific effects of information, psychotherapeutic relationship, relaxation training, or suggestion given either with or without hypnosis. Indeed it is not only likely that each has had an effect, but there may also be synergistic effects.

"More recent investigations have begun to include measurements of personality differences between patients so that the nature of the intervention can be more specific and appropriate to the individual's coping style.

"The reduction in length of hospitalization alone (clearly shown to result from pre-operative psychological preparation) argues forcefully on a cost benefit basis for the inclusions of careful pre-operative preparation. The reduction in pain is also of major importance, and may well reduce future avoidance behavior or post-traumatic disorders, although these latter potential outcomes have not been investigated. It should be kept in mind that there are also a number of studies which have failed to demonstrate the efficacy of psychological intervention on these outcome measures. Moreover, it is extremely difficult in studies of this nature to control adequately for the subtle effects on behavior of experimenter and subject expectation.

"A few points can be made about future strategies in this field. The evidence accumulated to date suggests that all patients undergoing surgery or certain difficult procedures be given the option of pre-operative psychological preparation. The preparation should emphasize what the patient will experience and when, and how to cope with it, i.e., how to move, or breathe, or relax. Rapidly evolving audiovisual capabilities and hospital televisions connected by cable to health education channels will routinely offer such preparation in the future. Patients could choose or not choose to watch (thereby protecting mechanisms of denial).

"Finally, future studies should focus on outcome measures uniquely important to a particular operation and also on longer term rehabilitation outcome measures. An example of the former might be post-operative sexual functioning after prostatectomy. A study by Zokar et al. [77] has shown that the likelihood of this post-operative function is correlated with not only the level of pre-operative anxiety and general 'life satisfaction', but also whether the patient received a pre-operative explanation of what to expect from the surgery" (pp. 45-46).

1985

Domangue, Barbara B.; Margolis, Clorinda; Lieberman, D.; Kaji, H. (1985). Biochemical correlates of hypnoanalgesia in arthritic pain patients. Journal of Clinical Psychiatry, 46, 235-238.

Self-reported levels of pain, anxiety, and depression, and plasma levels of beta-endorphin, epinephrine, nor-epinephrine, dopamine, and serotonin were measured in 19 arthritic pain patients before and after hypnosis designed to produce pain reduction. Correlations were found between levels of pain, anxiety, and depression. Anxiety and depression were negatively related to plasma norepinephrine levels. Dopamine levels were positively correlated with both depression and epinephrine

levels and negatively correlated with levels of serotonin. Serotonin levels were positively correlated with levels of beta-endorphin and negatively correlated to epinephrine. Following hypnotherapy, there were clinically and statistically significant decreases in pain, anxiety, and depression and increases in beta-endorphin-like immunoreactive material.

Gottschalk, Louis A. (1985). Hope and other deterrents to illness. American Journal of Psychotherapy, 39, 515-524.

Reviews animal and human research demonstrating that events during early development influence vulnerability to physical and mental illness. In addition, effectiveness of coping methods used to deal with problems of living can affect susceptibility to illness. The intervening mechanisms between stressful life experiences and illness appear to involve physiological homeostasis and immune competence.

1984

Achterberg, J. (1984, October). Cancer, immunology, psychological factors, and imagery. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

NOTES

Author developed a way of scoring imagery (which will be published in *Imagery and Disease*). In terms of predicting who will die and who will survive, the content of the images doesn't seem to be as important as the quality (strength, vividness, etc.), which supports Bernauer Newton's (1984) findings. "The image seems to be a basic pre-verbal component of our species that has survival value."

Hall, Howard R. (1984, October). Hypnosis, imagery, and the immune system. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

NOTES

Studied the relationship of hypnosis to immune functions, using imagery methods like the Simontons did with their cancer patients. Twenty normal volunteers were hypnotized and asked to imagine their white blood cells (WBCs) attacking weak germs like strong sharks would attack something, and they were told that the sharks would continue working after they came out of hypnosis (a post-hypnotic suggestion). They were asked to "feel it and experience it any way you can," to avoid emphasizing visual imagery too much. Then they were taught self hypnosis and sent home to practice twice a day for a week.

Three blood measures increased after hypnosis: --B-cells increased with pokeweed stimuli (an allergen) for younger Ss, not older Ss --WBC's increased for highly hypnotizable Ss who were young, not for poor hypnotizable Ss or for any older Ss (Age range was 22-80.) --Lymphocyte count increased, approaching significance for highly hypnotizable Ss who were young but not for poor hypnotizable Ss or for older Ss. A personality test administered before the hypnosis, the SLC-90, suggested that the higher the distress level, the lower the lymphocyte count before hypnosis

training. Two scores that summed up the distress level correlated  $-.49$  and  $-.53$ , respectively. The psychological distress measured by the personality test decreased after the week of self-hypnosis practice. Of the two scores that summed up distress, one decreased for everyone (General Severity Index) and the other decreased only for highly hypnotizable Ss (Positive Symptom Total). Thus, a week of self hypnosis with imagining one's WBC's eating up weak germs in the blood led to both an increase in immune response indicators and a decrease in psychological distress. Psychological distress decreased as lymphocytes increased.

Dr. Hall repeated these procedures with a small number of Ss who were told just to "lie down and rest" rather than being hypnotized and given instructions to imagine their WBC's increasing. None of the above changes occurred. However, he cautions that his research doesn't indicate whether the positive effects are due to relaxation, imagery, or hypnosis since all three were involved.

Newton, Bernauer (1984, October). The use of imagery in the treatment of cancer patients. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

Several hundred cancer patients were treated with the Simonton visualization method, with the additional factor that they were hypnotized for the visualization. In a long term follow-up study, those patients who were treated for at least 6 months and are still alive had imagery that was vivid, persistent, positive, and passive ("passive" here meaning an underlying sense of calm). Those who died had the opposite kind of images, and retrospective review of clinical notes indicates their aggressive images reflected desperation. Of the patients who were treated less than six months, a few lived. Their images also were vivid, persistent, and positive.

Schneider, John; Smith, C. Wayne; Whitcher, Sarah (1984, October). The relationship of mental imagery to white blood cell (neutrophil) function in normal subjects. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

#### NOTES

Reports three studies in which normal healthy volunteers visualized various things happening with their white blood cells.

He used imagery rather than hypnosis with college student volunteers who knew the goal of the study was to have people increase their white blood cell (WBC) count, and who thought they might be able to do it. Actually, the physiological model is that neutrophils increase, become sticky so that they stick to the blood vessel wall, and then insinuate themselves through the wall. So he did three studies to check out each aspect of the model.

Study I: Author asked Ss to increase WBC's though his three goals actually were to decrease WBC count, increase stickiness, and [missed words]. The neutrophil count dropped significantly, and he interpreted that result as due to the fact that the increased number of cells had already moved through the vessel walls. Also, stickiness decreased (counter to prediction), and there was a negative relationship

between imagery vividness and stickiness. The more people visualized "sticky" the less sticky the neutrophils became. He concluded they may have been too successful, as there had been a 60% drop in number of neutrophils (so perhaps the more successful neutrophils had left!) So he designed a second study, not to let the neutrophils leave the bloodstream.

**Study 2:** Author asked the Ss not to decrease the WBC but to increase the stickiness of the cells. As a result, the neutrophil count did not change. In fact, adherence did increase. Imagery ratings correlated positively with adherence.

**Study 3:** Author asked Ss to have their WBC's become less sticky, to leave the wall of the blood vessel and go into the blood. He found that stickiness decreased, but there was no increase in the number of WBC's though it was predicted. Imagery ratings correlated positively with adherence. Schneider concluded that neutrophil functioning (becoming sticky) can be affected by training and specific imagery, but that the relationship between imagining and the increase or decrease in WBC's is more complex. Relaxation decreases WBC's, imagery increases them, hyperventilating increases them. We don't know what biofeedback or hypnosis would do.

(A discussant pointed out that WBC count depends on blood volume, which wasn't measured in either this group of studies or in Hall's study of hypnosis and imagery effects on WBCs.)

**1983**

**Smith, Shirley J.; Balaban, Alvin B. (1983). A multidimensional approach to pain relief: Case report of a patient with systemic lupus erythematosus. International Journal of Clinical and Experimental Hypnosis, 31 (2), 72-81.**

A multidimensional approach to the relief of intense pain associated with a chronic, debilitating disease (Systemic Lupus Erythematosus) is illustrated in this case report. Techniques associated with behavioral therapy (deep muscle relaxation, systematic desensitization); hypnosis (trance states, guided imagery, age regression, anesthetic induction and transfer and auto-hypnosis); and psychodynamic psychotherapy (dyadic interchange, suggestion, encouragement, interpretation of resistance and the transference/countertransference relationship) were utilized in obtaining virtual freedom from disabling pain and the necessity for analgesic and tranquilizing medications. Follow-up over a 3-year period demonstrated the utility of the approach.

**Spiegel, David (1983). Hypnosis with medical/surgical patients. General Hospital Psychiatry, 5, 265-277.**

The role of hypnosis as a tool in the treatment of problems commonly encountered among medical and surgical patients is examined. Hypnosis is defined as a change in state of mind far more akin to intense concentration than sleep. Diagnostic implications of differences in hypnotic responsivity are explored, and scales suitable for use in the clinic are examined. Uses of hypnosis in treating anxiety, pain, childbirth, psychosomatic symptoms, seizure disorders, neuromuscular dysfunction, and habits are described and evaluated. The phenomenon of hypnosis is presented

as a means of exploring the mind-body relationship in a controlled fashion, providing information of diagnostic importance while at the same time allowing hypnotizable patients to intensify their concentration and interpersonal receptivity in the service of a therapeutic goal.

1982

Finkelstein, Selig; Greenleaf Howard, Marcia (1982-83). Cancer prevention: A three year pilot study. American Journal of Clinical Hypnosis, 25 (2-3), 177-183.

A review of the literature in the use of hypnosis for physiological alteration and ego strengthening indicates that the incidence of cancer may be alterable. A pilot study of three years duration for a subject population considered to be at risk for cancer (N = 43) has been completed. The results of this study, as well as the hypnotic model on which the intervention was based, are discussed. Suggestions for further research are noted.

Gardner, G. Gail; Lubner, Alison (1982-83). Hypnotherapy for children with cancer: Some current issues. American Journal of Clinical Hypnosis, 25 (2-3), 135-142.

The authors review some of the problems that now face clinicians and researchers working in the field of hypnotherapy for pediatric cancer patients. These include (1) understanding and dealing with resistance and refusal, (2) developing preventive hypnotherapeutic strategies for children who will survive cancer, and (3) carrying out research that clarifies the value of hypnotherapy with childhood cancer patients and elucidates when and how specific approaches can best be utilized.

Hall, Howard R. (1982-83). Hypnosis and the immune system: A review with implications for cancer and the psychology of healing. American Journal of Clinical Hypnosis, 25 (2-3), 92-103.

#### NOTES

Presents a review of the body's immune system as an introduction to a discussion of the implications of those processes for cancer and the healing mechanisms.

Hall, Marian D. (1982-83). Using relaxation imagery with children with malignancies: A developmental perspective. American Journal of Clinical Hypnosis, 25 (2-3), 143-149.

Developmental theory has been the foundation for this program of relaxation-imagery therapy with its goal of increasing the efficacy of immune mechanisms, thus increasing the survival rate of children with malignancies and/or improving the comfort and quality of their lives. Three basis constructs--the impact of social stress, the positive development of attachment and the negative effects of separation and loss, and the stages of concept formation relating to the functioning of the human

body, the processes of disease and death--are basic approaches to the use of imagery-relaxation as an integral part of a comprehensive care plan.

Hoffman, Mark L. (1982/83). Hypnotic desensitization for the management of anticipatory emesis in chemotherapy. American Journal of Clinical Hypnosis, 25 (2-3), 173-176.

A hypnotic treatment employing systematic desensitization was used to alleviate anticipatory nausea and vomiting in a middle-aged man undergoing chemotherapy for Hodgkin's Disease. After four treatment sessions, all nausea associated with chemotherapy was eliminated. Results of this treatment are compared with those of another hypnotic treatment recently reported by Redd et al (1982), and reasons for differences are discussed. [Redd, W. H., Andersen, G. V. & Minagawa, R. Y. (1982). Hypnotic control of anticipatory emesis in patients receiving cancer chemotherapy. Journal of Consulting and Clinical Psychology, 50, 14-19.]

Margolis, Clorinda G. (1982-83). Hypnotic imagery with cancer patients. American Journal of Clinical Hypnosis, 25 (2-3), 128-134.

This is a clinical report on the use of hypnotic imagery to reduce pain and discomfort in cancer patients. Deep relaxation, ego strengthening, imagery, and suggestions for changes in perception and awareness are the principal techniques used to reduce suffering and to produce a sense of well-being among cancer patients treated at different stages of disease. Hypnotic intervention involving six patients is described, with emphasis on the ease with which positive transference is established and the effectiveness with which it may be used to enhance therapeutic effects.

Meares, Ainslie (1982-83). A form of intensive meditation associated with the regression of cancer. American Journal of Clinical Hypnosis, 25 (2-3), 114-121.

Elsewhere I have reported a number of cases of regression of cancer following intensive meditation. This type of meditation is characterized by extreme simplicity and stillness of the mind, and so differs from other forms using a mantra, awareness of breathing or visualization of the healing process. Any logical verbal communication by the therapist stimulates intellectual activity in the patient. So communication is by unverbilized phonation, reassuring words and phrases, and most important, by touch. There follows a profound reduction in the patient's level of anxiety which flows on into his daily life. The non-verbal nature of the meditative experience initiates a non-verbal philosophical understanding of other areas of life.

Newton, Bernauer W. (1982-83). The use of hypnosis in the treatment of cancer patients. American Journal of Clinical Hypnosis, 25 (2-3), 104-113.

For nearly eight years, cancer patients have been treated at this outpatient facility using hypnosis and psychotherapy. Basic concepts, assumptions and procedures are

presented and the issues and problems encountered are discussed. Results are given as they relate to the three goals of treatment.

**Oliver, George W. (1982-83). A cancer patient and her family: A case study. American Journal of Clinical Hypnosis, 25 (2-3), 156-160.**

In recent years, increasing numbers of mental health workers have been attempting to use techniques of psychotherapy to influence the course of malignant disease. This paper reviews in detail the course of treatment of one female patient with an inoperable malignancy and conveys a sense of the clinical experience of working intensively with a cancer patient and her family. It shows the complex levels of interaction within the patient herself, between the patient and her family, and between the therapist and her family and within the therapist himself during different phases of the therapeutic journey.

**Rosenberg, Simon W. (1982-83). Hypnosis in cancer care: Imagery to enhance the control of the physiological and psychological 'side-effects' of cancer therapy. American Journal of Clinical Hypnosis, 25 (2-3), 122-127.**

The use of surgery, radiation, and chemotherapy has resulted in increased control of malignancy and prolonged survival for cancer patients. These modalities also carry significant morbidity. Normal physiological homeostasis is often altered by both the neoplasm and its treatment. The diagnosis, treatment, and social stigma of cancer exact profound psychological impact. Hypnosis effectively can control the range of both physiological and psychological 'side-effects' of cancer and its therapy. This paper will delineate those effects of hypnosis of proven value to the cancer patient. Incorporation of images into each phase of a hypnosis session will be demonstrated with an actual case history and annotated transcript. Imagery as a therapeutic modality will be discussed in general, and specific suggestions and images will be given.

**Shapiro, Arnold (1982-83). Psychotherapy as adjunct treatment for cancer patients. American Journal of Clinical Hypnosis, 25 (2-3), 150-155.**

During the past ten years psychotherapy as adjunct treatment for cancer patients has become increasingly common. The use of hypnosis as an integral part of that treatment has also burgeoned. This report will follow the progress of two cancer patients in psychotherapy. While each is highly individual, the commonalities which allow treatment to be systematic will be quite apparent. The ability to minimize pain and discomfort, the ability to keep the white cell count high despite ongoing chemotherapy, and augmenting the ability of the body's immune system to fight the disease are utilized by both of the patients. All of the above are accomplished through the use of visual imagery in the trance state. Visual imagery is also used to reach feelings which patients are often unable to verbalize, and of which they often claim to be unaware. Other aspects of therapy such as the gradual shift from

despair to hope and even confidence, and the development of more assertive behavior are discussed.

1964

Black, Stephen (1964). Mind and body. London: Kimber.

#### NOTES

Defines psychosomatic disease as one that responds to psychotherapy. Believes only 5% are highly hypnotizable, that hypnosis is learnable in 1/2 hour, that hypnosis is not a useful treatment for psychosomatic disorders because you can't use interpretation [of unconscious]. The 'unconscious' is "... a complex of informational systems derived from such primaevial mechanisms" (p. 133). "Primaevial mind is involved in these mechanisms of genetics and immunology" (p. 133). "There is thus a 'somatic mind' which is unconscious and presumably without any means of verbalization of experience--and a 'cerebral mind' which is conscious" (p. 133). The dividing line is not clear.

Rapport is discussed on pp. 160, 169 as one of the spontaneous characteristics of hypnosis, in the absence of suggestion. The same for posthypnotic suggestion (rapport and amnesia). Spontaneous physiological changes in hypnosis relate to mind-body relationships (p. 169)

Conditioned reflex is discussed on p. 161

"...the subjective evidence indicates that a perceptual change involving any sensory modality can be produced by DSUH" [direct suggestion under hypnosis] p. 178. Suggestion can selectively affect different parts of the body p. 197.

Research: "Hypnosis is not only the most important and practical way of proving the existence of the unconscious--which is still in doubt in some circles--but is in fact the only way in which unconscious mechanisms can be manipulated under repeatable experimental conditions for purposes of investigation" (p. 152).

Mind-body is "amenability to control" Catatonia, which characterizes both animal and human hypnosis, seen in hypnosis, is induced by constriction (i.e. disorientation). The Cartesian concept of mind and body tends to confuse the issue p. 157.

Rapport is discussed (p. 157).

Suggestion (p. 159) "It was this concept of 'suggestion'--which so obviously parallels 'amenability to control' in animals--that eventually established hypnosis in the French schools of psychiatry as a state of increased suggestibility. ... still the standard definition of hypnosis in most medical psychiatric textbooks and in lay dictionaries" (p. 159).

Black (1969) did some biochemical sleuthing to learn how information transmitted by words becomes information encoded somatically, as when psychosomatic allergies flare and recede or disappear. What accounts for suggestion "curing" an allergic skin reaction in one part of the body while another part not included in the suggestion remains reactive? What accounts for the instantaneous skin allergy cure which sometimes occurs with suggestion (in 24 hours)?

Skin sensitivity tests in highly hypnotizable Ss who were also very allergic were inhibited by direct suggestion under hypnosis under highly controlled experimental

conditions--and in one subject the effect (inhibition) was relatively permanent--ruling out (he suggests) a neurological mechanism. He did further experiments to examine whether the result was due to an instant neurological mechanism and a long-term endocrinal mechanism.

p. 212 He ruled out peripheral blood flow as the cause of diminished skin sensitivity (there was no change in blood flow with suggestions of heat or cold). Therefore decrease in blood flow couldn't explain in neurovascular terms the 'instant' inhibition of skin sensitivity (allergy) tests. Was it due to systemic--especially adrenal-- changes? He demonstrated increases in plasma cortisol under hypnosis with suggestions of fear. On p. 230 he summarizes the facts he established by skin sensitivity tests, plasma- cortisol studies, and histology - endocrinological.

## INDIRECT SUGGESTION

1998

Groth-Marnat, Gary; Mitchell, Kaye (1998). Responsiveness to direct versus indirect hypnotic procedures: The role of resistance as a predictor variable. International Journal of Clinical and Experimental Hypnosis, 46 (4), 324-333.

Empirical research attempting to demonstrate that indirectly phrased hypnotic suggestions result in greater responsiveness than do direct approaches generally has not shown any differences on formal hypnotizability scales. However, empirical research in related areas along with clinical observation suggests that client resistance might be a crucial moderating variable. specifically, participants with greater resistance would be expected to be more responsive to indirect approaches, whereas those with low levels of resistance would be more responsive to direct hypnotic procedures. To test this hypothesis, participants were given either a standardized test of hypnotic responsiveness that used direct suggestions (Harvard Group Scale of Hypnotizability) or a comparable indirect scale (Alman Wexler Indirect Hypnotic Susceptibility Scale) followed by administration of a measure of resistance (Therapeutic Reactance Scale). The hypothesis was not confirmed, in that those with higher (or lower) reactance/resistance did not score differently than those on either the indirect or direct hypnotizability measures.

1997

Fourie, D. P. (1997). 'Indirect' suggestion in hypnosis: Theoretical and experimental issues. Psychological Reports, 80 (3, Pt 2), 1255-1266.

"Indirect" suggestion is conceptualized in two distinct ways in the literature. From an Ericksonian perspective "indirect" suggestions are theoretically approached as suggestions which can circumvent the censorship of consciousness to reach the "unconscious" where they can activate dormant potentials. In contrast, from a research perspective "indirect" suggestion is operationally defined as a technique. Based on Ericksonian theory, it was claimed that "indirect" suggestion was more effective than traditional, "direct" suggestion. However, this claim could not be empirically substantiated. In this paper it is shown that the theoretical claim is

based on questionable assumptions about the existence of the "unconscious" as a reified entity and about the direct and lineal influence of certain suggestions on this entity. Also, it is argued that traditional research strategies which emphasize strict controls are unable to verify or unambiguously refute the Ericksonian claim because these strategies are biased toward "direct" suggestion. Finally, the paper provides a different, contextual perspective on "indirect" suggestion, thereby placing the theoretical and experimental issues in a different context of meaning. [PubMed Abstract]

1993

Lynn, Steven Jay; Neufeld, Victor; Mare, Cornelia (1993). Direct versus indirect suggestions: A conceptual and methodological review. International Journal of Clinical and Experimental Hypnosis, 31, 124-152.

The article reviews the literature on the effects of direct versus indirect hypnotic suggestions. A conceptual and methodological analysis of direct versus indirect suggestions is also provided. Three conclusions follow from the review: (a) Contrary to views of Ericksonian hypnotists, suggestion style has little effect on objective responding to hypnotic test items; (b) studies of clinical- and laboratory-induced pain and other measures of subjective experience have yielded contradictory results- -however, the best controlled studies have not indicated that indirect suggestions are superior to direct suggestions; and (c) there is insufficient evidence to conclude that hypnotizability level and suggestion wording interact, such that low hypnotizable subjects are particularly responsive to indirect suggestions. Methodological and conceptual problems in defining and studying hypnotic communications, the lack of rigorous experimental controls, and research issues and directions are highlighted.

NOTES

1:

NOTES: Although this article is primarily concerned with the nature of suggestion, the review also mentions several studies comparing hypnosis with other interventions for pain, in passing:

Crowley (1980)

Snow (1979)

Omer, Darnel, Silberman, Shuval, & Palti (1988)

Stern (1982)

Bassman (1983)

"Like the clinical studies using the RIA [Rapid Induction Analgesia], pain studies that did not use the RIA lack appropriate control groups: Neither Bassman's (1983) nor Stern's (1982) research explicitly compared direct and indirect suggestions. What our review does suggest is that studies (e.g., Crowley, 1980; Snow, 1979; Van Gorp et al., 1985) that imposed the greatest degree of methodological control yielded the outcomes least favorable to the hypothesis that indirect suggestions are effective and account for the pain relief achieved, above and beyond factors common to placebo treatments" (p. 132).

"Lynn and his colleagues' studies indicate that whereas indirect suggestions enhance archaic representations of the hypnotist, direct suggestions facilitate

involvement in the events of hypnosis, as measured by subjective involvement and involuntariness" (p. 136).

**Maurer, Candida; Santangelo, Michael; Claiborn, Charles D. (1993). The effects of direct versus indirect hypnotic suggestion on pain in a cold pressor task. International Journal of Clinical and Experimental Hypnosis, 41, 305-316.**

Past studies have investigated the usefulness of hypnosis in pain reduction. Although hypnotic analgesia has been found to be effective, it is generally only those subjects who are highly susceptible to hypnosis who benefit. Some experimenters have found that even low-susceptible subjects can use hypnotic analgesia, if the hypnotic induction uses indirect rather than direct hypnotic suggestions. In the present study, high- and low-susceptible subjects were tested for analgesia using either direct or indirect hypnotic suggestion on pain in a cold pressor task. Findings suggest that high susceptibles experience greater pain reduction than do low susceptibles. However, no significant differences were found between the pain reduction in the direct versus the indirect hypnotic suggestion groups. Possible explanations for this lack of differences are discussed. **NOTES 1:** **NOTES:** They noted that this study differed from Joseph Barber's (1979) in that the latter used continuous suggestion whereas in the current study only posthypnotic suggestion was employed. Also, they used the Harvard Scale to classify Ss, and Register and Kihlstrom (1986) found that only one third of their HGSHS:A tested high-susceptible subjects were able to be so classified on a subsequent administration of the Stanford Hypnotic Susceptibility Scale, Form C, perhaps due to social demands inherent in group hypnosis. Also, perhaps 1 minute was not sufficient time to challenge the effectiveness of alternative coping strategies that some "low" Ss could have used to endure the procedure.

**Szabo, Csaba (1993). The phenomenology of the experiences and the depth of hypnosis: Comparison of direct and indirect induction techniques. International Journal of Clinical and Experimental Hypnosis, 41, 225-233.**

The effect of two hypnotic induction styles on subjective experience was measured in an experiment in which 44 subjects participated in both traditional direct hypnosis, induced by the Stanford Hypnotic susceptibility Scale, Form A, and indirect hypnosis (presented in counterbalanced order), followed by 4 minutes of rest before dehypnosis. The depth of hypnosis was measured retrospectively by a subjective scale, and the structure of experiences was measured by the Phenomenology of Consciousness Inventory. Subjects were subsequently administered the Stanford Hypnotic Susceptibility Scale, Form B, so that awareness of their hypnotizability would not affect their subjective depth reports. No differences were found in a comparison of subjects' structure of experiences in direct and indirect hypnosis. In addition, low and medium hypnotizable subjects reported indirect hypnosis as deeper. This may reflect the possibility that while hypnotized different mechanisms come into play for subjects high in hypnotizability compared to those who are less hypnotizable.

**NOTES**

**Describes history of Erickson's relationship to the Palo Alto group and family therapy practice (both strategic and interactional), and identifies seven philosophical and methodological realms which represent the incorporation of Ericksonian principles into strategic and interactional family therapy models.**

**1988**

**Edgette, John H. (1988). 'Dangerous to self and others': The management of acute psychosis using Ericksonian techniques of hypnosis and hypnotherapy. In Lankton, Stephen R.; Zeig, Jeffrey K. (Ed.), Ericksonian Monographs: No. 3. Treatment of special populations with Ericksonian approaches (pp. 96-103). New York: Brunner/Mazel.**

**NOTES**

**Edgette shows how several agitated psychotics were hypnotized using an Ericksonian approach. His inductions were bold attempts to introduce hypnosis in a setting where drugs and restraints are often the only available tools. He offers some ideas concerning the myth that hypnosis will not work with such a population.**

**Lynn, Steven Jay; Weekes, John R.; Matyi, Cindy L.; Neufeld, Victor (1988). Direct versus indirect suggestions, archaic involvement, and hypnotic experience. Journal of Abnormal Psychology, 97 (3), 296-301.**

**This study examined the effects of direct (Harvard Group Scale of Hypnotic Susceptibility; Shore & Orne, 1962) versus indirect (Alman-Wexler Indirect Hypnotic Susceptibility Scales; Pratt, Wood, & Alman, 1984) suggestions on archaic involvement (Nash & Spinler, in press) with the hypnotists, objective responding, and subjective involvement and involuntariness ratings, when the scales were administered in all possible combinations (direct/indirect, N = 61; indirect/direct, N = 61, direct/direct, N = 57; indirect/direct, N = 95), across two sessions. At the initial testing, subjects who received indirect suggestions reported a greater emotional bond with the hypnotist and increased fear of negative appraisal than subjects who received direct suggestions. Repeated testing resulted in response decrements on measures of objective responding, subjective involvement, and involuntariness that were paralleled by diminished involvement with the hypnotist. The most stable relation between scales was evident when scales were defined as direct hypnosis across both sessions. Although direct and indirect suggestions produced comparable effects in the first session, in the second session, direct suggestions fostered greater subjective involvement and feelings of involuntariness.**

1987

Lynn, Steven Jay; Neufeld, Victor; Matyi, Cindy L. (1987). Inductions versus suggestions: Effects of direct and indirect wording on hypnotic responding and experience. Journal of Abnormal Psychology, 96 (1), 76-79.

This study examined the effects of direct wording (authoritative language, specific responses) versus indirect wording (permissive language, choice of responses) of hypnotic inductions and suggestions in measures of behavioral and subjective responding. Subjects experienced suggestion-related involuntariness and suggested effects to a greater degree in response to direct-word suggestions (Harvard Group Scale of Hypnotic Susceptibility; Form A; Shor & Orne, 1962) than in response to indirect-worded suggestions (Alman-Wexler Indirect Hypnotic Susceptibility Scale; Pratt, Wood, & Alman, 1984). No difference in behavioral responding was observed. Furthermore, induction wording did not have an effect on these measures, nor did the wording of the induction and the wording of the suggestion types interact with each other. Female subjects attributed less of their responsiveness to their own efforts when they received direct suggestions, and male subjects were less likely to attribute their responsivity to the hypnotist's ability when they received indirect suggestions. Rapport with the hypnotist did not vary as a function of induction or suggestion wording.

Price, Donald D.; Barber, Joseph (1987). An analysis of factors that contribute to the efficacy of hypnotic analgesia. Journal of Abnormal Psychology, 96, 46-51.

An analysis was made of factors that contribute to the magnitude of hypnotic analgesia produced by indirect hypnotic suggestions. Two groups of human volunteers made \_sensory\_ and \_affective\_ visual analogue scale (VAS) responses to nociceptive temperatures (44.5-51.5C) before and after hypnotic suggestions were given for analgesia. Group 1 was given suggestions for developing a hypnotic state only once just before analgesic testing and did not have significantly reduced VAS responses to experimental pain after hypnosis. Group 2 was continuously given cues for maintaining a hypnotic state during their analgesia testing session and had large reductions in both VAS- sensory and, especially, VAS-affective responses to pain. A small but statistically reliable correlation was found between hypnotic susceptibility and overall magnitude of reduction in VAS-sensory responses ( $R = .4$ ). The correlations were much larger for intense stimuli compared to those near threshold. Reductions in VAS-affective pain responses were not correlated with hypnotic susceptibility.

1986

Woolson, Donald A. (1986). An experimental comparison of direct and Ericksonian hypnotic induction procedures and the relationship to secondary suggestibility. American Journal of Clinical Hypnosis, 29 (1), 23-28.

Recent studies reporting the disparate effects of direct and indirect suggestion upon hypnotized subjects have indicated that standardized, direct hypnotic susceptibility

tests may not accurately predict the suggestibility of subjects exposed to an indirectly worded, albeit similar, test. Historically, primary suggestibility correlates highly with hypnotizability, while secondary suggestibility does not and has been reported to be a subject's response to indirect suggestion. In this study 56 volunteers for self-hypnosis training were first tested for secondary/indirect suggestibility, then each singly received either a direct standardized [sic] induction or an Ericksonian (indirect) version. While susceptibility scores between groups were close, a greater number of the Ericksonian group subjects were rated as medium or highly susceptible. This occurred regardless of their type of suggestibility. Also, the Ericksonian group subjects appeared to be less aware of their depth of trance, as judged by a comparison of their susceptibility scores and their self-report depth scores. - Journal Abstract

1985

Coe, William C.; Scharcoff, J. A. (1985). An empirical evaluation of the neurolinguistic programming model. International Journal of Clinical and Experimental Hypnosis, 33 (4), 310-318.

The neurolinguistic programming hypothesis that most people have a preferred way of dealing with the world -- a primary representational system -- was tested. 50 Ss were evaluated for sensory modality preference in 3 ways: (a) they chose among written descriptions using either visual, auditory, or kinesthetic wording (preference); (b) their eye movements were recorded during an interview; and (c) their verbal responses were scored for sensory predicates. The results did not support neurolinguistic programming theory in that preference of 1 modality on 1 measure did not relate to the same modality on the other measures as would be expected if primary representational systems were characteristic of the sample. Other studies have shown mixed results. The conclusion seems warranted that a good deal more empirical support is needed before the positive therapeutic claims of neurolinguistic programming proponents can be taken seriously.

Matthews, W. J.; Bennett, H.; Bean, W.; Gallagher, M. (1985). Indirect versus direct hypnotic suggestions - an initial investigation: A brief communication. International Journal of Clinical and Experimental Hypnosis, 33 (3), 219-223.

Keywords: indirect suggestion, suggestion

The clinical use of indirect hypnotic suggestion is purported to be an effective method of trance induction because it allows S a wider latitude of responsiveness than does a traditional hypnotic induction. In the present study, 15 male and 15 female Ss each received a traditional hypnotic induction followed by the Stanford Hypnotic Clinical Scale (SHCS) of Morgan and Hilgard (1978) and an Ericksonian hand levitation induction (Erickson, E. L. Rossi, & S. Rossi, 1976) followed by a rewritten SHCS, utilizing indirect suggestions for each scale item (Indirect Suggestion Scale -- ISS). The results revealed no significant main effect differences between hypnotic methods on the behavioral response measure. Ss did report feeling more deeply hypnotized during the indirect hypnotic procedure. High hypnotizable

male Ss felt more aware of the hypnotic suggestions and more in charge of their experience when they experienced ISS than they did on SHCS. This difference in self-reported experience may possibly be due to the time differential between SHCS and ISS, with the latter taking approximately one-third longer. Implication and limitations of the study are discussed.

Stone, Jennifer A.; Lundy, Richard M. (1985). Behavioral compliance with direct and indirect body movement suggestions. Journal of Abnormal Psychology, 94 (3), 256-263.

Investigated the effectiveness of 2 types of suggestions in eliciting body movement by presenting 96 high-, medium-, and low-susceptible undergraduates, in hypnotic or nonhypnotic conditions, with either of 2 series of body movement suggestions. The indirect suggestions were designed to represent the approach of M. H. Erickson (see PA, vol 60:11116 and 12262) and resulted in greater compliance in the hypnotic condition. Direct suggestions resulted in greater compliance in the nonhypnotic condition. Susceptibility to hypnosis was related to compliance in the hypnosis condition, but no interactions were found between susceptibility and type of suggestion. Sense of volition in responding was unrelated to the major findings. Discussion of the results includes a call for the accurate reporting of the wording of hypnotic suggestions in future research.

Van Gorp, Wilfred G.; Meyer, Robert G.; Dunbar, Karen D. (1985). The efficacy of direct versus indirect hypnotic induction techniques on reduction of experimental pain. International Journal of Clinical and Experimental Hypnosis, 33, 319-328.

The cold pressor test was used to investigate the efficacy of Rapid Induction Analgesia, a new, indirect hypnotic technique introduced by J. Barber (1977). Rapid Induction Analgesia was compared with traditional hypnosis, relaxation, suggestion without an induction, and a no-treatment control in Subject of high and low hypnotizability. Only traditional hypnosis was found to significantly reduce Subject's reported pain when compared to the control group Subject, and Rapid Induction Analgesia was not found to be an effective treatment in this study, in contrast to J. Barber's earlier findings

#### NOTES

105 subjects were randomly assigned to conditions, based on high (8-12) or low (0-4) scores on the Harvard Group Scale of Hypnotic Susceptibility. There were 9-13 Subjects per cell in the treatment conditions.

McConkey, Kevin M. (1984). The impact of an indirect suggestion. International Journal of Clinical and Experimental Hypnosis, 32 (3), 307-314.

The impact of an indirect suggestion was investigated in 2 different test contexts; real and simulating Ss were tested. The Experiential Analysis Technique was employed with real Ss in order to explore their perceptions and processing of the

indirect suggestion. Real Ss were seen to be more heterogeneous in their response to the indirect suggestion than were simulating Ss, and the pattern of response was similar in the 2 test contexts. Some real Ss perceived the indirect suggestion as an illegitimate basis for a change in their phenomenal awareness. Findings point to the ways in which real Ss differ in the detail of their hypnotic response, and comment is made on the relevance of cognitive style for understanding the response patterns of hypnotic Ss.

**1983**

Bassman, S. (1983). The effects of indirect hypnosis, relaxation and homework on the primary and secondary psychological symptoms of women with muscle contraction headache (Dissertation). Dissertation Abstracts International, 44, 1950-B.

**NOTES**

Compared the effects of indirect hypnosis (e.g., metaphors, stories, vague suggestions, and implied directives) on muscle contraction headaches with a relaxation and a no-treatment control condition. Both hypnosis and relaxation conditions reduced symptoms more than did the no-treatment condition. Unlike relaxation, indirect hypnosis did not reduce the intensity and duration of headaches, although it did reduce the amount of medication and also benefitted sleep.

**1982**

Stern, T. E. (1982). The effects of Ericksonian hypnosis and biofeedback on self-reported measures of pain (Dissertation). Dissertation Abstracts International, 43, 3744-B.

**NOTES**

Conducted a 6-subject case study comparing the effectiveness of so-called Ericksonian hypnosis and biofeedback on chronic pain. Two subjects improved more on subjective and behavioral pain measures using biofeedback, three improved more using hypnosis, and one did not improve in either condition.

**1980**

Crowley, R. (1980). Effects of indirect hypnosis (Rapid Induction Analgesia) for relief of acute pain associated with minor podiatric surgery (Dissertation). Dissertation Abstracts International, 40, 45-49.

**NOTES**

Lynn et al. (1993) cited this dissertation. They noted that all 30 volunteer subjects responded painfully when stimulated by a needle administered by a podiatrist and that the Rapid Induction Analgesia of Joseph Barber (RIA) was not as effective as local chemical analgesia. Furthermore, according to Lynn et al., RIA patients did not report a reduction in their anxiety following podiatric surgery comparable to that reported by patients who received chemical analgesia. The author also found that hypnotizability was related to multiple chronic pain indices.

Edwards, William Henry (1980). Direct versus indirect hypnosis for the relief of chronic pain in spinal cord injured patients (Dissertation, United States International University). Dissertation Abstracts International, 40 (10-B), 4996.

#### NOTES

This study compared effectiveness of direct hypnosis and indirect hypnosis (Rapid Induction Analgesia, developed by Joseph Barber) in reducing experimental and clinical pain in spinal cord injured patients. The 30 male paraplegic patients who had chronic benign pain volunteered for the study. They were administered three tests: the Pain Estimate Scale (Sternbach, 1974), Ischemic Muscle Pain Test (IMPT), and the Stanford Profile Hypnotic Susceptibility Scale, Form II -- SPHSS -- (Weitzenhoffer and Hilgard, 1967). Each patient experienced three sessions: (1) Baseline Control, (2) Direct Hypnosis, and (3) Indirect Hypnosis. Patients were randomly assigned to Sessions (2) and (3). The results indicated no significant statistical difference in the effectiveness of direct versus indirect hypnotic analgesia in these chronic pain patients. Direct and indirect hypnosis were equally effective; hypnotizability was not associated with outcome. Furthermore, there was no interaction between treatment effects and pretreatment pain level. The results were similar for both clinical and experimental pain.

McConkey, Kevin M.; Sheehan, Peter W. (1980). Inconsistency in hypnotic age regression and cue structure as supplied by the hypnotist. International Journal of Clinical and Experimental Hypnosis, 28 (4), 394-408.

Inconsistency in hypnotic age regression was elicited by asking Ss to write a complex sentence, in contexts that varied appreciably in the extent to which they cued Ss that illogical response was appropriate. Hypnotically responsive and unresponsive Ss were assigned to a real or simulating group in application of the real-simulating model of hypnosis and tested in 1 of 3 distinct cue conditions. Cue conditions either followed those of previous studies and communicated that no particular response was appropriate, or communicated that an illogical response was appropriate, or inappropriate. It was hypothesized that cue structure would have a significant impact. Data indicated that cues for logical response had a greater influence on the behavior of Ss than did cues for illogical response when compared with the base response condition; at times, real Ss behaved appreciably more illogically than simulating Ss. Also, detailed analysis of the reports of both groups of Ss indicated distinctive properties of experience that point to the importance of recognizing the complexities of consciousness underlying the experiences of highly susceptible Ss.

1975

Spear, J. E. (1975). The utilization of non-drug induced altered states of consciousness in borderline recidivists. American Journal of Clinical Hypnosis, 18, 111-126.

Utilizing non-drug induced altered states of consciousness, various modes of interior reflection, behavior modification and reprogramming of conscious attitudes and values were utilized with 49 borderline recidivists. Such offenders were so determined by the Department of Corrections, Probation and Parole Office, District II. No coercion was used to induce such individuals to enter the program and there was no reprisal for stopping therapy at any time. Over a two and one-half year period the recidivist rate among this group was less than 5%. It is suggested that non-drug induced altered states of consciousness combined with indirect as well as symbolic techniques may prove to be the most effective means of criminal rehabilitation.

#### NOTES

Borderline recidivists were "individuals, who, in the opinion of the P.O. [probation officer] were, in all probability, to be returned to prison within a few months, or less, if there wasn't a major change in attitude and actions" (p. 111). Therapy employed closed circuit TV with bi-directional audio and induction of altered state of consciousness using an ophthalmology-type rotary prism. Therapy involved (s) recall of relaxed state when under stress, (2) exploration of early conditioning events, (3) self evaluation during the ASC, (4) use of symbolic mental exercises and mental practice for similar circumstances in normal waking state, (5) suggestions for setting goals and ideals, (7) a type of logotherapy, (7) 'nudging' the person to examine their relationship with their concept of God. The author noted in the parolees: (1) low levels of self esteem, (2) depression, (3) going into deep levels of altered states once trust was established with the therapist.

1974

Behrs, John O. (1974). Dynamics of experiential therapy. American Journal of Clinical Hypnosis, 17, 1-4.

Modern experiential therapies have significant features in common with hypnotherapy. The essence of hypnotically oriented psychotherapy is described by Milton H. Erickson (1971) as 'meet the patient at the patient's level, thereby gaining rapport. As trust is developed, modify the patient's productions by covert suggestions, thereby gaining control. This control is then utilized in order to get the patient to institute therapeutic growth from within.' He further emphasizes the necessity of an indirect approach, of subtle manipulations leading the patient to circumvent his resistances. The modern experiential therapist follow Erickson's maxim and display many features in common with hypnotic therapies. It is our observation that successful experiential work almost always leads to a hypnotic trance, in even very resistant subjects, and that this greatly augments its therapeutic effectiveness. It differs from Erickson's therapy in not requiring the indirect, round-about approach. In essence, it is highly suited to the therapist who admires the ingenuity of Erickson but who is more suited, personality-wise, to a direct approach, of zeroing right in on a problem where the energy is. Instead of circumventing a patient's resistances, the therapist helps the patient fully experience them. The two

styles, however, are seen as both similar and compatible with one another. [Emphasis removed.]

1967

Evans, Frederick J. (1967). An experimental indirect technique for the induction of hypnosis without awareness. International Journal of Clinical and Experimental Hypnosis, 15, 72-85.

A procedure is described which has been used in an experimental setting as a method of indirectly inducing hypnosis without S's awareness. Ss are not told that hypnosis is involved in the procedure, but are told they will be taught how to relax. The aim of the indirect procedure is to create different expectations and preconceptions from those normally occurring in the special hypnotic relationship. Evidence from 3 studies (samples of 63, 63, 120) indicates that the procedure successfully induces hypnosis comparable in depth to other standard hypnotic procedures. About half of the Ss tested apparently do not recognize the procedure involves hypnosis. Approximately 30% of the Ss who receive the procedure, as well as 30% of the Ss in the control group who did not receive the procedure, but were tested with the same test suggestions, recognized that an attempt had been made to induce hypnosis. The perceptions about whether hypnosis was involved were unrelated to scores on typical hypnotic phenomena. It was concluded that the indirect induction technique successfully induces hypnosis and is a useful technique for manipulating S-expectations in an experimental context.

#### NOTES

[The Subject] is told, 'A series of experiments are being conducted investigating the effects of relaxation on behavior. Because of confusing results in the literature, this study is designed to examine the relationship between relaxation and several other psychological phenomena, some of which might remind you of a variety of other phenomena which you may have heard or read about.' The S was told that a technique had been devised that would assist him to relax completely. His main task was to relax as completely as possible. This would be facilitated by lying comfortably on a couch, and by allowing his mind to become completely blank. To prevent himself from falling asleep, he should concentrate his attention on some object or idea. To help exclude other thoughts from his mind, E would continue to talk in a monotonous voice saying little of importance, while the S stared at a spot on the wall. This shaping of the situation was continued with a considerable degree of apparent permissiveness.

"The S's attention was slowly directed to the rhythm of his own breathing as suggestions were given of eye fatigue. If S closed his eyes, he might find it convenient to concentrate on the rhythm of his own breathing. Perhaps this would be easy to think about if he visualized a pendulum swinging in time with his breathing. The E continued to talk and count in rhythm with S's breathing. Special words, such as 'breathing in and out; the pendulum swings back and forward,' were always spoken as S inhaled or exhaled. Counting was also timed to coincide with exhalation.

Deeper relaxation was suggested as E counted slowly from 1 to 21, and later, from 1 to 31.

"Throughout the procedure, phrases and words (such as 'hypnosis,' 'trance,' 'drowsy') traditionally employed with hypnotic induction techniques were avoided. After approximately 30 minutes, a natural transition was made to the testing procedure. Suggestions of continued deep relaxation were intermingled between various tests administered. Termination was effected by suggesting that the relaxation would end as E counted from 'A' to 'H'" (p. 75).

Barber, Theodore Xenophon (1965). Physiological effects of 'hypnotic suggestions': A critical review of recent research (1960-64). Psychological Bulletin, 201-222.

Recent studies are reviewed which were concerned with the effectiveness of suggestions given under "hypnosis" and "waking" experimental treatments in alleviating allergies, ichthyosis, myopia, and other conditions and in eliciting deafness, blindness, hallucinations, analgesia, cardiac acceleration and deceleration, emotional responses, urine secretion to sham water ingestion, narcotic-like drug effects, and other phenomena. The review indicates that a wide variety of physiological functions can be influenced by suggestions administered under either hypnosis or waking experimental treatments, and direct and indirect suggestions to show the particular physiological manifestations are crucial variables in producing the effects.

1957

Solovey, Galina; Milechnin, Anatol (1957). Concerning the induction of the hypnotic state. Journal of Clinical and Experimental Hypnosis, 5 (2), 82-98.

## NOTES

The hypnotic state has four attributes: "an effect of emotional stabiliztion, a retrogression to an infantile psychological functioning, suggestibility, and transmissibility of the hypnotic relationship" (p. 82). "SUGGESTIBILITY is a special motivation to accept, incorporate within one's self, and execute direct or implicit propositions, which is equivalent to the motivation of a child to accept, assimilate and carry out the propositions of its parents" (p. 84). The authors propose that verbal and non-verbal suggestions are incorporated during the course of education, lasting years and thus becoming in effect post-hypnotic suggestions. "The person will have in the future a \_special responsiveness,\_ that may be more or less pronounced according to the circumstances, \_for those data\_ (coming from books, movies, conversations, etc.) \_which agree with his emotionally-incorporated post-hypnotic suggestions\_" (p. 85). If while in an auto-hypnotic condition he comes in contact with someone "who appears to be the embodiment of the convictions or prejudices that on being stimulated started the process of emotional activation that led to the development of the hypnotic state, \_there may be a transformation of the auto-hypnotic condition into an interpersonal hypnotic relationship\_" (p. 86).

According to the authors, this theory can explain post-hypnotic (negative) sequellae. It also accomodates explantions of both Natural or Direct Orientation inductions

and Indirect Orientation inductons, and explains phenomena such as patients entering hypnosis rather automatically while awaiting the appearance of Mesmer in his waiting room.

"To conclude, we will stress that the psychological mechanism of hypnotic induction is exactly the same in everyday life and in the experimental environment. The apparent differences like [sic] in the behavior of the subject in the hypnotic state, and are due to the motivation that arises from the circumstances and to the convictions, capacities, psychological maturity, and degree of retrogression of the individual" (p. 96).

Solovey, Galina; Milechnin, Anatol (1957). Concerning the nature of hypnotic phenomena. Journal of Clinical and Experimental Hypnosis, 5 (2), 67-76.

#### NOTES

The authors write about the place of the hypnotic state in general psychology: "the study of the psychological mechanisms that make the appearance of the phenomenon possible, which need not be different from the normal and current psychological mechanisms in everyday life\_" (p. 67). They classify hypnotic phenomena into three groups:

"I. Phenomena which are a function of the state of psychological retrogression (hypnotic depth), appearing in spontaneously [sic] or when proposed by the operator.

II. Phenomena which appear without any specific suggestion, as a side issue of other suggestions, capable of originating emotional states in the subject.

III. Phenomena which are independent of all suggestion, being a constituent part of the hypnotic state itself, in its 'positive' or 'negative' forms" (p. 68).

Using this framework, the authors describe several aspects of hypnosis: catalepsy, anesthesia, retrogression, the taking of a role, negativism and resistance, visceral changes, emotional stabilization, psychotherapeutic benefits (indirect). They observe that direct suggestions are often not necessary for therapeutic benefit, and give as an example the tendency for less bleeding when dentists suggest that patients will not feel less pain.

"For the elucidation of this point, the authors carried out an experiment in a dental clinic, taking six easily hypnotizable subjects in whom dental extractions were to be performed. They were given only the suggestions that they would feel the doctor working, but not experience pain ... that they would pay no attention to it ... or even if they felt a little pain, this would not trouble them and they would bear it perfectly ... Nothing was said about the loss of blood. As a result, in all the cases the loss of blood was slight, practically insignificant, though technically difficult extractions of roots were included" (p. 74).

"The explanation of hypnotic phenomena as natural and normal consequences of the hypnotic emotional state, and of the state of psychological retrogression, eliminates the supposed mysterious powers of suggestion. Suggestion is thus relegated to the modest role of a litmus paper which reveals the psychological functioning of the individual in an experimental environment. On the other hand, in everyday-life hypnosis, in the principal hypnotic relationships of parents with

their children, of teachers with their pupils, etc. (11), suggestibility plays an important role in education or re-education" (p. 75).

1955

Fisher, Seymour (1955). An investigation of alleged conditioning phenomena under hypnosis. Journal of Clinical and Experimental Hypnosis, 3 (2), 71-103.

#### NOTES

"Summary and Conclusions.

"The primary objective of the present investigation was to present rational and empirical evidence supporting a reinterpretation of a number of alleged 'conditioning' studies performed under hypnosis. An experiment which contained no explicit verbal posthypnotic suggestion was conducted. The study was designed to expose the presence of characteristic features of an explicit posthypnotic act in hypnotically induced 'conditioned responses'; two responses, an olfactory hallucination and a coughing reaction, were induced under hypnosis by a conditioning procedure, and were examined under various experimental conditions in the subsequent waking state.

"Although the results are based upon a relatively small sample of Ss, the overall data seem to warrant the following principal conclusions:

"(1) Responses induced under hypnosis by means of a conditioning procedure do not conform to some of the expected principles of contemporary conditioning theory.

"(2) These responses do, however, show a marked similarity to behavior induced by explicit posthypnotic suggestion. Inasmuch as no significant discrepancies between these two classes of phenomena (posthypnotic behavior and the responses induced by a conditioning procedure) were observed, the results are interpreted as supporting the dual hypothesis that (a) evocation of the cough and olfactory hallucination by their respective stimuli is a function of hypnotically determined suggestive factors, and (b) aside from the omission of an explicit verbal suggestion, these responses differ in no essential way from a typical posthypnotic act.

"(3) As a corollary to the preceding conclusion, it follows that some deeply hypnotized Ss are capable of performing posthypnotic behavior solely on the basis of implicit hypnotic suggestion. Hence, the frequently accepted assumption that explicit verbal instructions are required to effect posthypnotic behavior seems untenable.

"(4) To the extent that these conclusions are valid, it seems doubtful whether the concept of 'conditioned response' is any more appropriate when applied to these hypnotically determined responses than when applied to typical posthypnotic behavior. It would appear, rather, that the only fundamental difference between these two forms of behavior lies in the degree to which E explicitly communicates his suggestions.

"The major implications of the results are discussed, and several secondary conclusions are suggested:

"(5) The results are interpreted to support the possible existence of 'operator attitude' as a significant variable in research with hypnosis.

"(6) The results seem best understood within a framework of role-taking theory which takes into consideration both S's expectations and the hypnotist's expectations.

"(7) Recognition of the active participation of hypnotic Ss prescribes extreme caution in the interpretation of results whenever hypnosis is utilized as a technique for controlling psychological variables" (p. 101).

1954

Erickson, Milton H. (1954). A clinical note on indirect hypnotic therapy. Journal of Clinical and Experimental Hypnosis, 2, 171-174. (Abstracted in Psychological Abstracts 55: 4292)

#### NOTES

Author describes treatment of a young married couple who presented with the problem of life-long enuresis. The treatment involved a prescription: "Each evening you are to take fluids freely. Two hours before you go to bed, lock the bathroom door after drinking a glass of water. At bedtime, get into your pajamas, and then kneel side by side on the bed, facing your pillows and deliberately, intentionally and jointly wet the bed" (p. 172). (Hypnotic induction was not used.)

The author opines that the procedure was based upon an indirect use of hypnosis. "The instructions were so worded as to compel without demanding the inntent attention of the unconscious" (p. 173).

Erickson, Milton H. (1954). Special techniques of brief hypnotherapy. Journal of Clinical and Experimental Hypnosis, 2, 109-129. (Abstracted in Psychological Abstracts 55: 2508)

#### NOTES

Author describes techniques used with patients who aren't able, for internal or environmental reasons, to undertake comprehensive therapy, "Intentionally utilizing neurotic symptomatology to meet the unique needs of the patient" (p. 109). He provides 8 case reports.

Patient 1 was reassured, in hypnosis, that his arm paralysis was due to "inertia syndrome" which he would continue to have, but it wouldn't interfere with his work.

Patient 2, also with arm paralysis had another comparable, non-incapacitating, symptom substituted.

Patients 3 and 4, for whome restrictions on therapy were the limits of time and situational realities, had their symptoms transformed (e.g. by introducing in hypnosis the obsessional thought or worry that he would NOT have the symptom for which he sought help).

Patients 5 and 6 were helped, through hypnosis, to symptom amelioration. (Patient 5 had an IQ of 65.)

Patient 7 "Therapy was achieved ... by a deliberate correction of immediate emotional responses without rejecting them and the utilization of time to palliate

and to force a correction of the problem by the intensity of the emotional reaction to its definition" (p. 121)

Patient 8 "the procedure was the deliberate development, at a near conscious level, of an immediately stronger emotion in a situation compelling an emotional response corrective, in turn, upon the actual problem" (p. 121).

Kline, Milton V.; Guze, Henry (1954). The alteration of oral temperature through hypnotic techniques: I. Pilot experimentation. Journal of Clinical and Experimental Hypnosis, 2 (3), 233-237.

## NOTES

The authors used a variety of hypnotic techniques to attempt to modify the oral temperature of a normal 30 year old male who was capable of both positive and negative hypnotic hallucinations and of reaching a somnambulistic level with spontaneous, complete, post-hypnotic amnesia. Techniques included direct suggestions (general for temperature rising as when ill, and specific, i.e. his oral area was getting hot), time regression to when he had experienced a fever, age regression to age 10 when he had a high fever, direct suggestion of temperature drop, and positive hallucination of extreme elevation in a plane. A waking simulation control was run for each condition.

Although the subject appeared uncomfortable and showed behavioral changes, the mean oral temperatures did not differ from the baseline mean significantly for either hypnosis or simulation conditions, except for the hallucinated experience of flying in a plane at an altitude of 100,000 feet. That condition lowered the temperature an average of 3 degrees Fahrenheit. In that experimental condition there was no mention of temperature alteration per se, "thus indirect mechanism rather than direct mechanism appears to be more effective in the hypnotic control of temperature" (p. 237).

## INDUCED MOOD

2000

Willmarth, Eric K. (2000, August). Modification of experienced pain with hypnotically induced positive mood. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, D. C..

This study investigated the relationship between chronic pain and depressed mood within the context of Associative Network Theory and the High Risk Model of Threat Perception. A bi-directional relationship was hypothesized and tested by comparing pain ratings before and after the hypnotic induction of positive mood by suggestion of positive memories. These results were compared to the pain ratings of two control groups: participants who received hypnotic suggestion for relaxation only and participants who received non-hypnotic suggestion for relaxation and enhanced mood. Participants were 96 patients of a hospital-based Pain Management Center. Following assessment of hypnotic ability using the Harvard Group Scale of Hypnotic Susceptibility: Form A, and the Subjective Experiences Scale, participants

recorded levels of depressed mood, sensory pain, affective pain, global pain and self control of pain before and after listening to an audio-taped treatment session. Results show that the induction of a positive mood did influence a decrease in self-reports of pain. In addition, the level of the participants' hypnotic ability was also found to be a significant factor, suggesting that screening for predisposing factors, such as hypnotic ability, and the clinical use of hypnosis for mood enhancement are warranted in a chronic pain population. - Abstract taken from *Psychological Hypnosis: A Bulletin of [Amer Psychol Assn] Division 30*, Fall 2000.

1993

Harris, Ruth M.; Porges, Stephen W.; Carpenter, Myrna E. Clemenson; Vincenz, Lilli M. (1993). Hypnotic susceptibility, mood state, and cardiovascular reactivity. *American Journal of Clinical Hypnosis*, 36 (1), 15-25.

In this study we explored the relationship between hypnotic susceptibility measured with the Harvard Group Scale of Hypnotic Susceptibility (HGSHS) and cardiovascular parameters. After assessing their degree of hypnotic susceptibility, we induced 21 female students into happy mood states and into sad mood states. During the mood state induction we monitored blood pressure, heart rate, and cardiac vagal tone continuously. The study demonstrated a strong relationship between hypnotic susceptibility and both cardiac vagal tone and heart rate reactivity. Subjects with lower heart rate and greater vagal tone during baseline and greater heart rate increases during mood induction were more susceptible to hypnosis. Multiple regression analyses indicated that approximately 40% of the individual difference variance of hypnotic susceptibility was accounted for by baseline cardiac vagal tone and heart rate reactivity during mood state. The data demonstrate that autonomic tone, assessed by cardiac vagal tone and heart rate reactivity, are related to hypnotic susceptibility as measured by the HGSHS. - Journal Abstract

Crowson, J. Jeffrey, Jr.; Conroy Aileen M.; Chester, Traci D. (1991). Hypnotizability as related to visually induced affective reactivity: A brief communication. *International Journal of Clinical and Experimental Hypnosis*, 39 (3), 140-144.

Numerous studies have explored the relationship between hypnotizability and individual differences in imaginative involvement and creativity. Most have assessed imaginative or affective involvement by involving Ss in a variety of imaging tasks. Unlike these earlier studies, however, the present study made no attempt to actively involve Ss in the film viewing task. Rather, individuals assessed as high, medium, or low in hypnotizability were exposed to either a violent film, a neutral film, or no film. Results provided tentative evidence to indicate that the level of negative affect reported was significantly greater for highly hypnotizable Ss. Results were discussed in terms of the limitations of the present study and implications for future studies.

1991

Zachariae, Robert; Bjerring, P.; Arendt-Nielsen, L.; Nielsen, T.; Gotliebsen, K. (1991). The effect of hypnotically induced emotional states on brain potentials by painful argon laser stimulation. Clinical Journal of Pain, 7, 130-138.

The relationship between pain perception and emotional states is well known. However, the nature of this relationship and how different emotional states affect sensory and cognitive dimensions of pain remains uncertain. Results from experimental investigations are often contradictory, which may be due to methodological difficulties in inducing pain and monitoring physiological responses. In addition, most studies have focused on a single emotion, and data on the relative effects of different emotional states are lacking. In the present study we attempted to eliminate some of these methodological problems. Laser evoked potentials were used as a quantitative correlate to pain perception and were measured in 12 highly hypnotically susceptible subjects during seven conditions: (a) a prehypnotic baseline condition; (b) a neutral hypnotic control condition; (c-e) hypnotically recalled anger, fear, and depression in randomized order; (f) a hypnotically recalled happy condition, and (g) a posthypnotic awake control condition. The pain evoked potentials were significantly decreased in the angry condition and significantly increased in the depressed condition compared with baseline. No differences could be detected for either the happy or the fear-related condition compared with the baseline or neutral hypnotic condition. A significant positive correlation between the subjective intensity of depression and the increase in evoked potentials was found, but none for the other three emotions. The results support earlier findings that clinical depression is related to increased pain perception, and findings that the expression of anger can inhibit the experience of pain. The lack of changes in pain-related potentials during the neutral and happy condition may indicate that effects of psychological interventions such as hypnotic analgesia may be due to specific cognitive processes rather than a relaxed or pleasant state in itself.

#### NOTES

Hypnosis was used as an experimental condition because the recall of emotion may be more intense and vivid than in nonhypnotized conditions. Pulse was measured as an indicator of arousal. Subjects (9 women, 3 men) scored at least 10 or 11 on the Danish version of the Harvard Group Scale of Hypnotic Susceptibility. Each S was interviewed to determine early life experiences associated with the emotions under study, and the Experimenter noted key words regarding the emotion-arousing situation (time, place, persons involved) to assist in evoking the emotional state.

Pain was evoked with laser stimulus (100 ms) in a 1 x 3 cm. target area, avoiding repeated stimulation at identical points within the area. Pain threshold (prehypnotic) was defined as 'a distinct sharp pin prick without any burning aftersensation.' During the baseline and experimental conditions, evoked potentials were elicited using a stimulus 1.5 times threshold.

Following a standardized 15 minute hypnotic induction, the four emotional states were induced (randomized across Subjects). Each emotion was the focus for 10 minutes, and evoked potentials were recorded during the last five minutes of each. Subjects were instructed to relax and clear their minds of images or emotions in

between each emotion condition. No suggestions were given regarding pain or pain perception.

After the hypnosis conditions, Subjects were asked to rate the intensity of each emotion on an analogue scale, and to rate their experience of pain on an analogue scale. (As it turned out, most of the Subjects were not able to recall the intensity of pain during all four emotional states.)

The size of the evoked potentials to painful stimuli increased during depression 35.8% over prehypnosis baseline, but decreased during anger 46.8% below prehypnosis baseline. The difference between prehypnosis baseline and neutral hypnosis was not significant statistically. Also, the differences between the happy condition, the fearful condition, or the posthypnotic condition, and prehypnosis were not significantly different. Pulse increased 6.5% over baseline during anger, decreased 4.1% under baseline in depression, and evidenced no difference from baseline for the other two emotions.

"A significant ( $p < 0.05$ ) positive correlation ( $r = +.60$ ) was found between the subjective intensity of the depressed emotional state as measured on the visual analogue scale and the increase in power of the evoked potentials in the depressed condition compared to the prehypnotic baseline condition. There was a small ( $r = +0.35$ ) nonsignificant positive correlation between the subjective intensity of fear and the increase in power of the evoked potentials in this emotional state compared with baseline. No correlations between the increase in evoked potentials and the condition of happiness ( $r = +0.05$ ) and the condition of anger ( $r = -0.07$ ) could be detected. ... There was a positive correlation between the subjective intensity of happiness and anger ( $r = +0.70$ ,  $p < 0.02$ ). A positive correlation ( $r = +0.56$ ,  $p < 0.05$ ) between the intensity of happiness and the intensity of depression was found. No other correlations between intensity ratings reached significance level" (p. 134).

In their Discussion, the authors present the possibility that the differences in evoked potentials observed between different emotional states might be due to differences in attention/distraction, or differences in arousal/inhibition. They reject the attention/distraction hypothesis because evoked potentials increase more in the depression state than in the anger state, though anger was more intense than depression.

"There are, however, several findings that point toward support for a hypothesis that specific affects, and not attention in itself, may account for the opposite changes in evoked potentials. ... Subjects rated fear as even more intense (87.5%) than anger, but with no similar effects on evoked potentials. ... We also found a significant positive correlation between increase in evoked potentials and intensity of experienced depression; a finding opposite of what could be expected from an attention/distraction hypothesis.

"A simple attention/distraction hypothesis, therefore, cannot explain the opposite directions of evoked potentials in the two emotional states. ...

"The differences in pain evoked potentials therefore could be hypothesized to be more related to mechanisms of arousal and inhibition than attention in itself. ...

"Modulation of pain evoked potentials is most likely not due to the state of hypnosis in itself, but to the specific suggestions given under hypnosis, which may be the reason that previous studies of hypnotic modulation of event-related potentials have

been inconsistent.... One must be careful not to assume a direct relationship between pain and evoked potentials. ...

"Based on earlier findings (6-10) one could have hypothesized that an increase in pain perception would be found during the condition of hypnotically induced fear. However our results did not show any significant difference in pain evoked potentials when the emotion of fear was induced. This may be due to the fact that the fear or anxiety did not relate to the painful stimulus in itself, but involved an earlier experienced anxiety or a phobic fear (i.e., of snakes or flying). ...

"Although the state of hypnosis itself does not seem to affect sensory pain perception, the hypnotic state might facilitate the effect of specific suggestions given under hypnosis by affecting cognitive processing. Chapman (44) has suggested that hypnotic analgesia is due to the control of the figure-ground transitions associated with the experience of pain. Likewise, different emotional states may affect figure-ground transitions differently. Whereas outwardly directed anger might prevent inner sensations of pain from emerging as figure, the emotion of depression and helplessness might force the surroundings in the background, letting inner sensations emerge as figure" (pp. 136- 137).

**1990**

Martin, Maryanne (1990). On the induction of mood. Clinical Psychology Review, **10**, 669-697.

#### **NOTES**

Increasing interest in the relation between emotion and cognition has led to the development of a range of laboratory methods for inducing temporary mood states. Sixteen such techniques are reviewed and compared on a range of factors including success rate, the possibility of demand effects, the intensity of the induced mood, and the range of different moods that can be induced. Three different cognitive models (self- schema theory, semantic network theory, and fragmentation theory) which have been successfully used to describe long-term mood states, such as clinical depression, are elaborated to describe the process of temporary mood induction. Finally, the use of mood induction is contrasted with alternative methods (such as the study of patients suffering from depression) for investigating emotion.

**1989**

Friswell, Rena; McConkey, Kevin M. (1989). Hypnotically induced mood. Cognition and Emotion, **3** (1), 1-26.

This article addresses theoretical and methodological issues that are central to an understanding of hypnotically induced mood. Initially, the hypnotic procedures that are typically used to induce moods are examined. Then the empirical research that has employed hypnotic moods is reviewed; specifically, the impact of hypnotic moods on physiological responses, behavioural performance, perceptual and cognitive responses, and personality, and clinical processes is examined. Finally, major theoretical and methodological issues are highlighted, and the research directions that will lead to a greater understanding of hypnotic mood are specified.

Samsom, Deborah; Rachman, S. (1989). The effect of induced mood on fear reduction. British Journal of Clinical Psychology, 28 (3), 227-238.

Investigated the effect on fear reduction in a laboratory study of fearful people. A musical mood-induction technique was utilized to induce either a happy mood or a sad mood in 84 female undergraduates who were fearful of spiders or snakes. Following the mood induction, Ss' fears were reduced by participant modeling. Measures of subjective fear and self-efficacy were taken before and after mood induction, after modeling, and 4 weeks later. Compared to the induced sad-mood condition, induced happiness was followed by a decrease in subjective fear and greater self-efficacy. No difference was found in the length of time taken to reduce fear for happy and sad Ss. Fear reduction during a sad mood was associated with greater return of fear than fear reduction during a happy mood.

1988

Robins, Clive J. (1988). Development of experimental mood induction procedures for testing personality-event interaction models of depression. Journal of Clinical Psychology, 44 (6), 958-963.

Developed 2 mood induction procedures for use in testing personality- event interaction hypotheses with regard to the onset of depressed mood of clinical depression. In these inductions, Ss listened to audiotapes depicting either a series of social rejections or achievement failures and were instructed to imagine themselves as the main character. Both tapes were found to produce a strong increase in reported depressed affect in 119 normal undergraduates. These effects were large in comparison to those elicited by commonly used mood induction procedures. Women reported greater mood shifts than men in response to both tapes. It is concluded that the present procedures have the advantage of content specificity, which permits test of personality-event interaction hypotheses.

1987

Weiss, F.; Blum, G. S.; Gleberman, L. (1987). Anatomically based measurement of facial expressions in simulated versus hypnotically induced affect. Motivation and Emotion, 11, 67-81.

NOTES

Cited by Bryant R. A. & McConkey, K. M. (1989) Hypnotic emotions and physical sensations: A real-simulating analysis, IJCEH, 37, 305-319, who state, 'Finally, future research could usefully focus on aspects of experiencing emotions that are not obvious to simulators. Recent research by Weiss et al. (1987), for instance, that focused on the onset latency and the fluctuation of muscular contraction associated with facial expression indicated a difference between posthypnotically cued and simulated emotions of anxiety and pleasure, and this points to the potential value of investigating specific aspects of emotional experience. Thus, future investigations of real and simulated emotions and physical sensations could usefully employ more

subtle and unobtrusive measures of the specific emotional responses of subjects" (p. 316).

1986

Madigan, R. J.; Bollenbach, A. K. (1986). The effects of induced mood on irrational thoughts and views of the world. Cognitive Therapy and Research, 10 (5), 547-562.

Sixty college students participated in an experiment concerning the influence of somatic mood induction statements on measurements of irrationality as defined by Ellis. Subjects were randomly assigned to depression, elation, and neutral mood induction groups. There were significant differences between groups on mood and irrationality. Results are discussed in terms of the Ellis and Beck cognitive models of depression, the Isen cognitive loop model, and the relationship between irrationality and depression. This study added irrational thinking as defined by Ellis to the growing list of cognitions that have been manipulated by mood, and it supports a body of findings that demonstrate the reciprocal influence of cognition and mood in depression. The study also has implications for the Beck and Ellis hypothesis that cognitions are the dominant causes of depression.

1985

Lundy, R. M.; Geselowitz, L.; Shertzer, C. L. (1985). Role-played and hypnotically induced simulation of psychopathology on the MMPI: A partial replication. International Journal of Clinical and Experimental Hypnosis, 33 (4), 302-309.

In Wilcox and Dawson (1977) hypnotized Ss who were simulating paranoia while taking the MMPI (Dahlstrom & Welsh, 1960) were not detected as simulators by 2 MMPI validity measures, the F scale and the Gough F minus K index (Gough, 1950). The present study found that hypnotized Ss were detected by the same measures, thus failing to replicate Wilcox and Dawson (1977). Hypnotized Ss in the present study, however, were different from a comparison group in not appearing to overplay psychopathology to the same degree.

1984

Stava, L. (1984). The use of hypnotic uncovering techniques in the treatment of pedophilia: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32 (4), 350-355.

This case study describes the use of the hypnotic uncovering techniques of induced dreams (Sacerdote, 1967) and the affect bridge (Watkins, 1971) in reducing inappropriate sexual arousal in a male pedophile. Treatment effects were examined through the use of both psychophysiological measures of penile tumescence and psychological tests. The hypnotherapeutic treatment regime consisted of 25 sessions over approximately 9 months. At the end of treatment, psychophysiological measures revealed a definite reduction of sexual excitation to slides of prepubescent children. Psychological testing indicated reduced defensiveness as well as reduced sexual anxiety to adult women. Various hypnotherapeutic experiences which may have contributed to the treatment effects are discussed.

**NOTES**

**Technical Memorandum 23-74 (October 1974), US Army Human Engineering Laboratory, Aberdeen Proving Ground, Maryland 21005, AMCMS Code 5910.21.68629, Contract No. DAAD05-73-C-0243, Dunlap and Associates, Inc. (now Stamford, CT), AD002557.**

**Sixty college men, divided into three equal groups, each attended two induced stress sessions in which their physiological, psychological and performance reactions were measured. Their responses were compared to determine if valid stress reactions could be induced through suggestion in an altered state (in this case, hypnosis), and also to determine the validity of such reactions if the subject had never before experienced that stress situation. It was demonstrated that valid stress reactions can be induced in an individual with the aid of suggestions, especially if the real stress situation has been experienced before. If no previous experience with that real situation exists, the subject still exhibits stressful reactions; however, the closest resemblance to real stress is found in the subjective or psychological measures, less similarity is found in the physiological measures, and the least similarity is found in the performance measures.**

1962

Das, J. P. (1962). Learning under conditions of hypnotically induced anxiety and nonanxiety. International Journal of Clinical and Experimental Hypnosis, 10 (3), 163-168.

The hypothesis that anxiety may serve as a drive in learning situations was tested. Easy and difficult lists of trisyllabic nonsense syllables were learned by 6 somnambulistic Ss under conditions of hypnotically induced high and low anxiety. Level of hypnotically induced anxiety was not found to affect either recall scores nor number of trials to criterion. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

#### NOTES

Healthy and psychosomatic patients participated in a series of experiments in which reactions were elicited by discussion of emotionally charged issues (discovered through interview and psychological tests) in hypnosis and in waking conditions. The experiments concerned the following:

1. The influence of emotions induced by hypnotic suggestions upon gastric secretion.
2. The influence of emotions induced by hypnotic suggestions upon gastric motility.
3. The influence of emotions induced by hypnotic suggestions upon colonic motility.
4. The influence of hyperventilation induced by emotional stress upon gastrointestinal function.
5. The influence of emotions induced by hypnotic suggestion upon the antibacterial activity of human blood.

In the fifth investigation, Colonies of E. Coli cultured in whole blood before and after a suggestion of fear were reduced in diameter following the suggestion; the same tendency was found in Staphylococcus Aureus. Albumin decreased and globulin increased after the suggestion of fear. The authors interpret this as antibacterial activity of human blood that is part of an "Alarm Reaction" of emotional stress.

1954

Kesner, Lawrence S. (1954). A comparison of the effectiveness of two psychotherapeutic techniques in the resolution of a post-hypnotic conflict. Journal of Clinical and Experimental Hypnosis, 2, 55-75. (Abstracted in Psychological Abstracts, 54: 7601)

#### NOTES

The author developed two experimental psychotherapies, based on Rogerian

(emotion-focused) and psychoanalytic (emotional reaction + factual data) principles, and investigated their effectiveness in resolving hypnosis-induced psychological conflict. The experimental design was:

"1. The subject was given a posthypnotic suggestion of an embarrassing situation of deriding a friend who later proved to have overheard the conversation, putting the subject in conflict. The situation was recalled intellectually and affectively upon awakening.

2. Upon awakening from hypnosis the subject was given a word association test consisting of 30 words related to the posthypnotic conflict and 30 neutral words. The words were presented alternately in groups of five Non-charged words and five Charged words.

3. One of the two therapy techniques was applied for a single session. The length of therapy was determined by the subject's desire. That is, the subject indicated that he had solved the conflict or that he did not wish to discuss it further after an attempt was made to handle the resistance.

It may be noted that in the present experiment both therapy techniques required a similar amount of time. The experimental therapy sessions ranged from nine to 30 minutes. A fairly typical session required about 20 minutes.

4. The word association list was repeated.

5. The subject was rehypnotized. He was told that the conflict was not real and no longer troubled him. Then amnesia was suggested for the conflict situation and the previous therapy session.

6. The word association list was administered again.

7. Steps one through four were repeated except that the alternate therapy technique was used after the second induction of the conflict.

8. To insure the subject's peace of mind, rather than for experimental purposes, after conclusion of the experiment the subject was rehypnotized, the fictional nature of the conflict was explained, and the residuals of the conflict were removed" (pp. 72-73).

Subjects averaged 23.6 years in age (range 17-42) and were screened from approximately 1,000 people. Psychological conflict was inferred from a significant difference in reaction time between Charged and Non-charged words.

"The Emotional therapy technique resolved the experimental conflict for more than three times as many subjects as did the Factual therapy technique" [but] "neither technique resolved the experimental conflict" [although] "both techniques caused some degree of resolution" (p. 74).

## INDUCTION

1994

Barabasz, Arreed F.; Barabasz, Marianne (1994, October). EEG responses to a reading comprehension task during active alert hypnosis and waking states. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

## NOTES

Evoked potentials differ between High & Low hypnotizables during hypnosis but not during waking (Barabasz & Lonsdale, 1983; Spiegel et al, 1985; Spiegel & Barabasz, 1988). Showed critical importance of instructions. We may not be aware of the suggestions that subjects are giving themselves. Or experimental cues may lead to de facto instructions.

Freeman, M. Barabasz & I found differences in high theta during cold pressor pain (reported elsewhere in this conference).

Active alert hypnosis improves attentional processing in military pilots (Barabasz, 1985, *Journal of Aviation, Space & Environmental Medicine*). INAP = Instantaneous Neuronal Activation Procedure. To enhance responsiveness to cockpit cues. Didn't have way of doing in flight measures of hypnosis. INAP was used clinically with airline pilots (Rhue, Lynn, & Kurtz *Handbook on Clinical Hypnosis*)

Active alert focused attention hypnosis increases frontal EEG topographic energy and frequency shifts (increased beta) in highly hypnotizable normal and attention deficit disordered children (Barabasz, Crawford & Barabasz, 1993; in press). No significant changes are found with low hypnotizables (Barabasz & Barabasz, 1993). But sample was small.

Can alert focused attention hypnosis alter EEG topography and attentional processing in subjects of average hypnotizability?

MRI type mapping shows that attention deficit kids don't have normal patterns.

Subjects: all 11 Ss (female) who volunteered for a vitamin B-6 depletion study, with EEG evaluation, also volunteered for hypnosis testing for a \$5.00 payment (SHCS score range 2-3).

Used active alert procedure during reading comprehension task, disguised as normal reading procedure. Counterbalanced waking, attentional instructions and alert focused attention hypnosis conditions were imbedded in standard EEG situation.

Nelson Denny H.S. Reading Comprehension Test. "Focus your attention to read faster than normal, paying attention to what you read."

Used an eye roll induction, and looked for signs of entering hypnosis before they roll their eyes down; were able to cut no. of sessions in neurofeedback training by 50% by using these instructions. To come out next year in Rhue and Lynn.

Reading rate and comprehension increased in alert hypnosis (and words per minute also in attentional instructions). Neurobehavioral feedback for ADD is to decrease theta and increase beta and it ordinarily takes 60 sessions; 40-80 sessions without hypnosis, 15-25 with hypnosis. Eye roll induction cuts that. (See Barabasz & Barabasz, 1996. Chapter in Lynn, Kirsch, & Rhue, "Casebook of Clinical Hypnosis." Washington, DC.: APA Press.)

1993

Bertrand, Lorne D.; Stam, Henderikus J.; Radtke, Lorraine (1993). The Carleton Skills Training Package for modifying hypnotic susceptibility--a replication and extension: A brief communication. International Journal of Clinical and Experimental Hypnosis, 41, 6-14.

This study employed the Carleton Skills Training Package (CSTP) to attempt to enhance both objective and subjective components of hypnotic susceptibility. In addition, changes in susceptibility were compared for subjects administered a standard hypnotic induction procedure and for subjects given brief "place yourself in hypnosis" instructions. Results indicated that subjects who were administered the CSTP exhibited significant gains in both objective and subjective susceptibility scores that were maintained at two separate posttests with different scales. No differences were observed between the groups administered the standard induction and those administered the self-induction instructions. NOTES 1:

#### NOTES

The authors do not make much of the latter finding, but I find it to be the more interesting outcome.

"Two experiments (Barber & Calverley, 1969; Stam & Fraser, 1986) found that subjects who sat quietly for 5 minutes following an instruction to "place yourself in hypnosis" attained similar scores when responding to test suggestions as did subjects who were administered a 5-minute hypnotic induction procedure. The CSTP informs subjects that hypnotic induction procedures do not achieve their effects by inducing a trance state and that such procedures function to produce relaxation rather than to enhance responsiveness to suggestion. In addition, the CSTP emphasizes to subjects that responses to suggestions do not 'just happen' but must be actively generated. To the extent that subjects attend to these aspects of the CSTP procedure, they should exhibit equivalent increments on behavioral and subjective indexes of susceptibility regardless of whether they are administered a formal hypnotic induction procedure or simply told to 'place themselves into hypnosis.'" (p. 7).

"That naive subjects can produce equivalent objective, subjective, and involuntariness scores following such instructions highlights the degree to which hypnotic responses are not dependent on formal induction procedures. The fact that so-called active-alert induction procedures are also equivalent in producing hypnotic responses supports this notion (Banyai & Hilgard, 1976)" (p. 13).

De Pascalis, Vilfredo (1993). EEG spectral analysis during hypnotic induction, hypnotic dream and age regression. International Journal of Psychophysiology, 15, 153-166.

EEG was recorded monopolarly at frontal (F3, F4), central (C3, C4) and posterior (in the middle of O1-P3-T5 and O2-P4-T6 triangles) derivations during the hypnotic induction of the Stanford Hypnotic Clinical Scale (SHCS) and during performance following suggestions of hypnotic dream and age-regression as expressed in the before-mentioned scale. 10 low-hypnotizable and 9 highly-hypnotizable and right-handed female students participated in one experimental session. Evaluations were Fast-Fourier spectral analyses during the following conditions: waking-rest in eyes-open and eyes-closed condition; early, middle, and late phases of hypnotic induction; rest-hypnosis in eyes closed condition; hypnotic dream and age regression. After spectral analysis of 0 to 44 Hz, the mean spectral amplitude

estimates across seven Hz bands (theta 1, 4-6 Hz, theta 2, 6-8 Hz; alpha 1, 8-10 Hz; alpha 2, 10-13 Hz; beta 1, 13-16 Hz; beta 2, 16-20 Hz; beta 3, 20-36 Hz) and the 40-Hz EEG band (36-44 Hz) for each experimental condition were extracted. In eyes-open and -closed conditions in waking and hypnosis highly-hypnotizable subjects produced a greater 40-Hz EEG amplitude than did low hypnotizable subjects at all frontal, central and posterior locations. In the early and middle hypnotic induction highly-hypnotizables displayed a greater amount of beta 3 than did low hypnotizables and this difference was even more pronounced in the left hemisphere. With posterior scalp recordings, during hypnotic dream and age regression, high hypnotizables displayed, as compared with the rest-hypnosis condition, a decrease in alpha 1 and alpha 2 amplitudes. This effect was absent for low hypnotizables. Beta 1, beta 2 and beta 3 amplitudes increased in the left hemisphere during age regression for high hypnotizable; low hypnotizables, in contrast, displayed hemispheric balance across imaginative tasks. High hypnotizables during the hypnotic dream also displayed in the right hemisphere a greater 40-Hz EEG amplitude as compared with the left hemisphere. This difference was even more evident for posterior recording sites. This hemispheric trend was not evidenced for low hypnotizable subjects. Theta power was never a predictor of hypnotic susceptibility, 40-Hz EEG amplitude displayed a very high main effect ( $p < 0.004$ ) for hypnotizability in hypnotic conditions by displaying a greater 40-Hz EEG amplitude in high hypnotizables with respect to lows. NOTES 1:

#### NOTES

In the Discussion section, the authors indicate that they have no idea why they didn't replicate results of other theta studies, including their own, except maybe due to complex interaction among personality, subject selection, situation-specific factors, and hypnotizability.

They observe that the alpha results conform with previous findings (p. 163). Beta bands were sensitive. Highs showed left-hemisphere prevalence in all beta bands during age regression; they also showed hemispheric balance in the hypnotic dream condition. Beta 3 amplitude was also greater among highs than lows. "among high hypnotizables, beta 3 amplitude in the early hypnotic condition was greater in the left hemisphere as compared to the right and as the hypnotic induction proceeded hemisphere balancing, with reduced beta 3 amplitude, was displayed. This result appears in agreement with the predictions of the neurophysiological model proposed by Gruzelier et al. (1984) and Gruzelier (1988) as well as with other studies in which beta rhythm was found to discriminate performances between high and low hypnotizables (e.g., Meszaros et al., 1986, 1989; Sabourin et al., 1990)" (p. 163-164). 40 Hz amplitude was higher in highs and increased in right hemisphere during the hypnotic dream, especially in posterior areas. "This pattern of hemispheric activation may be interpreted as an expression of the greater right-hemisphere activation and of the release of posterior cortical functions during the hypnotic dream and is compatible with the predictions of the Gruzelier model of hypnosis, however, the results obtained in this study for 40-Hz EEG amplitude failed to reveal an inhibition of the left-hemisphere activity with the progress of the hypnotic induction" (p. 164).

(They note that De Pascalis & Penna, 1990, agreed with the Gruzelier 1988 model: highs in early induction had increase of 40-Hz in both hemispheres, but as induction proceeded they had inhibition of left and increase in right hemisphere activity. In this current experiment, only beta 3 showed the hemispheric trend of Gruzelier's model. They cite other details of current study, p. 164, not consonant with Gruzelier.)

"The 40-Hz EEG rhythm, which according to Sheer (1976) is the physiological representation of focused arousal, appeared to discriminate between differential patterns of high and low hypnotizables. Both during hypnotic induction and during hypnotic dream and age regression highly hypnotizables exhibit greater 40-Hz EEG amplitude with respect to the lows. These findings support the validity of the assumption that hypnosis is characterized by a state of focused attention (Hilgard, 1965) and that 40-Hz EEG activity reflects differential attentional patterns among subjects high and low in hypnotizability. On the basis of these findings it would appear that 40-Hz EEG and beta 3 spectral amplitudes may prove to be useful measures of individual hypnotizability" (p. 164).

Lynn, Steven Jay; Neufeld, Victor; Mare, Cornelia (1993). Direct versus indirect suggestions: A conceptual and methodological review. International Journal of Clinical and Experimental Hypnosis, 31, 124-152.

The article reviews the literature on the effects of direct versus indirect hypnotic suggestions. A conceptual and methodological analysis of direct versus indirect suggestions is also provided. Three conclusions follow from the review: (a) Contrary to views of Ericksonian hypnotists, suggestion style has little effect on objective responding to hypnotic test items; (b) studies of clinical- and laboratory-induced pain and other measures of subjective experience have yielded contradictory results- -however, the best controlled studies have not indicated that indirect suggestions are superior to direct suggestions; and (c) there is insufficient evidence to conclude that hypnotizability level and suggestion wording interact, such that low hypnotizable subjects are particularly responsive to indirect suggestions. Methodological and conceptual problems in defining and studying hypnotic communications, the lack of rigorous experimental controls, and research issues and directions are highlighted.

NOTES

1:

NOTES

Although this article is primarily concerned with the nature of suggestion, the review also mentions several studies comparing hypnosis with other interventions for pain, in passing:

Crowley (1980)

Snow (1979)

Omer, Darnel, Silberman, Shuval, & Palti (1988)

Stern (1982)

Bassman (1983)

"Like the clinical studies using the RIA [Rapid Induction Analgesia], pain studies that did not use the RIA lack appropriate control groups: Neither Bassman's (1983) nor Stern's (1982) research explicitly compared direct and indirect suggestions.

What our review does suggest is that studies (e.g., Crowley, 1980; Snow, 1979; Van Gorp et al., 1985) that imposed the greatest degree of methodological control yielded the outcomes least favorable to the hypothesis that indirect suggestions are effective and account for the pain relief achieved, above and beyond factors common to placebo treatments" (p. 132).

"Lynn and his colleagues' studies indicate that whereas indirect suggestions enhance archaic representations of the hypnotist, direct suggestions facilitate involvement in the events of hypnosis, as measured by subjective involvement and involuntariness" (p. 136).

1992

Kirsch, Irving; Mobayed, C. P.; Council, J. R.; Kenny, D. A. (1992). Expert judgments of hypnosis from subjective state reports. Journal of Abnormal Psychology, 101, 657-662.

Suggestibility was assessed in 60 student subjects after a traditional hypnotic induction, an alert induction, progressive relaxation training, or instruction in goal-directed imagery. Responsiveness to suggestion did not differ between groups. Subjects also generated open-ended reports of their states of awareness and of their experience of three hypnotic suggestions. A sample of these reports from 24 moderately to highly suggestible subjects was evaluated by 18 experts in the field of hypnosis. Expert ratings of subjects' open-ended reports indicated that (a) traditional hypnotic inductions produce a state of consciousness that is indistinguishable from nonhypnotic relaxation training, (b) the subjective experience of hypnotic suggestions after imagination training is indistinguishable from that after hypnotic inductions, and (c) suggestibility is unrelated to state of consciousness as assessed by experts.

Lewis, D. O. (1992). Hypnoanalgesia for chronic pain: The response to multiple inductions at one session and to separate single inductions. Journal of the Royal Society of Medicine, 85, 620-624.

Serial hypnotic inductions conveying the same analgesic message produce a progressively longer response in an increasing number of patients. The resulting analgesia appears to be independent of the spacing of inductions--whether given at a single session or on separate occasions--and to depend upon their number. However, multiple inductions at a single session save time. Elimination of pain can be achieved, by either approach, for a year or more in up to 70% of patients.

1991

Miller, Mary Frances; Barabasz, Arreed F.; Barabasz, Marianne (1991). Effects of active alert and relaxation hypnotic inductions on cold pressor pain. Journal of Abnormal Psychology, 100 (2), 223-226.

Contrasted relaxation and active alert hypnotic inductions with or without a specific suggestion for cold pressor pain analgesia. Groups of high (n = 38) and low (n = 27)

hypnotizability subjects were tested; hypnotizability had been determined from results of the Stanford Hypnotic Susceptibility Scale, Form C. Cold pressor pain data were obtained after counterbalanced exposure to relaxation and active alert inductions. Highly hypnotizable subjects demonstrated lower pain scores than did low hypnotizability ones. Pain reports did not differ between induction conditions. Highly hypnotizable subjects given an analgesic suggestion showed lower pain scores than did those exposed only to hypnosis. The findings, conceptualized within E. R. Hilgard's (1977a) neodissociation theory, show that relaxation is not necessary for hypnotic analgesia. NOTES 1:

NOTES: The relaxation induction was the SHSS, Form B. The active alert induction used the same instructions except suggestions for alertness, invigoration, and freshness were substituted for drowsiness and relaxation. During the active alert induction, the subjects rode a bicycle ergometer at a constant load of 1-3 kg and a constant rate of 1-2 rotations per s (Banyai & Hilgard, 1976).

1990

Barber, Theodore Xenophon (1990, August). Some things I've learned about hypnosis after 37 years. [Audiotape] Presented at the annual meeting of the American Psychological Association, Boston.

NOTES

We are a unity of cells. Every cell is a citizen with it's own jobs, communicating all the time; cells send messages; the way we communicate with them is by suggestions. Each \_cell\_ is a mind-body.... When I do it now [hypnotic inductions], I say, 'We're going to go into hypnosis, we're \_both\_ going to go into hypnosis. I'm going to close my eyes (etc.)' - modeling hypnosis for them."

Cikurel, Katia; Gruzelier, John (1990). The effect of an active-alert hypnotic induction on lateral asymmetry in haptic processing. British Journal of Experimental and Clinical Hypnosis, 7, 17-25.

In order to elucidate further left hemispherical inhibitory dynamics in response to instructions of hypnosis, bilateral haptic processing times were compared before and during a traditional hypnotic relaxation procedure and an active-alert procedure in which subjects pedaled a bicycle ergometer and instructions on mental alertness were incorporated with hypnosis. Previous evidence suggesting a slowing of left hemispherical processing and a facilitation of right hemispherical processing in susceptible subjects was replicated, and was shown to characterize high rather than medium susceptibles, the latter showing a bilateral slowing of processing. These effects occurred with both induction procedures whose influence on susceptibility was highly correlated. In fact the lateral shift in processing in the direction of left hemispherical inhibition and right hemispherical facilitation was favoured by the active-alert procedure, indicating that neuropsychological changes which occur with hypnosis cannot be discounted as a by-product of relaxation.

1989

Moss, Barry F.; Magaro, Peter A. (1989). Personality types and hetero- versus auto-hypnosis. Journal of Personality and Social Psychology, 57, 532-538.

The Multivariate Personality Inventory (MPI; Magaro & Smith, 1981), the Harvard Group Scale of Hypnotic Susceptibility, and the Inventory of Self-Hypnosis (ISH; Shor, 1970) were used to investigate the relationship between personality style and hypnotic procedure in the determination of hypnotic susceptibility. On the basis of MPI scores, a normal college population was segregated into 5 personality styles: hysteric, manic, depressive, character disorder, and compulsive. The hysteric personality was found significantly more hypnotizable than the other personality types in the HGSHS induction context, whereas the compulsive personality was found significant more hypnotizability in the ISH induction context. Results are discussed in terms of personality and situational factors in relation to previous hypnotic susceptibility research.

1988

Hammond, D. Corydon; Haskins-Bartsch, Catherine; Grant, Claude W.; McGhee, Melanie (1988). Comparison of self-directed and tape-assisted self-hypnosis. American Journal of Clinical Hypnosis, 31, 129-137.

Previous research on self-hypnosis has concentrated on the relationship between heterohypnosis and either self-directed self-hypnosis or self-initiated self-hypnosis. Despite widespread use of audiotapes to assist the process of self-hypnosis, no previous research has compared tape-assisted and self-directed self-hypnosis. Forty-eight inexperienced volunteers were hypnotized and taught self-hypnosis by posthypnotic suggestion and immediate practice in the office. They were randomly assigned to one of two experimental orders to practice self-directed and tape-assisted self-hypnosis. No differences were found between heterohypnosis or either type of self-hypnosis in response to behavioral suggestions. Experiential ratings, however, consistently favored heterohypnosis over either type of self-hypnosis. Tape-assisted self-hypnosis was consistently evaluated as superior to self-directed practice by newly trained subjects. NOTES 1: NOTES: The tapes were more or less identical with the in-office hypnosis, including voice of the hypnotist, except that those doing self-directed self hypnosis received a posthypnotic suggestion for how to enter hypnosis by themselves. (All Subjects received written instructions to remind them about the procedures for home practice.)

When self hypnosis was evaluated, use of a tape produced greater concentration and absorption, less distraction, greater subjective depth, greater perception of nonvoluntary response to suggestion, and more changes in body perception (e.g. loss of awareness of the body, feelings of heaviness or of floating). Therefore, the tape-assisted experience could be viewed as more convincing to the Subjects. People tended to fall asleep more when they did self-directed self hypnosis than when they used a tape. However, people enjoyed heterohypnosis more than either self hypnosis experience, and reported more nonvoluntary experiences. The more positive response to heterohypnosis replicates research by Johnson et al. (1983)., in which

preceding self-hypnosis by a heterohypnosis induction may results in less positive experiences with the self-directed self hypnosis.

In their Discussion, the authors note that finding no differences between self hypnosis and heterohypnosis in the number of behavioral suggestions successfully passed replicates earlier research (Shor & Easton, 1973; Ruch, 1975; Johnson, 1979; Johnson, Dawson, Clark, & Sikorsky, 1983).

"Thus, our present study has replicated previous findings concerning the relationship of heterohypnosis and self-directed self-hypnosis. In clinical practice, it appears that a heterohypnosis experience virtually always precedes training in self-hypnosis. Our findings and those of the Johnson (1983) study suggest, however, that generally patients will experience self-hypnosis as significantly less powerful than their previous office experience. But, by using a tape to assist the patient in initial practice, the discrepancy between the quality of the experiences appears reduced. It should be noted that Johnson et al. (1983) provide the innovative suggestion that there may be something gained by having self-hypnotic instruction and practice precede a hypnotic experience by a therapist. Initial self-hypnotic experience may create a mental set of being more actively involved" (p. 136).

"However, we know nothing about how tape-assisted vs self-directed experiences are perceived by Ss with more self-hypnotic and heterohypnotic experience, and particularly if they are utilizing the same tape recording(s) over and over again. Other research (Hammond, 1987) recently followed up premenstrual syndrome patients who were trained in self-hypnosis. In this study, patients showed a clear preference for using tapes to assist them in self-hypnosis shortly after initial training. However, on 6-month follow-up, patients were found to be utilizing self-directed self-hypnosis much more frequently than tapes, with which they may have become somewhat bored. The issue of boredom has thus far not been adequately addressed in the self-hypnosis literature" (p. 136).

Immelman, Aubrey (1988, November). The effects of three pain management procedures on the experience of cold pressor. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

#### NOTES

This research was motivated by Joseph Barber's (1977) claim of 99% success rates with dental patients. This research had 3 conditions or levels of treatment: direct suggested analgesia; indirect suggested analgesia; and self-generated cognitive strategies. 60 male and female psychology students volunteered for the pain experiment; they were divided into Low Medium High hypnotizable Subjects. The Experimenter was blind to hypnotizability scores and there was random assignment to treatment groups. The Ss were tested three times with cold pressor test, with left hand in ice water, and assessed after each immersion. Order of conditions was: Pretest, 5' Rest, Baseline, Experimental Treatment, Post-test using Hilgard's procedures.

The Direct suggested analgesia condition used a modified Stanford Scale of Hypnotic Susceptibility Form C induction, with suggested analgesia. The Indirect suggested analgesia condition was Barber's Rapid Induction Analgesia script. For

the third condition, Ss listened to a history of the Fast Food Industry and were instructed to 'do whatever you can do to decrease the pain.'

The authors hypothesized that direct suggestion analgesia would be more effective for Highs, and indirect suggestion analgesia would be unaffected by level of hypnotizability.

## RESULTS

ANOVA for repeated measures produced sequential main effects for both pain and distress. 2. By 3 treatment levels: Indirect reduced pain more, though not significantly. (The pretest looks different, with the direct higher, not significantly so however). 3. For High Ss receiving direct suggestion there are similar decreases from baseline to posttest. For Lows receiving indirect suggestion, there were decreased pain ratings, but for those Lows receiving direct suggestion there is no decrease. But these are just trends and not significant.

## SUMMARY

Ratings of pain and distress, irrespective of hypnosis level, decrease from initial to second trial in absence of any intervention. The trends provide limited support for Barber's claims.

Nathanson, Donald L. (1988). Affect, affective resonance and a new theory for hypnosis. Psychopathology, 21, 126-137.

Suggests new theory of hypnosis based on recent experimental and theoretical work on emotion that shows neurological systems (including structural effectors and chemical mediators affecting specific sites of action). Tomkins' nine innate affects are organizers of the other moieties, genetically determined prewritten subcortical programs that convert quantitative stimuli into qualitative experience. Emotion in the adult involves subtle and complex combinations of innate affect with associations to previous experiences of affect provided by neocortical mechanisms. The infant initially expresses affect in an all-or-none fashion, while the caregiver, usually mother, acts as an external modulator of infantile affect display. All the techniques by which the mother learns to achieve affect mutualization and interaffectivity are analogues of what later may be seen as the techniques of hypnotic induction. Hypnosis may be viewed as the intentional alteration of neocortical cognition made possible by the state of primitive interaffectivity achieved when the hypnotic operator enters the central assembly system of the adult by techniques reminiscent of maternal modulation of infantile affect display.

Omer, H.; Darnel, A.; Silberman, N.; Shuval, D.; Palti, T. (1988). The use of hypnotic-relaxation cassettes in a gynecologic-obstetric ward. In Lankton, S. R.; Zeig, J. K. (Ed.), Research, comparisons and medical applications of Ericksonian techniques (pp. 28-36). New York: Brunner-Mazel.

## NOTES

They did three studies in which they gave women having gynecologic procedures tapes with a Rapid Induction Analgesia hypnosis experience.

**STUDY 1.** Women heard tapes before a painful Fallopian tube procedure (salpingography). The patients reported less pain, tension, anxiety, and fear than control patients. (N.B. Physicians' ratings did not show that difference.)

**STUDY 2.** Women practiced with the tapes at home before labor and delivery. One day after delivery, there was no difference in pain report or experience report between treated and control patients.

**STUDY 3.** Women used the tapes during labor. They reported worse pain and labor experiences than the control patients.  
The authors conclude that their research does not support the hypothesis that Rapid Induction Analgesia is useful for acute pain.

**1987**

**Patterson, David R.; Questad, Kent A.; Boltwood, Michael D. (1987).** Hypnotherapy as a treatment for pain in patients with burns: Research and clinical considerations. Journal of Burn Care and Rehabilitation, 8 (3), 263-268.

Hypnotherapy has increasingly been included in the management of burn patients, particularly in the area of acute pain. To better understand such issues as (1) overall efficacy of hypnotherapy to alleviate acute burn pain, (2) instances in which hypnotherapy is contraindicated, (3) interaction of hypnotherapy with medication, (4) standard induction techniques to use with various age groups, (5) role of nursing and other staff in facilitating hypnotic effects, and (6) future methodological directions, they examined the clinical and methodological merits of recent studies of hypnoanalgesia. A literature search found 17 studies in which hypnotherapy was applied to the management of burns. The literature generally supports the efficacy of this approach to reduce burn pain; however, little else can be concluded from these studies. Several recent studies have applied hypnotherapy to aspects of burn care other than pain using excellent experimental designs. It is suggested that future studies of acute pain management follow suit.

**1986**

**Mitchell, George P.; Lundy, Richard M. (1986).** The effects of relaxation and imagery inductions on responses to suggestions. International Journal of Clinical and Experimental Hypnosis, 34, 98-109.

Theoretical attempts to understand the meaning and importance of induction procedures in producing hypnotic phenomena suggest that 2 critical components, relaxation and imagery, should be isolated and their relative effect on hypnotic responding studied. Objectively and subjectively scored responses to 12 hypnotic suggestions, which had followed relaxation, imaginal, or combined inductions, were obtained from 59 Ss, divided into 3 levels of hypnotizability. Regardless of

hypnotizability level, the combined induction led to a greater subjective report of hypnotic response than did either the relaxation or the imagery inductions; and the relaxation led to a greater subjective report than the imagery induction. It may follow that the subjective experience of hypnosis is facilitated by inductions which include relaxation. The inductions were equally effective in producing objectively measured behavioral responses. There were no significant interactions found between induction type and hypnotizability level. NOTES 1:

## NOTES

(From the Discussion Section)

As suggested by Sacerdote (1970), the combination procedure was the most generally effective in producing hypnotic responses. The difference between combined and imagery inductions reached statistical significance on four dependent variables, and the difference between combined and relaxation reached significance on three. It may also be of interest that Ss receiving the combined procedure scored consistently higher on all nine dependent variables.

A somewhat unexpected finding was that the relaxation induction produced scores on four of the dependent variables that were statistically higher than the imagery induction scores. Considering the difficulty of isolating relaxation and imagery components, it is quite noteworthy that these differences between inductions were found.

The four variables in which the combination and relaxation conditions produced significantly higher scores than the imagery condition were subjective reports--subjective score, degree hypnotized, response volition, and Field Inventory. In contrast to Ss in the imagery induction, Ss in the other two induction conditions believed that they were responding more, felt that their responses were more nonvolitional, and felt that they were more deeply hypnotized.

The fact that relaxation instructions were present in both conditions that were superior to the imagery condition would appear to support Edmonston's (1981) position which posits relaxation as essential for the production of the state of neutral hypnosis. For Edmonston the condition of neutral hypnosis is defined as the relaxed state and precedes other phenomena, such as dissociation and increased suggestibility, which other theoreticians may include in the definition of hypnosis.

However, the statistically significant superior effect of the combined over the relaxation induction on three measures casts doubt on Edmonston's position. The S believes that he or she is more deeply hypnotized and is responding less volitionally when an imagery component is combined with relaxation. The Ss also responded more to the Field Inventory when the combined induction was used.

Another explanation for imagery's relatively poor showing may lie in Ss' differential expectations. The Ss, especially those with previous experience with a traditional hypnotic induction, as was the case in the present study, may not expect to be hypnotized when presented with an imagery alone induction. Such expectations, of course, might reduce responses. On the other hand, there is no reason to believe that the reduced expectation in the imagery condition would not affect the behavioral responses as well, and such was not the case.

Thus, we may be left with the explanation that relaxation adds to the subjective experience of hypnosis. This is in keeping with Edmonston's (1981) position as well as with previous research, such as that by Hilgard and Tart (1966), which finds traditional inductions, with their relaxation components, superior to nontraditional inductions, such as fantasy or task-motivational. If future research should find that bodily involvements such as the physical exertion or repetitive motor behavior (Banyai and Hilgard, 1976) lead to the same level of subjective experience as relaxation did, then we may need to broaden the concept of the somatic component beyond relaxation alone.

In terms of the behavioral compliance of Ss, the results of the present study are in accord with some previous studies in finding all procedures equally effective. Neither imagery, relaxation, nor the combined procedure was superior for the behavioral measure.

Personality factors (social desirability, internality/externality, and absorption) did not affect the basic findings. To the degree that the Tellegen scales measure the ability to engage in imagery there seems to be little basis for believing that imagery ability is related to the general findings.

Sarbin (1983) would call the inductions studied here 'entrance rituals,' and he has recently asked in his review of Edmonston's book, "Which ritual is more suitable... [p. 58]' for preparing S to respond in various hypnotic ways? One answer from the present results is that an entrance ritual should include muscular relaxation if one wants a better subjective response from S. From Sarbin's point of view, the relaxation component may be more ego-involving, producing more subjective experience and meaning for S.

If one wants to produce only a behavioral response, either a relaxation or imagery ritual will serve.

1985

Matthews, William J.; Kirsch, Irving; Mosher, Donald (1985). Double hypnotic induction: An initial empirical test. Journal of Abnormal Psychology, 94 (1), 92-95.

#### NOTES

In separate experimental sessions, 34 undergraduate students experienced audiotapes of a standard hypnotic induction and a double induction similar to that described by Bandler and Grinder (1975). In the double induction, subjects heard a hand-levitation induction through the ear that is contralateral to the dominant cerebral hemisphere and, simultaneously, heard grammatically childlike messages through the other ear. Half of the subjects experienced the double induction first. There were no significant within-subject differences between the two inductions. However, subjects who experienced the double induction prior to the standard induction were significantly less responsive to suggestions following both inductions, which suggests that the double induction as a first experience of hypnosis may have a negative impact on subsequent experiences of hypnosis.

**Kirsch, Irving; Council, James R.; Vickery, Anne R. (1984). The role of expectancy in eliciting hypnotic responses as a function of type of induction. Journal of Consulting and Clinical Psychology, 52 (4), 708-709.**

#### **NOTES**

**Combined data from a study by J. R. Council et al (see PA, vol 7:4975) and from a study by the present 3rd author (1983) on cognitive skill hypnotic induction to test the hypothesis that the relationship between expectancy and suggestibility varies as a function of type of induction. Analysis of data on 100 Ss shows significant Expectancy x Type of Induction interactions on the Stanford Hypnotic Susceptibility Scale, the Creative Imagination Scale, and an inventory of hypnotic depth. Within-cells correlations revealed a significant relationship between expectancy and responses to skill induction. Correlations between expectancy and responses to a traditional trance induction were nonsignificant**

**Malott, James M. (1984). Active-alert hypnosis: Replication and extension of previous research. Journal of Abnormal Psychology, 93 (2), 246-249.**

#### **NOTES**

**Compared levels of hypnotic responsiveness resulting from 4 induction procedures: (a) verbal active-alert induction alone, (b) bicycle pedaling alone, (c) verbal active-alert induction plus bicycle pedaling and (d) traditional relaxation induction. Ss were 48 undergraduates. Stanford Hypnotic Susceptibility Scale scores indicated that the verbal induction plus pedaling procedure was significantly more effective than either the verbal- or pedaling-alone procedures. There were no significant differences in scores produced by the verbal plus pedaling and traditional relaxation inductions. Findings are consistent with A. M. Ludwig's (1966) proposal that there exists a range of stimulation necessary for the maintenance of normal waking consciousness and that levels of stimulation above or below that range are conducive to the production of altered states of consciousness.**

**This study adds experimental controls to the research design used by Banyai for active alert induction.**

**Bassman, S. (1983). The effects of indirect hypnosis, relaxation and homework on the primary and secondary psychological symptoms of women with muscle contraction headache (Dissertation). Dissertation Abstracts International, 44, 1950-B.**

#### **NOTES**

**Compared the effects of indirect hypnosis (e.g., metaphors, stories, vague suggestions, and implied directives) on muscle contraction headaches with a relaxation and a no-treatment control condition. Both hypnosis and relaxation conditions reduced symptoms more than did the no-treatment condition. Unlike relaxation, indirect hypnosis did not reduce the intensity and duration of headaches, although it did reduce the amount of medication and also benefitted sleep.**

Council, James R.; Kirsch, Irving; Vickery, Anne R.; Carlson, Dawn (1983). 'Trance' versus 'skill' hypnotic inductions: The effects of credibility, expectancy, and experimenter modeling. Journal of Consulting and Clinical Psychology, 31 (3), 432-440.

A hypnotic induction procedure based on social learning principles (skill induction) was compared with a traditional eye-fixation/relaxation trance induction, a highly credible placebo induction, and a no-induction base-rate control. The trance induction surpassed the skill induction only on the Field Inventory, a measure of hypnotic depth that contains items corresponding to suggestions contained in the trance induction. Experimenter modeling was not found to enhance the effectiveness of the skill induction. Skill and trance inductions elicited slightly higher behavioral scores on the Stanford Hypnotic Susceptibility Scale: Form C than did the placebo induction. However, this difference was not obtained on other measures of hypnotic responsibility and depth. Significant correlations were found between expectancy, absorption, and responsiveness on all dependent measures. Multiple regression analyses indicated that the relationship between absorption and responsivity was mediated by expectancy. The results are interpreted as supporting the hypotheses that hypnotic responses are elicited by the expectancy for their occurrence and that induction procedures are a means of increasing subjects' expectancies for hypnotic responses.

#### NOTES

Trance induction resulted in a higher score on subjective experiences (cognitive & perceptual distortions) but not higher suggestibility scores than cognitive-behavioral skill induction. 2) Trance and cognitive-behavioral inductions got slightly higher scores in suggestibility than placebo biofeedback induction. 3) All inductions did better than a "no induction" control group on subjective and behavioral indices of hypnosis.

One of the goals of this research was to examine the contribution of experimenter modeling to the behavioral skill induction that "trains the subject in hypnosis skills and requires the subject's conscious cooperation in learning cognitive strategies that will enhance hypnotic responsivity" (p. 432). Another goal was to assess the contribution of "a subject's expectancies for the occurrence of behaviors perceived as being involuntary" (p. 433). A third goal was to determine whether congruence between a subject's beliefs about hypnosis and the rationale for a particular induction would increase expectancy. Two different skill inductions were employed (one with, one without a model). Subjects were asked to predict their performance, based on a description of the induction that they would receive. The contributions of credibility and expectancy were assessed using a highly credible placebo (pseudo biofeedback of EEG theta rhythm).

The investigation used only subjects who had never experienced hypnosis.

Independent variables included Rotter's (1966) Internal-External Locus of Control Scale, Rotter's (1967) Interpersonal Trust Scale, and Tellegen's Absorption Scale (Tellegen & Atkinson, 1974). Mediating variables included a measure of induction

credibility based on Borkovec and Nau (1972), and a 20-item inventory measuring expectancies for hypnotic performance. Dependent variables included 20 standard hypnotic suggestions taken from the Stanford Hypnotic Susceptibility Scale, Form C; the Creative Imagination Scale; ratings of the 'realness' or experienced intensity of each suggestion; and the Field Inventory of Hypnotic Depth (Field, 1965).

The authors conclusion reads as follows: "The results of this study may be summarized as follows: (a) Traditional trance hypnotic inductions and cognitive-behavioral skill inductions were shown to be equally effective in eliciting experiential and behavioral responses to hypnotic suggestions, although trance subjects reported a somewhat greater alteration in conscious experience. (b) Experimenter modeling was not found to be an effective component of the skill induction package. (c) Subjects' expectancies for hypnotic responses, reported prior to hypnotic induction, bore a very strong relationship to hypnotic responsiveness. (d) A highly credible placebo induction resulted in levels of expectancy and hypnotic responsiveness generally comparable to those produced by trance and skill hypnotic inductions. (e) Absorption was significantly correlated with expectancy, but was not found to be significantly related to responsiveness once variance due to expectancy was taken into account. Thus the relationship between absorption and hypnotic responsiveness appears to be mediated by expectancies.

"In sum, these results suggest that various hypnotic inductions elicit expectancies for responding to hypnotic suggestions and that these expectancies are sufficient to elicit hypnotic responses. Further studies are needed to determine the nature of the relationship between absorption and hypnotic response expectancies" (p. 439).

**Diamond, Michael Jay (1980). The client-as-hypnotist: Furthering hypnotherapeutic change. International Journal of Clinical and Experimental Hypnosis, 28, 197-207.**

A novel hypnotic induction technique is described wherein the client reverses roles and serves as hypnotist for the therapist. Relevant theoretical processes are discussed as are mutual hypnosis, modeling, and the uncommon techniques of Erickson (1964). 3 case illustrations are presented and implications discussed. It is hypothesized that the 'client-as-hypnotist' may in certain special situations further hypnotherapy by: (a) increasing client motivation; (b) enhancing therapeutic rapport; (c) increasing both client trust and skills in utilizing unconscious processes; (d) overcoming resistance and increasing hypnotizability; (e) providing a useful psychodiagnostic and behavior assessment index; (f) presenting a role 'model' for dealing with feelings, alterations in consciousness, and self-control; (g) providing a client-centered framework for subsequent therapeutic interventions; (h) increasing client self-esteem, mastery, and ego strength; and (i) increasing client self-control skills. Potential risks and contraindications for use of the technique are also discussed.

**Edwards, William Henry (1980). Direct versus indirect hypnosis for the relief of chronic pain in spinal cord injured patients (Dissertation, United States International University). Dissertation Abstracts International, 40 (10-B), 4996.**

## NOTES

This study compared effectiveness of direct hypnosis and indirect hypnosis (Rapid Induction Analgesia, developed by Joseph Barber) in reducing experimental and clinical pain in spinal cord injured patients. The 30 male paraplegic patients who had chronic benign pain volunteered for the study. They were administered three tests: the Pain Estimate Scale (Sternbach, 1974), Ischemic Muscle Pain Test (IMPT), and the Stanford Profile Hypnotic Susceptibility Scale, Form II -- SPHSS -- (Weitzenhoffer and Hilgard, 1967). Each patient experienced three sessions: (1) Baseline Control, (2) Direct Hypnosis, and (3) Indirect Hypnosis. Patients were randomly assigned to Sessions (2) and (3). The results indicated no significant statistical difference in the effectiveness of direct versus indirect hypnotic analgesia in these chronic pain patients. Direct and indirect hypnosis were equally effective; hypnotizability was not associated with outcome. Furthermore, there was no interaction between treatment effects and pretreatment pain level. The results were similar for both clinical and experimental pain.

Hart, R. (1980). The influence of a taped hypnotic induction treatment procedure on the recovery of surgery patients. International Journal of Clinical and Experimental Hypnosis, 28, 324-331.

A study of 40 open heart surgery patients assigned to 1 of 2 equal size treatment groups sought to evaluate the efficacy and utility of a tape-recorded hypnotic induction procedure that preoperatively prepared patients for surgery. The dependent variables included daily blood pressure measurements and postsurgical outcome data pertaining to postoperative units of blood required, state/trait anxiety, and locus of control dimensions. Results of the study tended to provide some support for the tape-recorded hypnotic induction procedure in lessening state anxiety and in promoting a more self- directed attitude toward surgical recovery.

1977

Barber, Joseph (1977). Rapid induction analgesia: A clinical report. American Journal of Clinical Hypnosis, 19, 138-149.

This is a report of clinical dental experience using a newly developed, hypnotic pain control procedure. Characteristics of the procedure are outlined, an explanation for its success is suggested, and the broader implications of this success are discussed. The unusually high incidence of clinical analgesia rapidly obtained with this procedure leads the author to question the meaning and relevance of the concept of 'hypnotic susceptibility' for the practical clinical application of hypnosis.

Buckner, Linda G.; Coe, William C. (1977). Imaginative skill, wording of suggestions and 3 groups of 20 s based on preselected imaginative capacity were administered either a hypnotic susceptibility scale containing item wording that suggested a goal-directed fantasy or one that did not. Preselected imaginative ability did not predict hypnotic susceptibility or the production of goal-directed fantasies during hypnosis. However, Ss who received the hypnotic scale containing item

wording that suggested goal-directed fantasies reported more goal-directed fantasies than Ss who received the other scale. Limitations of the study are discussed and the causal role of goal-directed fantasy in hypnotic responsiveness is questioned.

**1976**

Erickson, Milton H.; Rossi, Ernest L. (1976). Two level communication and microdynamics of trance and suggestion. American Journal of Clinical Hypnosis, **18**, 153-171.

The authors provide the transcript and commentaries of an hypnotic induction and an effort to achieve automatic writing. An unusual blend of Erickson's approaches to two level communication, dissociation, voice dynamics and indirect suggestion are made explicit in the commentaries. The junior author offers a 'context theory of two level communication' that conceptualizes Erickson's clinical approaches in terms consonant with Jenkins' (1974) recent contextual approach to verbal associations and memory. A summary of the microdynamics of Erickson's approach to trance induction and suggestion is outlined together with a utilization theory of hypnotic suggestion.

Jenkins, J. J. (1974). Remember that old theory of memory? Well, forget it! American Psychologist, **29**, 785-795.

Jackson, T. L.; Barkley, R. A.; Pashko, S. M. (1976). The effects of hypnotic induction versus high motivation on oral temperature. International Journal of Clinical and Experimental Hypnosis, **24**, 22-28.

The hypothesis that changes in oral temperature are associated with neutral hypnotic induction was investigated using neutral hypnosis and a high motivation condition as controls. 33 Ss were assigned to 3 experimental conditions: (1) neutral hypnotic induction, (2) high motivation control, and (3) no treatment control. Ss in all 3 conditions received pre- and post-treatment oral temperature measurements after a 20-minute temperature stabilization showed a significantly greater increase in oral temperature as compared to Ss in both the high motivation and no treatment control conditions. Ss in the latter 2 conditions did not differ from each other in this regard. The methodological considerations of future research in this area are also discussed.

**1972**

Barber, Theodore Xenophon; de Moor, Wilfried (1972). A theory of hypnotic induction procedures. American Journal of Clinical Hypnosis, **15** (2), 112-135.

The first part of the paper delineates nine variables in hypnotic induction procedures that give rise to heightened responsiveness to test-suggestions: (a) defining the situation as hypnosis; (b) removing fears and misconceptions; (c) securing cooperation; (d) asking the subject to keep his eyes closed; (e) suggesting relaxation, sleep, and hypnosis; (f) maximizing the phrasing and vocal characteristics of suggestions; (g) coupling suggestions with naturally-occurring

events; (h) stimulating goal-directed imagining; and (i) preventing or reinterpreting the failure of suggestions. Data are presented to support the theory that the nine variables augment responsiveness to test-suggestions by giving rise to positive attitudes, motivations, and expectancies which, in turn, tend to produce a willingness to think with and vividly imagine those things that are suggested. The second part of the paper specifies situational variables and variables involved in induction procedures that produce a trance-like appearance, changes in body feelings, and reports of having been hypnotized.

1971

Beahrs, J. O. (1971). The hypnotic psychotherapy of Milton H. Erickson. American Journal of Clinical Hypnosis, 14, 73-90.

The principles of hypnosis and suggestion permeate most of Milton Erickson's psychotherapy, although formal trance induction is used in less than ten percent. Characteristic of Erickson's style is his indirect manner of phrasing suggestions or interpretations. They come not as outside impositions, but as subtle manipulations leading the patient to institute constructive behavior from within, often without full conscious awareness. Usually Erickson first attempts to meet the patient at the patient's level, thereby gaining rapport. As trust is developed, he modifies the patient's productions by covert suggestions, thereby gaining control. In this manner, he is able to convert a chaotic psychotic hallucination into an orderly hypnotic one, or the desperate cries of a terminal cancer patient into hypnotic anesthesia. As interpreted here, Erickson's therapeutic approaches can be divided into three categories. First are techniques resembling modern behavior therapy, with frequent use of desensitization. Second, uncovering or abreactive techniques are only rarely used for rigidly resistant and severe symptom patterns. With these, extreme care is taken to protect against too rapid a disclosure to conscious awareness. Third and most important, are techniques enabling the patient to shift or displace large amounts of emotional cathexis from his original problem to some new constructive outlets, usually involving the development of trusting interpersonal relationships. These techniques are the cornerstone of Erickson's therapeutic technique.

1970

Donk, Leonard J.; Vingoe, Frank J.; Hall, Roger A.; Doty, Richard (1970). The comparison of three suggestion techniques for increasing reading efficiency utilizing a counter-balanced research paradigm. International Journal of Clinical and Experimental Hypnosis, 18, 126-133.

Reports an experiment in which both Barber-type and alert-trance procedures significantly increased reading speed while maintaining comprehension when compared to a control group; a traditional hypnotic procedure followed by the specific suggestions failed to obtain these results. 32 volunteer undergraduates were randomly assigned to 4 groups in terms of a counterbalanced design. 2 groups were administered trance inductions (traditional and alert) followed by specific suggestions, a 3rd simply the suggestions, while the 4th served as control. Reading

suggestions were to eliminate specific problems, increase speed, and increase or maintain comprehension. (Spanish & German summaries) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

**1969**

Barber, Theodore Xenophon (1969). An empirically-based formulation of hypnosis. American Journal of Clinical Hypnosis, 12 (2), 100-130.

A formulation is presented which does not invoke a special state of consciousness ("hypnosis" or "trance") to account for the behaviors that have been historically associated with the word hypnotism. Instead, so-called hypnotic behaviors - e.g., "analgesia," "hallucination," "age-regression," and "amnesia" - are conceived to be functionally related to denotable antecedent variables which are similar to those that control performance in a variety of interpersonal test-situations. The antecedent variables which determine behavior in a "hypnotic" situation include Ss' attitudes, expectancies, and motivations with respect to the situation, and the wording and tone of instructions- suggestions and of questions used to elicit subjective reports. The formulation is exemplified by several dozen experimental studies, and prospects for further research are delineated.

Baykushev, S. (1969). Hyperventilation as an accelerated hypnotic induction technique. International Journal of Clinical and Experimental Hypnosis, 17, 20-24.

Describes a rationale and procedure for the use of hyperventilation as a facilitator of hypnotic trance induction. Results with 56 neurotic patients are reported. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Bartlett, K. A. (1968). A rationale of the nature of hypnosis. American Journal of Clinical Hypnosis, 11, 112-118.

A rationale of the nature of hypnosis without formal trance induction is presented. Central to this viewpoint is meeting the needs of the patient in accord with his perception of them and in a manner based on patient-oriented treatment. Case material illustrates practical applications.

**1968**

Chambers, Helen (1968). Oral eroticism revealed by hypnosis. International Journal of Clinical and Experimental Hypnosis, 16, 151-157.

A CASE STUDY OF THE OUTPATIENT TREATMENT OF A SEVERELY DEPRESSED WOMAN. THE CASE WAS COMPLICATED BY THE S'S REFUSING USUAL ANTIDEPRESSANT TREATMENTS. COMMUNICATION WAS DIFFICULT BUT WAS FINALLY ACHIEVED BY THE USE OF ETHER AT ALTERNATE INTERVIEWS. WITHDRAWAL OF ETHER WAS THEN USED TO CREATE A SITUATION OF DEPRIVATION TO AROUSE IN THE

TRANSFERENCE ATTITUDE THE FEELINGS PRODUCED BY THE EARLY TRAUMA. THE S'S COMPULSION TO EAT RAW POTATOES WAS STUDIED WHILE SHE WAS DEEPLY HYPNOTIZED. PSYCHOANALYTIC THEORIES THAT PLACE THE ORIGIN OF DEPRESSION AT THE TIME WHEN THE ORAL PHASE IS PRIMARY WERE CONFIRMED. THE S REFUSED ANY OTHER ANTIDEPRESSANT TREATMENT. Evans, Frederick J. (1967). An experimental indirect technique for the induction of hypnosis without awareness. International Journal of Clinical and Experimental Hypnosis, 15, 72-85.

A procedure is described which has been used in an experimental setting as a method of indirectly inducing hypnosis without S's awareness. Ss are not told that hypnosis is involved in the procedure, but are told they will be taught how to relax. The aim of the indirect procedure is to create different expectations and preconceptions from those normally occurring in the special hypnotic relationship. Evidence from 3 studies (samples of 63, 63, 120) indicates that the procedure successfully induces hypnosis comparable in depth to other standard hypnotic procedures. About half of the Ss tested apparently do not recognize the procedure involves hypnosis. Approximately 30% of the Ss who receive the procedure, as well as 30% of the Ss in the control group who did not receive the procedure, but were tested with the same test suggestions, recognized that an attempt had been made to induce hypnosis. The perceptions about whether hypnosis was involved were unrelated to scores on typical hypnotic phenomena. It was concluded that the indirect induction technique successfully induces hypnosis and is a useful technique for manipulating S-expectations in an experimental context.

## NOTES

[The Subject] is told, 'A series of experiments are being conducted investigating the effects of relaxation on behavior. Because of confusing results in the literature, this study is designed to examine the relationship between relaxation and several other psychological phenomena, some of which might remind you of a variety of other phenomena which you may have heard or read about.' The S was told that a technique had been devised that would assist him to relax completely. His main task was to relax as completely as possible. This would be facilitated by lying comfortably on a couch, and by allowing his mind to become completely blank. To prevent himself from falling asleep, he should concentrate his attention on some object or idea. To help exclude other thoughts from his mind, E would continue to talk in a monotonous voice saying little of importance, while the S stared at a spot on the wall. This shaping of the situation was continued with a considerable degree of apparent permissiveness.

"The S's attention was slowly directed to the rhythm of his own breathing as suggestions were given of eye fatigue. If S closed his eyes, he might find it convenient to concentrate on the rhythm of his own breathing. Perhaps this would be easy to think about if he visualized a pendulum swinging in time with his breathing. The E continued to talk and count in rhythm with S's breathing. Special words, such as 'breathing in and out; the pendulum swings back and forward,' were always spoken as S inhaled or exhaled. Counting was also timed to coincide with exhalation. Deeper relaxation was suggested as E counted slowly from 1 to 21, and later, from 1 to 31.

"Throughout the procedure, phrases and words (such as 'hypnosis,' 'trance,' 'drowsy') traditionally employed with hypnotic induction techniques were avoided. After approximately 30 minutes, a natural transition was made to the testing procedure. Suggestions of continued deep relaxation were intermingled between various tests administered. Termination was effected by suggesting that the relaxation would end as E counted from 'A' to 'H'" (p. 75).

**Kramer, E. (1966). Group induction of hypnosis with institutionalized patients. International Journal of Clinical and Experimental Hypnosis.**

25 hospitalized mental patients, mainly with schizophrenic diagnoses, were tested in group sessions for hypnotic susceptibility. The hypnotic induction and the susceptibility tests were part of the Harvard Group Scale of Hypnotic Susceptibility, a scale which has been standardized on a nonpsychiatric population. Os scored the patients' behavior; the patients filled out self-report forms. Contrary to some reports in the literature, the average hypnotic susceptibility of these patients was similar to that of normals. Self-reports of their behavior during the hypnosis session were significantly correlated with O ratings, but less highly than has been reported for normals. 1965

Coe, William C. (1965). A method of self-teaching for experimental hypnosis. International Journal of Clinical and Experimental Hypnosis, 13 (3), 144-149.

A student's interest in hypnotic research may actually be discouraged because of the difficulty in obtaining a formal course or close supervision in hypnotic techniques. A method tried by 2 students to overcome this problem is presented. The "self-teaching" procedure attempts to fulfill 3 basic criteria: safeguarding the S, requiring minimal supervisory time, and learning to administer a standard hypnotic scale. Some benefits seem to have been realized. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Das, J. P. (1965). Relationship between body-sway, hand-levitation, and a questionnaire measure of hypnotic susceptibility. International Journal of Clinical and Experimental Hypnosis, 13 (1), 26-33.

67 randomly selected college students were administered the body-sway test, a questionnaire measure of tranceability, and an induction procedure utilizing hand-levitation to determine hypnotic susceptibility. The 6 Es varied in age, sex; 5 of them had little experience as hypnotists. All reference to "hypnosis" was omitted from the induction procedure. Significant phi-coefficients between body-sway and levitation (.52), levitation and tranceability frequency (.28) and intensity (.25), and body-sway and tranceability intensity (.33) were obtained. (16 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Field, Peter B.; Evans, Frederick J.; Orne, Martin T. (1965). Order of difficulty of suggestions during hypnosis. International Journal of Clinical and Experimental Hypnosis, 13, 183-192.

This study tests the hypothesis that successful response to suggestion during hypnosis predisposes to further successful response, but failure leads to subsequent failure. The Harvard Group Scale of Hypnotic Susceptibility was administered to 2 groups of 51 volunteer students. For 1 group, 8 of the 12 items were administered in the order easy-to-difficult; for the 2nd group, in the order difficult-to-easy. Total and 8-item mean scores, and frequency distributions, did not differ significantly between groups. Except for the item measuring posthypnotic amnesia, item difficulties for the 2 groups did not differ significantly. Although the difficult-to-easy group was more amnesic, the 2 groups recalled a similar number of additional items when amnesia was "lifted." The block of 4 easier items was relatively easier when preceded by a block of 4 harder items and, similarly, the harder items were relatively less difficult if preceded by a block of easier items. The magnitude of this effect was small, and the order effect hypothesis was basically not supported. Future research should consider the S's subjective impression of success and failure. (16 ref.) McCord, Hallack (1965). Trance induction under unusual circumstances. International Journal of Clinical and Experimental Hypnosis, 13, 96-102.

In order to obtain a test under naturalistic field conditions of the possible facilitatory or inhibitory effects of ongoing tasks on hypnotizability and the interaction of such effects with S's set either to oppose or not oppose entering hypnosis, a series of Ss were hypnotized either singly or in groups while they were performing a variety of tasks typical of those encountered in office or factory situations. Included were such tasks as typewriting, reading a book, engaging in creative writing, performing the Bennett Hand Tool Dexterity and the Minnesota Rate of Manipulation tests, and performing the Pennsylvania Bi-Manual Worksample. In many cases, it was found that hypnosis could be induced under these conditions. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Erickson, Milton H. (1964). The confusion technique in hypnosis. American Journal of Clinical Hypnosis, 6, 183-207.

1964

The confusion technique is "a play on words or communications of some sort that introduces progressively an element of confusion into the question of what is meant, thereby leading to an inhibition of responses called for but not allowed to be manifested and hence to an accumulating need to respond. ... [Added to the play on words] are the modification of seemingly contradictory, or irrelevant unrelated concepts, non sequiturs and ideas, variously communicated, and each of which out of context is a simple reasonable assertion, meaningful and complete in itself. In context, such communications given in a meaningfully emphatic manner become a medley of seemingly valid and somehow related ideas that leads the subject to try to combine them into a single totality of significance conducive to a response, literally compelling a response. But the rapidity of the communications inhibits any true understanding, thereby precluding responses and resulting in a state of confusion and frustration. This compels a need for some clear and understandable idea. As this state develops, one offers a clearly definite easily comprehensible idea which is seized upon immediately and serves to arouse certain associations in the subject's mind. The medley is then continued and another comprehensible idea is offered, enhancing the associations of the previous clear understanding. And in the process, one throws in irrelevancies and non sequiturs as if of pertinent value, thereby enhancing the confusion" (p. 256 in the article as reprinted in Jay Haley).

Hammer, A. G.; Arkins, W. J. (1964). The role of photic stimulation in the induction of hypnotic trance. International Journal of Clinical and Experimental Hypnosis, 12, 81-87.

The relative effectiveness of the ordinary verbal method of trance induction is compared with 2 forms of induction utilizing mechanical photic stimulation, and with methods combining the personal and mechanical features. The criterion of trance adopted was the compulsive carrying out of a difficult suggestion. Results show that mechanical procedures alone are ineffective. On the other hand, the addition of a particular sort of photic driving probably improves trance induction, which suggests that induction is a complex matter involving both social interactions

and relatively nonmeaningful impacts on the brain. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

**1963**

Hoskovec, J.; Svorad, D.; Lanc, O (1963). The comparative effectiveness of spoken and tape-recorded suggestions of body sway. International Journal of Clinical and Experimental Hypnosis, **11**, 163-166.

The relative effectiveness of tape-recorded vs. spoken suggestions of body sway was measured. Both types of suggestion produced increased body sway. Spoken suggestions following recorded suggestions were the most effective. The expectation by Ss of a greater effectiveness of live presentation may have produced this result. ## **NOTES**

(Author's Summary and Conclusions). "After fifty years of experience with hypnosis, it is evident that it is not a superficial and careless technic but should be utilized only by capable, trained physicians, as are the other complex and difficult medical technics. ... In order to induce hypnosis, the patient must be perfectly willing to be hypnotized, he must have confidence in the practitioner, and he must concentrate on doing exactly as he is told. In selected cases, drugs or electrical impulses may be used for the initial induction of hypnotic sleep, but if hypnotherapy is to be continued, the physician must keep in contact with the patient by repeated suggestions. The technic used should fit the individual patient, but in most cases, verbal suggestions are all that is necessary to bring about dissociation. Hypnosis may be used to facilitate the beginning of mental catharsis, the establishment of transference, and may be easily instituted following narcosynthesis, electroshock therapy, minimum stimulus, or Sedac. Suggested activity under hypnosis may be carried out at a designated time, place, and manner after awakening. This is a result of autosuggestion and may be mistaken for psychopathic behavior. Such suggestions

may be instituted by television, movies, radio, telephone, or recorded or written instruction. Hypnosis may be used to plant suggestions; if misused, it may create an obsessive-compulsive neurosis, while when properly used, it may overcome many functional symptoms and may be used to supplement other forms of psychotherapy" (p. 32).

1959

Cheek, David B. (1959). Use of rebellion against coercion as mechanism for hypnotic trance deepening. International Journal of Clinical and Experimental Hypnosis, 7 (4), 223-227.

## NOTES

### Summary

Observation that student subjects often go into a deeper level of hypnosis after suggestions have been given for ending the session has led the writer to explore the reactions of subjects to this phenomenon and to set up a simple experiment using ideomotor responses in ten gynecological patients who needed hypnosis for therapy. In each of the ten patients there was a deepening of the trance after the suggestion to awaken had been given. It was the opinion of the subjects that they deepened the trance in rebellion against the direction for terminating a pleasant experience" (p. 227).

Kroger, William S.; Schneider, Sidney A. (1959). An electronic aid for hypnotic induction: A preliminary report. International Journal of Clinical and Experimental Hypnosis, 7, 93-98.

## NOTES

The BWS or brain wave synchronizer is "an instrument specifically designed to induce various levels of hypnosis by subliminal and photic stimulation of the brain waves" (p. 93). It was developed after noticing that radar operators on ships sometimes fell into deep hypnotic states while watching signals on a radar screen. It has been used with 2500 subjects, 200 of whom were receiving pre-natal training for childbirth under hypnosis.

"For the first five minutes there is a gradual increase in the number of subjects who enter deep hypnosis. At this level, a figure of 50% reach the deep state" (p. 95).

The instructions given were, "Concentrate on the center of the instrument. When your eyes become tired and heavy, as they will, just let them close and feel yourself going deeper and deeper into a relaxed state." It is acknowledged that this procedure worked when Ss expected to experience hypnosis; the rate of deep hypnosis increased as the expectancy of hypnosis increased. "Deep hypnosis in individual inductions reached 80% under the following conditions:

A. Synchronizer on 5 minutes

B. Expectation Level of 50 [on a scale in which 100 represented having seen demonstrations of conventional hypnosis and an explanation of what the instrument would do]" (p. 97).

Pascal, G. R.; Salzberg, H. C. (1959). A systematic approach to inducing hypnotic behavior. International Journal of Clinical and Experimental Hypnosis, 7 (3), 161-167

NOTES

1:

"Summary

The paper reports an experiment in inducing hypnotic behavior. Hypnotic behavior is considered as operant behavior subject to the principles of such behavior. Using a procedure based on this systematic position 52 per cent of 56 subjects were brought to the deep trance state in one session, a considerable gain over results reported in the literature. It is felt that the approach presented suggests that hypnosis may be brought into the realm of behavioral science" (p. 166).

A detailed description of the procedure is provided. It begins with providing information, establishing rapport, using demonstrations of hypnotic-like behavior (the Kohnstamm phenomenon and body sway suggestions), followed by relaxation in a stimulus-attenuated room with verbal suggestions and operant (verbal) reinforcement. It proceeds with a series of frankly hypnotic suggestions for arm analgesia and lightness/floating, amnesia, etc.

1956

Christenson, James A., Jr. (1956). An operational approach to hypnosis. Journal of Clinical and Experimental Hypnosis, 4 (2), 89-91.

NOTES

The author helps subjects and patients to achieve somnambulistic trance by informing them it is akin to things like sleepwalking, dreams, amnesic alcoholic episodes, etc., then suggests that most of us have experienced this before, that we are unconsciously aware of "just what hypnosis really is," and finally invites the subject to achieve that state using the subject's own inner criteria. He distinguishes between hypnotic induction and hypnotic state and critiques researchers who do not make that distinction. "Unwitting hypnosis, the developing of trances by contagion, or in moments of extreme emotional stress, suggest that the achieving of hypnosis is actually a very simple and easy process. I believe that eventually all but a very small percentage of people can be easily and deeply hypnotized" (p. 89). He describes the use of motor signals (e.g. elevated arm) for depth reporting by deeply hypnotized subjects.

1953

Dittborn, Julio (1953). Conditioning of hypnosis to different signs of the same significance. Journal of Clinical and Experimental Hypnosis, 1 (3), 1-3.

1. The difference of the periods of latency to condition a deep hypnotic trance between the different signs of the number six, is remarkable. This difference is significant between the pair (6; six,) and the pair (VI; 12:2).
2. The mean periods of latency are peculiar to each subject, but the subjects tend to gather themselves into two groups: a more rapid (subjects C and D) and a slow one (subjects A and B).

3. It is worthy of notice that one of the subjects, B, did not respond to the idea of six when this was not presented explicitly, but had to be deducted from a calculation (12:2=).

..... It is suggestive that with three somnambulists the idea was enough to produce the phenomenon, while the other always required the objectivation of the idea, even though the sign implied it in a very evident and simple way. It might be worth while to ask if this phenomenon might not be another way to measure the depth of a somnambulatory trance.

Ellis, Albert (1953). Reactions of psychotherapy patients who resist hypnosis. Journal of Clinical and Experimental Hypnosis, 1 (3), 12-15.

#### NOTES

When one of my psychotherapy patients has difficulty in remembering or bringing forth salient material, I or the patient sometimes suggests the use of hypnosis. At such times, I usually find one of two major modes of reaction: either the patient comfortably accepts the idea of hypnosis, and we proceed forthwith to establish a hypnotic relationship; or else the patient, even though he has himself first suggested using hypnosis, is visibly uncomfortable about engaging in it, and in one way or another resists being hypnotized.

"In the latter case, particularly where the patient backs down completely and manages to structure the therapeutic relationships so that hypnosis is never actually attempted, I frequently find that the threat of being hypnotized is so intense that, rather than submit to it, the patient begins to surrender some of his neurotic symptoms or makes unusual psychotherapeutic progress without it."

The author presents three case studies.

#### INFLAMMATION

1997

Schafer D. W. (1997). Hypnosis and the treatment of ulcerative colitis and Crohn's disease. American Journal of Clinical Hypnosis, 40 (2), 111-117.

Ulcerative colitis and Crohn's Disease can be cured if they are treated as autoimmune diseases with a special understanding of the personality conflicts in the patient. The author hypothesizes that all autoimmune diseases are characterized by a high normal amount of the aggressive instinctual drives and ambivalence about their realization. Each patient's personality causes the ambivalence to be somaticized into specific autoimmune bodies that aggressively are overproduced and then attack specific tissues. Hypnosis helps in gaining insight, reinforcing interpretations, handling stress, visualizing normal intestinal areas, and controlling of the autoimmune antibodies to the normal level. This paper deals specifically with these 2 diseases.

## NOTES

1:

We reviewed studies of the effects of hypnotic suggestion to enhance or suppress immediate type hypersensitivity (ITH) or delayed type hypersensitivity (DTH) skin responses (investigations between 1960-1994). In the early 60's most of the studies occurred in England with Black and colleagues. In Black's studies there weren't many subjects.

In most studies the stimulus was an allergen to the patient, or histamine injections that mimic immediate type hypersensitivity response. In one study we have used ultraviolet stimulation. Most studies involve decreasing the response, but a few studies used both increasing and decreasing the response.

Measures include the wheal response (local) and erythema (mediated by the nervous system). Most studies find a reduction in both types of response, but in some of our later studies and also the study by Beahrs, Harris, & Hilgard (1970) they didn't find a wheal response but did find erythema reduction. In the ultraviolet response we didn't get a reduction in erythema but did in blood flow.

Studies in delayed type hypersensitivity usually measure induration and erythema; 3 used tuberculin, 3 used varicella zoster, 1 used multiple antigens, 1 used mumps. Antigen in mumps is latent in the body so the immune response will be different. Most studies tried to increase and decrease the response; two tried just to increase, one just to depress it. Some tried to increase the response in one arm and suppress it in the other arm. In ours we separated the two conditions by a week.

## RESULTS

ITH in general can be suppressed, both the wheal and flare response. Erythema was altered in six studies, unchanged in three; wheal response was altered in [missed number] and unchanged in four. Some studies used allergic patients or those with a psychosomatic history; others screened them out.

DTH results are inconclusive for erythema and induration. All studies using PPD as the antigen were positive; one study using DCP and DNCB was positive. Negative results are found in three studies using Varicella Zoster; 1 study using the Multitest, and 1 study using mumps as antigen.

One could think the reasons for positive vs. negative results relate to the antigens used, and also the dosages given. Some studies use very small doses; one of ours uses such a large dose it is actually felt and sensed. Health status of Ss also could make a difference: a healthy immune response would resist modification if it's not needed. Timing between stimulus and measurement also varies. Suggestions and rapport may affect results, and also the presentation of suggestions. (Some studies taped the suggestions, some use scripts, but using tapes or scripts may lessen rapport with the Subjects.) Measurements differ, e.g. from area tested, diameter of measurement, type of measurement (ultrasound to measure skin thickness, caliper measurement of skin thickness). In measuring hypnotizability and selecting only high hypnotizables, you may eliminate people who can modify their physiological processes. Ss differ

with degree of prior training (those with training are more able to effect responses than on the first time). Operator differences between hypnotists may have some effect.

Mechanisms of the process being studied are at issue: Are we dealing with immune or non-immune processes. Changes in skin temperature and blood flow suggest the latter (vaso dilation and vaso constriction), because of lack of changes seen in lymphocytes etc, although two studies found some kind of changes.

Damage to cutaneous sensory nerves has produced clearing of psoriasis.

**COMMENTS FROM THE AUDIENCE:**

**H. Bennett:** How about hypnotizability of the Subjects? Also, T. X. Barber indicated in a long review article that local vascular response accounts for all of this.

**Response:** Just testing for hypnotizability isn't enough. Local response may be important; immunologists say this isn't immunology because you are affecting nonimmune responses.

**1990**

Schwarz, Shirley P.; Taylor, Ann E.; Scharff, Lisa; Blanchard, Edward B. (1990). Behaviorally treated irritable bowel syndrome patients: A four-year follow-up. Behaviour Research and Therapy, 28 (4), 331-335.

A 4-yr longitudinal study evaluated 19 patients (aged 23-60 yrs) suffering from Irritable Bowel Syndrome (IBS) who had completed a multicomponent treatment involving progressive muscle relaxation, thermal biofeedback, cognitive therapy, and IBS education at baseline. 17 Ss rated themselves as more than 50% improved. Six of the 12 Ss who submitted symptom monitoring diaries met the criteria for clinical improvement, (i.e., achieving at least a 50% reduction in primary IBS symptom scores). The means on all measures at long-term follow-up were lower than those obtained prior to treatment. When follow-up symptom means were compared with pretreatment means, significant reductions were obtained on abdominal pain/tenderness, diarrhea, nausea, and flatulence.

**1989**

Zachariae, Robert; Bjerring, P.; Arendt-Nielsen, L. (1989). Modulation of type I mediated and type IV delayed immunoreactivity using direct suggestion and guided imagery during hypnosis. Allergy, 44 (8), 537-542.

Cutaneous reactivity against histamine skin prick test (Type I) and purified tuberculin protein derivative (Mantoux reaction, Type IV) was studied in eight volunteers under hypnosis. Types I and IV immunoreactivity were modulated by direct suggestion (Type I) and guided imagery (Type IV). When the highly susceptible volunteers underwent hypnotic suggestion to decrease the cutaneous reaction to histamine prick test, a significant (P less than 0.02) reduction of the flare reaction (area of erythema) was observed compared with control histamine skin tests. The wheal reaction did not respond to hypnotic suggestion. Neither wheal nor flare reaction could be increased in size by hypnotic suggestion compared with control histamine skin-prick tests. A hypnotic suggestion of increasing the Type IV

reaction on one arm and decreasing the reaction on the other revealed a significant difference in both erythema size (P less than 0.02) and palpable induration (P less than 0.01). In two cases the reactions were monitored by laser doppler blood flowmetry and skin thickness measurement by ultrasound. The difference between the suggested increased and decreased reaction was 19% for the laser doppler bloodflow (in favor of the augmented side), and 44% for the dermal infiltrate thickness. This study objectively supports the numerous uncontrolled case reports of modulation of immunoreactivity in allergic diseases involving both Type I and Type IV skin reactions following hypnotic suggestions.

1983

Smith, Shirley J.; Balaban, Alvin B. (1983). A multidimensional approach to pain relief: Case report of a patient with systemic lupus erythematosus. International Journal of Clinical and Experimental Hypnosis, 31 (2), 72-81.

A multidimensional approach to the relief of intense pain associated with a chronic, debilitating disease (Systemic Lupus Erythematosus) is illustrated in this case report. Techniques associated with behavioral therapy (deep muscle relaxation, systematic desensitization); hypnosis (trance states, guided imagery, age regression, anesthetic induction and transfer and auto-hypnosis); and psychodynamic psychotehrapy (dyadic interchange, suggestion, encouragement, interpretation of resistance and the transference/countertransference relationship) were utilized in obtaining virtual freedom from disabling pain and the necessity for analgesic and tranquilizing medications. Follow-up over a 3-year period demonstrated the utility of the approach.

## INHIBITION

2002

Raz, Amir; Shapiro, Theodore; Fan, Jin; Posner, Michael (2002). Hypnotic suggestion and the modulation of Stroop interference. Archives of General Psychiatry, 59, 1155-1161..

This study was designed to determine whether a hypnotic suggestion to hinder lexical processing could modulate the Stroop effect. Behavioral Stroop data were collected from highly suggestible and 16 less suggestible subjects; both naturally vigilant and under posthypnotic suggestion. Subjects were urged to only attend to the ink color and to impede reading the stimuli under posthypnotic suggestion. Whereas posthypnotic suggestion eliminated Stroop interference for highly suggestible subjects, less suggestible control subjects showed no significant reduction in the interference effect. This outcome challenges the dominant view that word recognition is obligatory for proficient readers, and may provide insight into top-down influences of suggestion on cognition. (PsycINFO Database Record (c) 2003 APA, all rights reserved)

[Abstract taken from the Archives of General Psychiatry 2002 article by Raz, Shapiro, Fan, & Posner.]

1998

Crawford, Helen J.; Knebel, Timothy; Kaplan, Lyla; Vendemia, Jennifer M. C.; Xie, Min; Jamison, Scott; Pribram, Karl H. (1998). Hypnotic analgesia: 1. Somatosensory event-related potential changes to noxious stimuli and 2. Transfer learning to reduce chronic low back pain. International Journal of Clinical and Experimental Hypnosis, 46 (1), 92-132.

Fifteen adults with chronic low back pain ( $M = 4$  years), age 18 to 43 years ( $M = 29$  years), participated. All but one were moderately to highly hypnotizable ( $M = 7.87$ ; modified 11-point Stanford Hypnotic Susceptibility Scale, Form C [Weitzenhoffer & Hilgard, 1962]), and significantly reduced pain perception following hypnotic analgesia instructions during cold-pressor pain training. In Part 1, somatosensory event-related potential correlates of noxious electrical stimulation were evaluated during attend and hypnotic analgesia (HA) conditions at anterior frontal (Fp1, Fp2), midfrontal (Fe, F4), central (C3, C4), and parietal (P3, P4) regions. During HA, hypothesized inhibitory processing was evidenced by enhanced N140 in the anterior frontal region and by a prestimulus positive-ongoing contingent cortical potential at Fp1 only. During HA, decreased spatiotemporal perception was evidenced by reduced amplitudes of P200 (bilateral midfrontal and central, and left parietal) and P300 (right midfrontal and central). HA led to highly significant mean reductions in perceived sensory pain and distress. HA is an active process that requires inhibitory effort, dissociated from conscious awareness, where the anterior frontal cortex participates in a topographically specific inhibitory feedback circuit that cooperates in the allocation of thalamocortical activities. In Part 2, the authors document the development of self-efficacy through the successful transfer by participants of newly learned skills of experimental pain reduction to reduction of their own chronic pain. Over three experimental sessions, participants reported chronic pain reduction, increased psychological well-being, and increased sleep quality. The development of

"neurosignatures of pain" can influence subsequent pain experiences (Coderre, Katz, Vaccarino, & Malzack, 1993; Melzack, 1993) and may be expanded in size and easily reactivated (Flor & Birbaumer, 1994; Melzack, 1991, 1993). Therefore, hypnosis and other psychological interventions need to be introduced early as adjuncts in medical treatments for onset pain before the development of chronic pain.

## NOTES

1:

The authors suggest that "the anterior frontal region deals with the active allocation of attention and disattention, whereas spatiotemporal aspects of the somatosensory perceptions involve the posterior cortical systems" (p. 113) They acknowledge that "other inhibitory pain systems are actively interacting with the frontal attentional system, including the limbic and thalamic systems" and mention evidence that the inhibitory processing "may extend as far as spinal cord antinociceptive mechanisms as evidenced by reductions in brief latency (Hagbarth & Finer, 1963) and R-III amplitude (Kiernan, Dane, Phillips, & Price, 1995) of spinal reflexes" (p. 113). Both pain perception and strategies of pain control may involve the anterior cingulate cortex (Kropotov et al. 1997), which has many connections with anterior frontal cortex "and is thought to be an area that organizes responses to noxious stimuli" (p. 113).

For the chronic low back pain Ss there were reductions in reported low back pain during the experimental sessions, and significant improvements in psychological well-being and sleep quality across the three sessions. "The importance of developing self-efficacy through learning to control experimental pain and the understanding of one's own attentional and disattentional abilities was demonstrated as being a significant intervention in the modulation and control of chronic pain" (p. 123).

Danziger, N.; Fournier, E.; Bouhassira, D.; Michaud, D.; De Broucker, T.; Santarcangelo, E.; Carli, G.; Chertock, L.; Willer, J. C. (1998). Different strategies of modulation can be operative during hypnotic analgesia: A neurophysiological study. *Pain*, 75 (1), 85-92.

Nociceptive electrical stimuli were applied to the sural nerve during hypnotically-suggested analgesia in the left lower limb of 18 highly susceptible subjects. During this procedure, the verbally reported pain threshold, the nociceptive flexion (RIII) reflex and late somatosensory evoked potentials were investigated in parallel with autonomic responses and the spontaneous electroencephalogram (EEG). The hypnotic suggestion of analgesia induced a significant increase in pain threshold in all the selected subjects. All the subjects showed large changes (i.e., by 20% or more) in the amplitudes of their RIII reflexes during hypnotic analgesia by comparison with control conditions. Although the extent of the increase in pain threshold was similar in all the subjects, two distinct patterns of modulation of the RIII reflex were observed during the hypnotic analgesia: in 11 subjects (subgroup 1), a strong inhibition of the reflex was observed whereas in the other seven subjects (subgroup 2) there was a strong facilitation of the reflex. All the subjects in both subgroups displayed similar decreases in the amplitude of late somatosensory evoked cerebral potentials during the hypnotic analgesia. No modification in the

autonomic parameters or the EEG was observed. These data suggest that different strategies of modulation can be operative during effective hypnotic analgesia and that these are subject-dependent. Although all subjects may shift their attention away from the painful stimulus (which could explain the decrease of the late somatosensory evoked potentials), some of them inhibit their motor reaction to the stimulus at the spinal level, while in others, in contrast, this reaction is facilitated. Nociceptive electrical stimuli were applied to the sural nerve during hypnotically-suggested analgesia in the left lower limb of 18 highly susceptible subjects. During this procedure, the verbally reported pain threshold, the nociceptive flexion (RIII) reflex and late somatosensory evoked potentials were investigated in parallel with autonomic responses and the spontaneous electroencephalogram (EEG). The hypnotic suggestion of analgesia induced a significant increase in pain threshold in all the selected subjects. ## **INSOMINIA & DEPRESSION**

**1976**

**Barabasz AF. Treatment of insomnia in depressed patients by hypnosis and cerebral electrotherapy. American Journal of Clinical Hypnosis 1976;19(2):120-2**

Investigated the influence of suggestion on recovery in the treatment of sleep disturbances by cerebral electrotherapy (CET). 60 adult psychiatric outpatients (diagnostic classification--mild depressive neurosis) were randomly assigned to 4 groups. Group A received CET only; Group B received a CET placebo; Group C received CET with hypnosis; and Group D received a CET placebo with hypnosis. Group A reported a significantly higher recovery than Group B, Group C a significantly higher recovery than Group A, and Group D a significantly higher recovery than Group B. No significant differences were found between Group C and Group D or between Group A and Group D. Findings support suggestion via passive hypnosis with CET as a powerful variable in the treatment of sleep disturbances with depressed patients.

**1988**

**Council, James R.; Loge, D. (1988). Suggestibility and confidence in false perceptions: A pilot study. British Journal of Experimental and Clinical Hypnosis, 5, 95-98.**

**Subjects received audiotaped instructions implying that they would perceive increases in odor or heaviness while comparing stimuli in a sensory-judgment task. Stimuli were actually indiscriminable. Subjects pretested as higher or lower in hypnotizability performed the task in either hypnotic or non-hypnotic conditions. In both treatments, greater hypnotizability was associated with more perceived changes in the stimuli and greater confidence in the reality of those perceptions. Results support a general factor underlying suggestibility in hypnotic and nonhypnotic situations. The findings are discussed in relationship to false confidence effects reported in hypermnesia research.**

**Jones, Lynette A. (1988). Motor illusions: What do they reveal about proprioception. Psychological Bulletin, 103 (1), 72-86.**

**Five illusions involving distortions in the perception of limb position, movement, and weight are described in the context of their contribution to understanding the sensory processes involved in proprioception. In particular, these illusions demonstrate that the position sense representation of the body and the awareness of limb movement results from the cross-calibration of visual and proprioceptive signals. Studies of the vibration illusion and phantom-limb phenomenon indicate that the perception of limb movement and position are encoded independently and can be dissociated. Postural aftereffects and the illusions of movement induced by vibration highlight the remarkable lability of this sense of limb position, which is a necessary feature for congruence between the spatial senses. Finally, I discuss the role of corollary discharges in the central processing of afferent information with respect to the size-weight and vibration illusions.**

**1981**

**Dosamantes-Alperson, Erma (1981). Experiencing in movement psychotherapy. American Journal of Dance Therapy, 4, 33-44.**

**Experiencing is a process variable in psychotherapy which deals with the manner with which individuals use their internal, ongoing bodily-felt flow of experience to gain self-awareness and to communicate about themselves. A consistent finding across research process studies in psychotherapy is that successful clients start, continue, and end therapy at higher experiencing levels than do less successful clients. The implication of this finding for all therapists, irrespective of their theoretical framework, is that they need to help their clients process the content they**

raise in therapy at a high level of experiencing throughout the course of therapy. This paper discusses and demonstrates several body movement based procedures that enhance clients' experiencing level while working within the context of experiential movement psychotherapy, a form of psychotherapy which emphasizes the acquisition of personal meanings by clients from any of the following three experiential and expressive modalities: body movement, kinetic imagery, or verbal communication.

1979

Dosamantes-Alperson, Erma (1979). The intrapsychic and the interpersonal in movement psychotherapy. American Journal of Dance Therapy, 3, 20-31.

The adaptive function of two states of consciousness and corollary movement experiences is described. Movement in which a relaxed state of attention is maintained on inner kinesthetic sensations and imagery is contrasted with movement which is characterized by conscious, active interacting with the external world of people and events. Clinical examples from individual and group psychotherapy sessions are cited to demonstrate how meaning and conflict resolution may be achieved by clients while moving in either mode.

## L RESEARCH

### Language

1985

Kerry Buhk; Rhue, Judith; Henry, Stephanie; Lynn, Steven Jay (1985, November). Fantasy proneness: Are their word associations richer?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

## NOTES

Experimenters screened 7000 students to get 6 samples of fantasy prone Ss (top 2.4% on Wilson and Barber's ICMI). They found less association between fantasy proneness and hypnotizability than did Wilson and Barber.

They had fantasizers hallucinate a second cup next to a first styrofoam cup. Results were that 87% of High fantasizers, < 50% Medium fantasizers, < 25% Low fantasizers could do it, but they didn't describe seeing the hallucinated cup "as real as real" as Wilson and Barber said they did.

Experimenters were concerned about context effects (expectancy) because the Creativity and Fantasy Proneness tests were run proximal in time, so they separated in time the administration of Fantasy Prone and Creativity tests and also looked at word associations.

23 High and 20 Low fantasy prone students selected by ICMI, which was administered to Subjects 18 mos before the creativity study. At the time of the creativity study, Ss were informed they were randomly picked. There were two 90' sessions, counterbalanced.

Sessions: 1. Hallucinate image of R.A. and of styrofoam cup. Other tests were administered for intelligence and personality: Shipley-Hartford, MMPI, Crowne-Marlowe, etc. 2. Creativity tests (Revised Art Scale, Hilgard's Alternate Uses; story production which was scored on detail, imagery and fantasy and on imagery nouns.) Results of this study which was independent of context (i.e. the tests being correlated were administered independently of each other, separated by time). 1. Fantasizers were more creative than low fantasizers on both Creativity Scales. 2. Fantasizers show more divergent thinking on Hilgard Alternate Uses test, but relationship between fantasy proneness and creativity were not strong,  $r = .30$ . 3. Fantasizers and non fantasizers did not differ on the story measures! This diverges from Wilson and Barber's results. Fantasizers may have more vivid images, but storytelling does not capture that.

1954

Dittborn, Julio (1954). Dehypnotization and associated words. Journal of Clinical and Experimental Hypnosis, 2 (2), 136-138.

#### NOTES

Author tested Freud's hypotheses about signs of emotional conflict gleaned from a word association test. A highly hypnotizable subject who had been accused of theft was tested with the word association test repeatedly. He had been given the suggestion, while in deep hypnosis, that any word provoking emotional conflict would automatically bring him out of hypnosis. That is, "dehypnotization was used as a new method to investigate the conflict-provoking quality of certain stimulus-words in an association word test" (p. 139). Freud's predictions were only partially supported.

#### Laterality

1990

Cikurel, Katia; Gruzelier, John (1990). The effect of an active-alert hypnotic induction on lateral asymmetry in haptic processing. British Journal of Experimental and Clinical Hypnosis, 7, 17-25.

In order to elucidate further left hemispherical inhibitory dynamics in response to instructions of hypnosis, bilateral haptic processing times were compared before and during a traditional hypnotic relaxation procedure and an active-alert procedure in which subjects pedaled a bicycle ergometer and instructions on mental alertness were incorporated with hypnosis. Previous evidence suggesting a slowing of left hemispherical processing and a facilitation of right hemispherical processing in susceptible subjects was replicated, and was shown to characterize high rather than medium susceptibles, the latter showing a bilateral slowing of processing. These effects occurred with both induction procedures whose influence on susceptibility was highly correlated. In fact the lateral shift in processing in the direction of left hemispherical inhibition and right hemispherical facilitation was favoured by the active-alert procedure, indicating that neuropsychological changes which occur with hypnosis cannot be discounted as a by-product of relaxation.

**1989**

**Bick, C. H. (1989). An EEG-mapping study of 'laughing': Coherence and brain dominances. International Journal of Neuroscience, 47, 31-40.**

**Laughter is triggered by pleasurable psychoemotional stimuli and may have healing potential. According to split-brain studies, psychoemotional stimuli are bound up with emotional activity in the right side of the brain. This suggested the idea of studying laughter generated by different sources with regard to electrical brain activity in the right and left hemispheres. This study first used subjects in normal consciousness and with laughter under hypnosis to study the neurophysiological processes connected with laughter.**

In Waxman, David; Misra, Prem C.; Gibson, Michael; Basker, M. Anthony (Ed.), Modern trends in hypnosis (pp. 97-108). New York: Plenum Press.**

**There is a vast amount of literature demonstrating that hypnotic susceptibility is a stable personality trait. In the course of our practice of teaching beginners to hypnotize, however, it occurred to us that hypnotists without sufficient previous training frequently measured a lower level of hypnotic susceptibility than the true score. It has to be emphasized that hypnosis is a special altered state of consciousness which develops as a result of an interaction between a hypnotist and a subject. The failure of beginners to induce hypnosis could be explained by considering an insufficient participation of the hypnotist in this interaction. The purpose of the present study was to analyze the necessary and sufficient subjective, behavioral and physiological alterations in both participants of the hypnotic interaction. During successful and unsuccessful hypnotic inductions the subjective experiences, behavioral manifestations and physiological indicators including respiration, ECG, EMG, EOG, GSR and bilateral fronto- occipital EEG leads, were recorded simultaneously in the hypnotists and the hypnotized subjects. The results indicate that hypnotic induction is successful if a mutual "tuning" of the other person occurs not only on the subjective and behavioral levels, but first of all on the psychophysiological level.**

**1984**

**Bakker, Dirk J. (1984). The brain as a dependent variable. Journal of Clinical Neuropsychology, 6, 1-16.**

**The mainstream of neuropsychological research and practice has been devoted to the impact of the brain as an independent variable on behavior as a dependent variable. Evidence is currently available to make clear that the order of causation may be reversed: Behavioral changes can have a durable impact on the brain. The results of extensive research indicate that a large number of neuroanatomical,**

neurophysiological, neurochemical, and neuropsychological parameters of the animal brain can be modified through environmental manipulation, sensory experience, and systematic training. Some evidence is available to show that psychological stimulation has certain effects on the physiology of the human brain. For instance, hemisphere-specific stimulation through the presentation of words flashed in a visual hemifield appears to modify the electrophysiological activity of the contralateral hemisphere in dyslexic children and to affect their subsequent reading performance. Neuropsychology may profit from paying more attention to the ecology of the human brain.

## NOTES

An 18th Century anatomist in Italy, Malacarne, demonstrated increased cerebellar folds in the brains of trained (vs. untrained) dogs and birds. His approach to neuroanatomy was not continued because psychology has been more concerned with innate traits of the individual, and because of philosophical rationalism (citing Walsh, 1981). Until very recently, scientists have viewed the brain as "structurally insensitive to environmental experience" (p. 3).

Now we have evidence that animal brains are modifiable by experience, in gross morphology, fine (synapse) morphology, and neurochemicals. "Rich environments [for rats] ... produce heavier and thicker cerebral cortices and callosal connections (Walsh, 1981), larger cortex/subcortex weight ratios, larger cell bodies and nuclei (Walsh, 1981), and higher metabolic activity as suggested by increased RNA/DNA ratios (Rosenzweig, Bennett, & Diamond, 1972)" (p. 4). Enrichment leads to more extensive dendritic fields (occipital and temporal cortex, some hippocampal regions); this implies that each neuron has more synapses. Researchers have found large Purkinje-cell bodies and many dendrites in richly educated monkeys.

"Some evidence is available to show that 'preventive' and 'therapeutic' environments positively affect behavioral performances of brain-lesioned animals. However, knowledge about the brain mechanisms which underly these effects is, as yet, lacking" (p. 6). Rats that were handled during the first 21 days of life exhibited different brain lateralization from rats that were not (Denenberg, cited by Marx, 1983). Those stimulated early stored memories mainly in the right hemisphere.

The author also reviews evidence that human brains are psychologically modifiable. Children with astigmatism generate weakened cortical response to visual stimulation (Freeman & Thibos, 1973), because they experience difficulty in processing some visual-spatial patterns. People who have visual-field defects due to brain damage can improve in vision when forced to make eye movements toward lighted targets flashed in the blind areas (Zihl, 1981).

Bakker theorizes that hemispheric control of reading shifts from right to left during the learning-to-read process of normal readers; at least some aspects of reading are successively mediated by the right hemisphere at age 6 and by the left hemisphere at age 8, according to electrophysiological data in a longitudinal study (Licht, Bakker, Kok, & Bouma, 1983). He thinks P-type dyslexia results from continuing to rely on right-hemispheric strategies, leading to slow reading with fragmentation errors and repetitions. L-type dyslexia results from prematurely adopting a left-hemispheric strategy, i.e. at the very beginning of the learning process, making child insensitive

to the perceptual features of script with consequent substantive errors such as omissions and additions. Thus, P- type dyslexics presumably show functional overdevelopment of the right hemisphere and L-types of the left hemisphere. Treatment would involve specific stimulation of the hemisphere that they are ignoring.

He presents data suggesting that "some electrophysiological parameters of the cerebral hemispheres can be modified in dyslexic children through hemisphere-specific stimulation and loading, and that these modifications may induce better reading" (p. 12).

1982

Brende, Joel O. (1982). Electrodermal responses in post-traumatic syndromes: A pilot study of cerebral hemisphere functioning in Vietnam veterans. Journal of Nervous and Mental Disease, 170, 352-361.

This paper summarizes the findings of a pilot study which found a relationship between the post-traumatic symptoms of a) psychic numbing, b) intrusive recollections of traumatic events, and c) hypervigilance and lateralization of electrodermal response (EDR) measurements in six victims of psychological trauma. Hypnotically induced imagery of past traumatic events was often associated with left-sided EDR increases, psychic numbing with left-sided EDR decreases or bilateral EDR unresponsiveness, and revivifications of hypervigilant states with right-sided EDR lateralization. In several cases control of the experience of fear was associated with left- sided or bilaterally decreased EDR. These pilot study findings support previously stated hypotheses: a) EDR obtained from an extremity reflects contralateral cerebral hemisphere functioning; b) left hemisphere functioning is associated with hypervigilance; and c) right hemisphere functioning is associated with emotions and imagery. In addition, the pilot study findings suggest additional hypotheses: a) Post- traumatic symptoms are associated with poorly controlled or integrated cerebral hemisphere functioning; b) psychic numbing and intrusive images, flashbacks, and nightmares are associated with abnormal activation, suppression, or integration of right hemisphere functioning in relationship to the left; c) aggressive behavior, hypervigilance, and character pathology are associated with abnormal activation, suppression, or integration of functioning of the left hemisphere function in relationship to the right; and d) "splitting" as a psychological defense in Vietnam veterans with Borderline Personality Disorders is associated with physiologically impaired interhemispheric integration.

#### NOTES

The authors report that previous research suggests that electrodermal asymmetry may be related to emotional factors. They further suggest that electrodermal responsiveness reflects contralateral cerebral hemispheric functioning, with lower GSR associated with higher activation of the opposite cerebral hemisphere (see Lacroix and Comper, 1979). They indicate that the right hemisphere, which is involved in experience of emotion, also is associated with depression (when there is abnormal inhibitory function of right hemisphere) and affective disorders. The left hemisphere is involved in vigilance (Dimond & Beaumont, 1974). "Based on these

findings, the post-traumatic symptoms hypervigilance, anxiety, and behavior disorders appear to be associated with atypical left hemisphere activation, intrusive recollections of traumatic memories and disturbing emotional states with atypical right hemisphere activation, and psychic numbing or emotional unresponsiveness with diminished right hemisphere activation, or overactivation of the left hemisphere" (p. 354).

In this pilot study, the therapist, who used hypnosis in all but one case, interviewed the patient for 30-50 minutes, focusing on helping the S to recall experiences of a traumatic nature. The therapist was supportive when disturbing emotions were evoked, responding flexibly by monitoring S's anxiety and moving back and forth between uncovering and supportive techniques.

### **SUMMARY**

There were observably variable changes and bilateral differences in EDR within each of the six subjects in relationship to varying verbal, emotional, and imagery content, postulated to reflect contralateral hemispheric functioning. These observed changes were considered conclusive evidence of such functioning in post-traumatic states" (p. 358). "1. Lateralization of EDR to the left is associated with unpleasant emotions and traumatic imagery. ... "2. Lateralization of EDR to the right is associated with hypervigilance and aggressive outbursts. ... "3. Psychic numbing is associated with inhibition of bilateral EDRs (for example, lack of bilateral EDR activation occurred in every case at times) or with suppression of the left EDR. ... "4. General physiological arousal, a normal response to fear, is associated with increased EDRs bilaterally. ... "5. Relaxation and the subjective experience of safety and well-being, which have been reported to foster interhemispheric integration in normal subjects ... were observed to be associated with bilaterally decreased EDR in case I, an example of a less severe post- traumatic condition, but not observed during attempts at relaxation in Vietnam veterans with more severe post-traumatic symptoms. "6. Voluntary efforts to cognitively control fear were related to left hemispheric functioning, as observed in case IV when the subject attempted to control intrusive thoughts with cognitive activity and in Case III following the revivification of a frightening event when he made a shift from the hypnotic trance state to waking cognitive activity. In both cases, such cognitive activity was associated with a decreased right-sided EDR" (p. 359).

### **DISCUSSION**

The results of this pilot study, which demonstrated frequent EDR differences between hands during subjects' recollections of or attempts to suppress recollections of prior traumatic experiences, alters the traditional belief that increased skin conductance is always a predictable physiological measurement when the electrode is placed on only one hand, as Lacroix and Comper (46) have pointed out.

"The finding of EDR lateralization is consistent with the findings of deBonis and Baque (10) who reported that the degree of anxiety determines the presence of lateralization of EDR responses, of Gruzelier and Venables (30, 32) and Myslobodsky and Horesh (53) who reported that the presence or absence of

psychopathology determines the direction of the lateralized response, and of Lacroix and Comper (46) that activation of one hemisphere may suppress

Crawford, Helen J. (1982). Cognitive processing during hypnosis; much unfinished business. Research Communications in Psychology, Psychiatry and Behavior, 7, 169-179.

Studies of cognitive processing during hypnosis per se are reviewed suggesting that hypnotically responsive individuals not only experience subjective changes during hypnosis that are seen as often being discontinuous from their normal consciousness but also may exhibit measurable cognitive changes. Evidence (ego functioning changes, enhanced creativity, enhanced imagery processing, etc.) is presented to support the hypothesis that hypnosis may involve a shift in cognitive functioning away from a verbal, detail-oriented strategy towards a more imaginal, non-analytic, holistic- oriented strategy. Limitations of present research and potentially valuable research areas are discussed.

#### NOTES

The author reviews evidence for cognitive changes during hypnosis--evident especially in high hypnotizables but also to some degree in moderate hypnotizables. She concludes that there may be changes in ego functioning, imagery functioning, creativity, and strategy preferences and that high hypnotizables are more flexible in cognitive processing . "The question remains whether or not there are accompanying objectively measurable cognitive changes during hypnosis" (p. 170).

In normal waking consciousness, the hypnotically responsive individual is typically found to be more involved in nonhypnotic imaginative activities and experiences (Hilgard, 1979; Tellegen & Atkinson, 1974), more able to image things (for review, see Sheehan, 1979) and daydream vividly and positively (Crawford, 1982), more able to perceive gestalt closure figures (Crawford, 1981), more able to divert attentional process (e.g., Karlin, 1979), and more creative on certain tasks (e.g., P. Bowers, 1979). Experiential reports indicate that it is these very cognitive processes, amongst others, which are perceived to be enhanced or changed during the hypnotic state" (p. 170).

"Levin and Harrison (1976) found that hypnosis ego changes occurred most in those individuals who also demonstrated good capacity for adaptive regression in the waking state" (p. 171).

"Dave (1979) compared hypnotically induced dreams with rational-cognitive treatment as to their effects on creative problem solving of the problems or projects. 'Conditional support' was given to the significantly stronger effect form the hypnotically induced dreams" (p. 172).

There are many investigations of the effect of hypnosis on imagery, with a number of methodological problems. "Self-reports can be criticized on the grounds that they are easily subject to demand characteristics, subject expectations, and social desirability influences. Coe et al. (1980) found order of condition influenced their

findings, while Crawford (1979) found that imagery rating scales suffered from a low ceiling effect among high imagers" (pp. 172-173).

"Surprisingly, while the field of cognitive psychology has devoted extensive attention to the study of the enhancing effects of imagery upon memory, few of their paradigms have been applied to the study of hypnotic processing of information. Germaine to the field of hypnosis are three operational approaches to the investigation of imagery: (a) the manipulation of the availability of imagery as a coding device, such as varying the degree to which stimuli may evoke imagery, (b) the manipulation of the processing strategy in cognitive performance, such as asking subjects to use imagery in the mediation of stimuli information, and (c) the comparing of information processing strategies and performance in subjects who are low and high in imagery ability (Paivio, 1971)" (p. 173).

"Several studies (Nomura, Crawford, & Slater, 1981; Walker, Garrett, & Wallace, 1976; Wallace, 1978) found that a very few high hypnotizables can successfully produce eidetic imagery, using nonfakable stereograms, during hypnosis even though they cannot during waking. Spanos, Ansari, & Stam (1979) were unable to replicate these findings. It was only self-reported childhood eidetikers who exhibited eidetic imagery during hypnosis, and then only a few. This research suggests that hypnosis permits certain individuals to access the "lost" ability to image eidetically, possibly through a shift in cognitive strategies" (p. 174).

"An underlying emphasis of this paper is the need for hypnotic investigators to integrate findings from cognitive psychology into their research, as well as apply the many new approaches to understanding brain functioning which are now being developed, in their search for a better understanding of what occurs during hypnosis" (p. 176).

1981

Chen, Andrew C.; Dworkin, Samuel F.; Bloomquist, Dale S. (1981). Cortical power spectrum analysis of hypnotic pain control in surgery. International Journal of Neuroscience, 13, 127-136.

Cortical power spectrum (CPS) of brain potentials was recorded from the scalp between prefrontal and parietal regions in both right hemisphere (RH) and left hemisphere (LH). A pattern of laterality shift in CPS occurred at different stages during an extensive oral surgery, performed under hypnosis, in a young female patient. Video and audio recordings as well as psychophysiological recordings were obtained through the following 6 stages: Baseline, Hypnosis, Surgery (1 hr, no cortical recording), Immediate Postsurgery Procedure, Hypnotic Re-experience, Hypnotic Rest, and Posthypnotic Baseline. Indications of anxiety and pain scores were reported in writing by the patient through verbal command by the hypnotist. In each stage, 10 min of CPS (10 spectrum/stage, 8 epochs/spectrum, 6 seconds/epoch) were analyzed by a PDP-11 computer. The results of CPS analysis demonstrated significant large total power reduction at different stages. There was significant correlation between both hemispheres at baseline, but dissociation of hemispheric power output occurred during hypnosis stages. LH was more dominant than RH during baseline and presurgery hypnosis, but both were leveled-off

immediately following the surgery procedure. However, RH became more dominant during all postsurgery hypnosis stages. Interestingly, this pattern shifted back to the original relationship during the posthypnotic baseline stage. Specific changes of spectral power in theta and alpha of EEG activities in both hemispheres also occurred in conjunction with hypnosis.

## NOTES

Subject was a 25 year old woman, described as only medium in hypnotizability. She scored 3 on the 5-point Stanford Hypnotic Clinical Scale, 7 on the 12-point Stanford Hypnotic Susceptibility Scale, and 3 on up-gaze, between 2 and 3 on eye roll, on the Spiegel eye roll test.

The principal hypnotic approach was a suggestion of dissociation, i.e. that the patient "experience herself swimming freely and powerfully, in a deep cold mountain lake, pre-occupied with the intensity of the blue-black color of the water, the shimmering of light from above, and the possibilities of exploration of rock formations, caves, etc. It was suggested that while she was experiencing the exhilaration and strenuous stimulation of the cold water and the vigorous exercise, an 'observing-self' would remain on the shore, watching and ensuring that no harm would come to the person. The suggestion was reinforced that any stimulation experienced was experienced in the body, not in the person" (p. 129).

The patient was trained in inductions and dissociation first in the therapist's office, then with two sessions in the research laboratory (where tooth pulp stimulation pain thresholds were measured), and then two sessions in the hospital dental operatory.

The results of the computerized CPS were analyzed by hemispheres. "Large reductions in total power occurred at different stages associated with hypnosis and these reductions in power output of the CPS showed significant left-right differences" (p. 130).

"The total energy output of LH [left hemisphere] continued to diminish as hypnosis continued by as much as 80% of baseline value, while RH [right hemisphere] power output tended to be stabilized from the initial hypnosis recording stage until the awake baseline stage" (p. 130).

"Those stages involving hypnosis were characterized by dominant RH energy output in the alpha spectrum. ...

"Alpha output for the LH decreased an average of 65% between awake baseline levels and postsurgery hypnosis stages, while RH alpha only decreased approximately 50% of resting levels. This resulted in a relative shift of alpha output which was approximately equal in both hemispheres prior to surgery, to a 2:1 shift in favor of RH alpha output as hypnosis progressed. This differential shift in laterality of alpha was reversed when the subject awakened from hypnosis.

"Of interest was the observation that total power reductions and laterality shifts associated with hypnosis were not altered by the profound instrumentation of surgery and postoperative pain, nor were observed laterality shifts affected by hypnotic suggestions aimed at recreating the surgical experience (see Stage 5)" (p. 130).

During the experiment when the investigators used hypnotic suggestion to recreate the surgical experience, LH output continued to diminish while RH output did not

change, making the LH-RH contrast highly significant. "This suggests that the RH is active during deep stages of hypnosis and can remain so despite hypnotic suggestions which are presumed to be intensely aversive" (p. 131).

In their Discussion, the authors reinforced the conclusion that overall cortical functioning is reduced during hypnosis, and that the left cerebral hemisphere shows a greater reduction than the right. They discuss the increased theta density in RH and LH during the postsurgery hypnosis stage in terms of reports that theta is associated with altered states of consciousness (Tebecis et al., 1975; Ulett et al., 1972; Anad, China, & Singh, 1961; Banquet, 1973; Kasamatsu & Hirai, 1966; Wallace, 1970) and with cognitive tasks like mental arithmetic (Dolce et al., 1974).

The authors note that their results are congruent with Hilgard's neodissociation theory of hypnosis, and add that since their suggestions were dissociative in nature rather than of local anesthesia, the EEG may reflect the brain physiology of dissociation.

Finally, they comment on the implications for pain neurophysiology. "The total power changes and shifting patterns in laterality of cortical functioning observed more closely tracked the hypnosis experience than the pain experience; this is, in fact, a very puzzling issue. It appears on the face of it that the EEG measurements recorded are not reflective of EEG-related pain phenomenology despite the strenuous and invasive surgical procedures used. The observations that overall power output continued to decrease during the several hypnosis stages after strenuous surgery and then increased as the patient came out of hypnosis makes reasonable the possibility that hypnosis has some functional brain correlates; we cannot conclude from the present cortical power spectrum analysis that any brain correlates of surgical pain were revealed. We are well aware that EEG recordings were not available during actual surgery itself, because of artifacts resulting from head movements, etc. Nevertheless, it can be fairly claimed that recordings obtained immediately after such oral surgery of one hour duration, could reasonably be expected to be associated with a person in pain. But, both by verbal report and available objective data, any surgically induced traumatic pain was of brief duration under hypnosis" (p. 135).

1970

Bakan, Paul (1970). Handedness and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 18, 99-104.

Carried out 2 studies with 251 and 228 undergraduates to determine the relationship between self-reports of handedness and scores on a shortened version of the Harvard Group Scale of Hypnotic Susceptibility, Form A. It was found that left-handed Ss were more likely than right-handed Ss to score at the extremes of the hypnotizability scale, either low or high, and less likely to score in the middle of the scale. Results of 2 independent studies were in agreement. (Spanish & German summaries) (15 ref.) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

Learning

1992

Appel, Philip R. (1992). Performance enhancement in physical medicine and rehabilitation. American Journal of Clinical Hypnosis, 35, 11-19.

Performance enhancement or mental practice is the "symbolic rehearsal of a physical activity without any gross muscular movements" to facilitate skill acquisition and to increase performance in the production of that physical activity. Performance- enhancement interventions have been well known in the area of sports psychology and medicine. However, clinical applications in physical medicine and rehabilitation have not flourished to the same extent, though the demand for improved physical performance and the acquisition of various motor skills are as important. In this paper I will describe how hypnosis can potentiate mental practice, present a model of mental practice to enhance performance, and describe how to help patients access an ideal performance state of consciousness.

1991

Block, Robert I.; Ghoneim, M. M.; Sum Ping, S. T.; Ali, M. A. (1991). Efficacy of therapeutic suggestions for improved postoperative recovery during general anesthesia. Anesthesiology, 75, 746-755.

There have been claims that the postoperative course of patients may be improved by presentation during general anesthesia of therapeutic suggestions which predict a rapid and comfortable postoperative recovery. This study evaluated the effectiveness of such therapeutic suggestions under double-blind and randomized conditions. A tape recording predicting a smooth recovery during a short postoperative stay without pain, nausea, or vomiting was played during anesthesia to about half the patients (N = 109), while the remaining, control patients were played a blank tape instead (N = 100). The patients were primarily undergoing operations on the fallopian tubes, total abdominal hysterectomy, vertical banding gastroplasty, cholecystectomy, and ovarian cystectomy or myomectomy. The anesthesia methods consisted of either isoflurane with 70% nitrous oxide in oxygen to produce end-tidal concentrations of 1.0, 1.3, or 1.5 MAC; or 70% nitrous oxide in oxygen combined with high or low doses of opioids. Assessments of the efficacy of the therapeutic suggestions in the recovery room and throughout the postoperative hospital stay included: the frequency of administration of analgesic and antiemetic drugs; opioid doses; the incidence of fever; nausea, retching, and vomiting; other gastrointestinal and urinary symptoms; ratings of pain; ratings of anxiety; global ratings of the patients' physical and psychological recoveries by the patients and their nurses; and length of postoperative hospital stay. There were no meaningful, significant differences in postoperative recovery of patients receiving therapeutic suggestions and controls. These negative results were not likely to be due to insensitivity of the assessments of recovery, as they showed meaningful interrelations among themselves and numerous differences in recovery following different types of surgery. Widespread utilization of therapeutic suggestions as a routine operating room procedure seems premature in the absence of adequate

replication of previously published positive studies. (Key words: Anesthesia, depth: Awareness, Memory, Recall, Learning.)

## NOTES

Patients ages 19-55 were accepted into the study and they were paid for participation. (Older patients were excluded to guard against memory or hearing problems.) Other criteria for exclusion were: ASA physical status 4 or 5 indicating significant systemic disease, visual or hearing problems, middle ear disease (because it increases probability of nausea and vomiting), if their condition might require heavy sedation, if they were currently taking medication that interferes with memory (e.g. benzodiazepines, if there were intolerance to opioids, or if there were a likelihood of using postoperative pain treatment other than opioids.

The Spielberger State-Trait Anxiety Inventory was administered before surgery. Either suggestions (lasting 6 minutes) or a blank tape were played through headphones, starting 5 minutes after the surgical incision. The tape was played once for the first 59 patients, continuously for the remaining 150 patients. The first 139 patients received additional verbal materials on the tape, for memory tests to test possibility of learning under anesthesia. Operating room sounds were recorded by a tape recorder near the patient's head, throughout period of unconsciousness (except when tape was being played).

After the first 25% of cases, the team decided that lack of effect on therapeutic suggestions attributable to type of anesthesia did not warrant restriction to a single anesthetic method; also, multiple presentations of the suggestions on tape did not show an effect different from a single presentation.

After the patient regained consciousness and was reoriented, pain, nausea, retching, and vomiting were assessed every 30 minutes. Pain was rated orally on a scale from 1 to 10 in the recovery room, then on visual analogue scales every 2 hours on the day of surgery and the second day, and every 4 hours on subsequent hospital days during waking hours. Variables that were rated by staff every 24 hours included: opioids, other analgesics, antiemetics, nausea, vomiting, retching, presence or absence of nasogastric tube, passage of flatus, bowel movement, fluid intake, solids intake, urination. Temperature was recorded every 4 hours for the first 2 days after surgery, and after that less often. The anxiety measures were repeated on Day 3 postsurgery, as well as self ratings and nurse ratings on physical and psychological recovery. Staff recorded length of postoperative hospital stay and reasons for any delay of discharge. Separate analyses were performed for patients receiving opioids via patient-controlled analgesia (52%) vs traditional administration (48%), but no differences were found for effects of therapeutic suggestions except on postoperative Day 8.

"The inability to detect beneficial effects of therapeutic suggestions probably was not due to insensitivity of the measures of recovery. These measures were sensitive enough to show numerous significant differences in recovery after different types of surgery" (p. 751). The authors supported their contention that the measures were sufficiently sensitive by demonstrating meaningful correlations among the measures themselves; and by demonstrating adequate statistical power for detecting the

effects of theoretical interest--at least 1 day in postoperative hospital stay or one half day in fever.

**Discussion:** The authors note that a recent investigation that found positive results in a double-blind, randomized design with 39 hysterectomy patients (Evans & Richardson, 1988. Improved recovery and reduced postoperative stay after therapeutic suggestions during general anaesthesia. *Lancet*, 2:491-493) may not have controlled for variables such as presence of malignancy, physical status of patients before surgery, or ethnicity. Authors note that Evans and Richardson observed shorter periods of pyrexia despite there being no relevant suggestions, but no differences in pain intensity, nausea, vomiting, or urinary difficulties despite there being suggestions relating to those symptoms. There also were no differences in mood and anxiety test scores postoperatively for the experimental and control groups.

The authors note that McLintock, Aitken, Downie, & Kenny (Postoperative analgesic requirements in patients exposed to positive intraoperative suggestions. *Br M J* 301:788-790. 1990) reported a 23% reduction in opioids by patients receiving suggestions, but no reduction in pain, nausea, or vomiting. They contrast the present study with these earlier studies that had obtained positive results.

"We studied patients who had more than one type of surgery to obtain a large sample size and to assess the possibility that beneficial effects of therapeutic suggestions would be restricted to certain types of operations. Had this been the case, interactions of therapeutic suggestions with type of surgery would have been significant in the overall analyses, and follow-up analyses would have indicated that they were attributable to beneficial effects of therapeutic suggestions for certain surgeries. This did not occur. The two types of surgeries involving the largest numbers of patients seemed particularly promising for demonstrating beneficial effects. It has been reported that therapeutic suggestions presented during anesthesia are likely to be less successful with major and extensive surgery. Certainly, surgery on the fallopian tubes and gastric stapling did not involve a great deal of tissue trauma and blood loss. Patients were motivated to have the surgery and to recover quickly; particularly motivated were those having operations on the fallopian tubes, who were very eager to become pregnant, and those having vertical banding gastroplasties, who wanted desperately to lose weight" (pp. 753-754).

"In practice, we observed no beneficial effects of therapeutic suggestions, and there was no hint that anesthesia methods influenced the efficacy of the therapeutic suggestions. Interestingly, anesthetic methods also did not influence learning under anesthesia in the implicit memory tests we have used previously. Patients anesthetized with nitrous oxide and opioids did not differ from those anesthetized only with inhalational agents. In general, implicit or unconscious memory occurs in patients regardless of anesthesia methods or dosages of drugs" (p. 754).

"The few significant effects of therapeutic suggestions in our study did not point toward a beneficial influence of these suggestions. We found, in fact, an increased frequency of retching (but not nausea or vomiting) in the experimental group. The multiple variables examined in this study increased the likelihood of significant differences arising by chance, such that the null hypothesis was rejected when it should have been accepted. This is the way we interpret the effect on retching---i.e.,

as a type I error. We used in our therapeutic suggestions one negative or exclusionary sentence, 'You won't feel nauseous or have to vomit', among several positive or affirmative statements, e.g., 'You will enjoy eating, drinking...You will swallow to clear your throat and everything will go one way, straight down. . . The food will taste good....Your stomach will feel fine.' We do not think that the negative sentence led to paradoxical results. Evans and Richardson (personal communication) used in their therapeutic suggestions a negative sentence ('You will not feel sick'), which they repeated, yet the reported incidence of nausea and vomiting did not differ between the experimental and control groups" (p. 754).

## Life experience

1994

Sivec, Harry; Lynn, Steven Jay; Segal, David; Malinoski, Peter; Crothers, Marie K.; Wilson, Holly; Roche, C. (1994, October). Autobiographical memories in hypnosis, relaxation, and waking conditions. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

This is an update of what was presented at last year's meeting. It presents data on waking relaxation vs waking hypnosis conditions.

Research Design: 3 groups: relaxation, hypnosis, and control All Ss were highs (scoring at least 9) and also high on Fantasy Proneness. But Ss were informed that they were randomly selected from the subject pool.

Administered the SCL-90R [?], POMS, and PES (a measure of hypnosis related experiences), and the Stanford-Form C. Early memory protocol required that Ss report the earliest specific childhood event that they could recall; they were told to remember that the time is the present [?].

Recalled two early and two recent memories, in counterbalanced order.

Ss completed the PES for a second time. Positive affect, negative affect, affect intensity, and primary process were evaluated.

Hypotheses about more primary process and affect were not supported.

When early memory was probed first, it was about age 3; when recent memory was probed first, the earliest memory was about 4. The second memory recalled was older (among younger memories) for hypnotized Ss than for non-hypnotized Ss.

For negative affect the relationships were different. Relaxation might have diminished the negativity of affect that was remembered.

1991

Smith, William H. (1991). Antecedents of posttraumatic stress disorder: Wasn't being raped enough? A brief communication. International Journal of Clinical and Experimental Hypnosis, 39, 129-133.

Many rape victims, like those traumatized by war, accidents, and natural disasters, are able to recover from their ordeal with supportive, crisis-oriented treatment. For others, however, symptoms may persist and require more intensive treatment. Hypnosis allows a modulated re-experiencing and abreaction of the traumatic event

that can help to provide the victim with a relieving sense of mastery, and it fosters a receptive context for reassurance and interpretation regarding the irrational or exaggerated thoughts and feelings involved. 2 case examples are presented in which earlier conflicts appeared to play a role in perpetuating the patients' symptoms. Detecting and addressing these antecedents resulted in complete alleviation of long-standing problems through relatively brief treatment using hypnosis.

Gottschalk, Louis A. (1985). Hope and other deterrents to illness. *American Journal of Psychotherapy*, 39, 515-524.

Reviews animal and human research demonstrating that events during early development influence vulnerability to physical and mental illness. In addition, effectiveness of coping methods used to deal with problems of living can affect susceptibility to illness. The intervening mechanisms between stressful life experiences and illness appear to involve physiological homeostasis and immune competence.

**1962**

As, Arvid; Lauer, Lillian W. (1962). A factor analytic study of hypnotizability and related personal experiences. *International Journal of Clinical and Experimental Hypnosis*, 10 (3), 169-181.

To throw further light on the exclusivity of "primary suggestibility" as reported by other investigators, a factor analysis was performed in a sample of 102 female college students on the basis of the intercorrelations of 23 items of personal experiences earlier shown to be related to hypnotizability, and 19 items from 2 hypnosis scales. No simple factor structure emerged. 2 factors were interpreted: the 1st as a hypnotic factor with special emphasis on the capability to sustain the effect of suggestion over time, and the 2nd as a combination of psychological changeableness and social influencibility. A brief discussion was given of the composite picture of hypnotic susceptibility emerging from the fact that many hypnotic items loaded on both factors. Rose, J. T. (1962). The use of relevant life experiences as the basis for suggestive therapy. *International Journal of Clinical and Experimental Hypnosis*, 10, 221-229. (Abstracted in *Imagery* 63: Mar., S-543)

A brief, directive method of hypnotherapy is described which combines limited insight therapy with hypnotic suggestions based on relevant life experiences of the patient. By integrating suggestions and experiences familiar to the patient, the former are more likely to have greater meaning to the patient and are therefore more effective. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Shor, Ronald E.; Orne, Martin T.; O'Connell, D. N. (1962). Validation and cross-validation of a scale of self-reported personal experiences which predicts hypnotizability. Journal of Psychology, 53, 55-75. (Abstracted in Psychological Abstracts, 62: 4 II 55S)

A paper-and-pencil self-report questionnaire was designed to measure the incidence of "hypnotic-like" experiences which have occurred naturally in the normal course of living. The questionnaire as evolved was found to predict hypnotizability, especially in the deepest region of the hypnotizability, especially in the deepest region of the hypnotizability continuum. Ramifications of the data are presented in terms of theoretical formulations where both ability factors and nonability factors (such as attitudes and motives) are viewed as components of achieved hypnotizability. From Psyc Abstracts 36:04:4II55S. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Locus of control

1988

Spinhoven, Philip; Baak, Diana; Van Dyck, Richard; Vermeulen, Peter (1988). The effectiveness of an authoritative versus permissive style of hypnotic communication. International Journal of Clinical and Experimental Hypnosis, 36, 182-191.

The differential effectiveness of an authoritative versus permissive style of hypnotic communication was investigated, with locus of control as a moderator variable. 44 Ss received in counterbalanced order both the more authoritatively worded Harvard Group Scale of Hypnotic Susceptibility, Form A and the Wexler-Alman Indirect Hypnotic Susceptibility Scale (WAIHS), which is a more permissive scale with the same item content as HGSHS:A. Permissively worded suggestions did not enhance the level of hypnotic responsiveness. Locus of control did not predict the response level on one of the scales. Unexpectedly, significantly more female Ss preferred the WAIHS, and more male Ss preferred HGSHS:A. It is concluded that Ss' characteristics (i.e., hypnotizability) are more important for hypnotic responsiveness than variations in style of hypnotic communication or scale preference.

1986

Mitchell, George P.; Lundy, Richard M. (1986). The effects of relaxation and imagery inductions on responses to suggestions. International Journal of Clinical and Experimental Hypnosis, 34, 98-109.

Theoretical attempts to understand the meaning and importance of induction procedures in producing hypnotic phenomena suggest that 2 critical components, relaxation and imagery, should be isolated and their relative effect on hypnotic responding studied. Objectively and subjectively scored responses to 12 hypnotic suggestions, which had followed relaxation, imaginal, or combined inductions, were

obtained from 59 Ss, divided into 3 levels of hypnotizability. Regardless of hypnotizability level, the combined induction led to a greater subjective report of hypnotic response than did either the relaxation or the imagery inductions; and the relaxation led to a greater subjective report than the imagery induction. It may follow that the subjective experience of hypnosis is facilitated by inductions which include relaxation. The inductions were equally effective in producing objectively measured behavioral responses. There were no significant interactions found between induction type and hypnotizability level.

## NOTES

(From the Discussion Section).

As suggested by Sacerdote (1970), the combination procedure was the most generally effective in producing hypnotic responses. The difference between combined and imagery inductions reached statistical significance on four dependent variables, and the difference between combined and relaxation reached significance on three. It may also be of interest that Ss receiving the combined procedure scored consistently higher on all nine dependent variables.

A somewhat unexpected finding was that the relaxation induction produced scores on four of the dependent variables that were statistically higher than the imagery induction scores. Considering the difficulty of isolating relaxation and imagery components, it is quite noteworthy that these differences between inductions were found.

The four variables in which the combination and relaxation conditions produced significantly higher scores than the imagery condition were subjective reports--subjective score, degree hypnotized, response volition, and Field Inventory. In contrast to Ss in the imagery induction, Ss in the other two induction conditions believed that they were responding more, felt that their responses were more nonvolitional, and felt that they were more deeply hypnotized.

The fact that relaxation instructions were present in both conditions that were superior to the imagery condition would appear to support Edmonston's (1981) position which posits relaxation as essential for the production of the state of neutral hypnosis. For Edmonston the condition of neutral hypnosis is defined as the relaxed state and precedes other phenomena, such as dissociation and increased suggestibility, which other theoreticians may include in the definition of hypnosis.

However, the statistically significant superior effect of the combined over the relaxation induction on three measures casts doubt on Edmonston's position. The S believes that he or she is more deeply hypnotized and is responding less volitionally when an imagery component is combined with relaxation. The Ss also responded more to the Field Inventory when the combined induction was used.

Another explanation for imagery's relatively poor showing may lie in Ss' differential expectations. The Ss, especially those with previous experience with a traditional hypnotic induction, as was the case in the present study, may not expect to be hypnotized when presented with an imagery alone induction. Such expectations, of course, might reduce responses. On the other hand, there is no reason to believe that the reduced expectation in the imagery condition would not affect the behavioral responses as well, and such was not the case.

Thus, we may be left with the explanation that relaxation adds to the subjective experience of hypnosis. This is in keeping with Edmonston's (1981) position as well as with previous research, such as that by Hilgard and Tart (1966), which finds traditional inductions, with their relaxation components, superior to nontraditional inductions, such as fantasy or task-motivational. If future research should find that bodily involvements such as the physical exertion or repetitive motor behavior (Banyai and Hilgard, 1976) lead to the same level of subjective experience as relaxation did, then we may need to broaden the concept of the somatic component beyond relaxation alone.

In terms of the behavioral compliance of Ss, the results of the present study are in accord with some previous studies in finding all procedures equally effective. Neither imagery, relaxation, nor the combined procedure was superior for the behavioral measure.

Personality factors (social desirability, internality/externality, and absorption) did not affect the basic findings. To the degree that the Tellegen scales measure the ability to engage in imagery there seems to be little basis for believing that imagery ability is related to the general findings.

Sarbin (1983) would call the inductions studied here 'entrance rituals,' and he has recently asked in his review of Edmonston's book, "Which ritual is more suitable... [p. 58]' for preparing S to respond in various hypnotic ways? One answer from the present results is that an entrance ritual should include muscular relaxation if one wants a better subjective response from S. From Sarbin's point of view, the relaxation component may be more ego-involving, producing more subjective experience and meaning for S.

If one wants to produce only a behavioral response, either a relaxation or imagery ritual will serve.

1983

Saavedra, Ramon Luis; Miller, R.J. (1983). The influence of experimentally induced expectations on responses to the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 31, 37-46.

A sample of 75 female and 63 male undergraduates were told that their hypnotizability was predictable through the application of a battery of questionnaires and physiological measures. Three levels of hypnotizability expectations were created, with 3 groups of Ss informed that they were highly hypnotizable, moderately hypnotizable, or low in hypnotizability, respectively. A control group received no such expectations. All Ss were then administered the Harvard. Results indicated a significant main effect due to the assigned hypnotizability expectations. Only Ss in the low expectation group, however, scored significantly differently from the other groups on the Harvard. Four other variables were examined as covariates: locus of control, attitude toward hypnosis, absorption, and self-predictions of hypnotizability. All but locus of control correlated significantly with the Harvard. It also was shown that the degree to which assigned expectations influenced Harvard scores was a function of the confidence Ss had in those expectations.

## NOTES

The authors state that research has shown that it is easier to lower hypnotizability scores by providing negative expectancies than to increase hypnotizability scores through provision of positive expectancies. In this study, very little of the variance of hypnotizability scores was accounted for by the expectancy manipulation.

1982

Pickett, Carolyn; Clum, George A. (1982). Comparative treatment strategies and their interaction with locus of control in the reduction of postsurgical pain and anxiety. Journal of Consulting and Clinical Psychology, 50, 439-441.

Relaxation training, relaxation instructions, and an attention-redirection approach were compared with no treatment in terms of their ability to affect postsurgical anxiety and pain in patients undergoing gallbladder surgery. In addition, two hypotheses involving an interaction between treatment and locus of control were investigated. The results indicate that the attention-redirection approach reduced postsurgical anxiety relative to the other interventions. The effectiveness of attention redirection for reducing postoperative pain is more equivocal, whereas neither of the relaxation procedures reduced either anxiety or pain. Support was also found for one of the interaction hypotheses. The results support the effectiveness of brief interventions for reducing state anxiety associated with surgery but indicate that more intensive techniques may be necessary to affect postsurgical pain.

1980

Hurley, John D. (1980). Differential effects of hypnosis, biofeedback training, and trophotropic responses on anxiety, ego strength, and locus of control. Journal of Clinical Psychology, 36 (2), 503-507.

Pretested 60 college students on three scales: the IPAT Anxiety Scale, the Barron Ego-strength scale, and the Rotter I-E scale. The Ss then were assigned randomly to one of four treatment groups designated: hypnotic treatment, biofeedback treatment, trophotropic treatment, and control. Three of these groups met separately for 60 minutes once a week for 8 weeks. The control group did not meet during this time. During the sessions, each group was trained in a different technique for self-regulation. At the end of the 8-week period the scales were readministered to all groups. A series of covariance analyses indicated that hypnosis was a more effective self-regulatory technique for lowering anxiety levels when compared to biofeedback or trophotropic response procedures. With regard to increasing ego strength, both the hypnotic training group and the biofeedback training group proved to be significant. No significant difference was found between the experimental and control groups on the I-E scores.

Pereira, M. J.; Austrin, H. R. (1980). Locus of control and status of the experimenter as predictors of suggestibility. International Journal of Clinical and Experimental Hypnosis, 28 (4), 367-374.

The present study investigated locus of control and manipulated status of the experimenter as predictors of suggestibility. Rotter's (1966) Internal-External Locus of Control Scale was used as the paper-pencil measure of locus of control, and the Barber (1965) Suggestibility Scale was used as the measure of suggestibility. We predicted two main effects on suggestibility; one for high externality, and one for high status. In addition, we predicted an interaction between locus of control and status of experimenter. A main effect for locus of control was not found, but one for status was significant, with externals significantly more suggestible than internals in the high status experimenter condition and significantly less suggestible in the low status condition. This interaction effect was viewed as the most significant finding, and implications for prediction were discussed.

1979

Di Nardo, Peter A.; Raymond, Jayne B. (1979). Locus of control and attention during meditation. Journal of Consulting and Clinical Psychology, 47 (6), 1136-1137.

Undergraduates were assigned to an internal or external group on the basis of their locus of control scores. A meditation task required subjects to focus their attention on an actual stimulus or an imagined stimulus while recording intruding thoughts by pressing a button on a counter. Results showed that an internal locus of control was related to fewer intrusions than was an external locus and that the actual stimulus resulted in fewer intrusions than did the imagined stimulus. These results suggest that performance in meditation, and possibly in other self-control procedures, may be influenced by individual differences in deployment of attention.

1978

Zuroff, David C.; Schwarz, J. Conrad (1978). Effects of transcendental meditation and muscle relaxation on trait anxiety, maladjustment, locus of control, and drug use. Journal of Consulting and Clinical Psychology, 46 (2), 264-271.

Sixty undergraduate volunteers were randomly assigned to receive training in transcendental meditation (Transcendental meditation), training in a muscle relaxation technique, or no treatment. The training in muscle relaxation was designed to be maximally similar in structure and atmosphere to training in Transcendental meditation. Measures of trait anxiety, locus of control, maladjustment, and drug use were collected before and after the 9-week treatment period. On a behavioral measure of trait anxiety, the scores of all three groups decreased equally, but on a self-report measure the Transcendental meditation subjects reported steady decreases in anxiety, whereas the scores of the other two groups remained unchanged. There were no differences in maladjustment, locus of control, or drug use as a function of treatment. Although Transcendental meditation subjects held higher expectancies for benefits, and were slightly more regular in practicing their technique, individual differences in expectancy and frequency of practice were not correlated with degree of reported anxiety reduction. It is

concluded that Transcendental meditation may reduce trait anxiety, but it has not been shown to be of value in inducing general personality change.

**1976**

Miller, Lawrence J. (1976). A comparison of hypnotic susceptibility for internal and external locus of control subjects in hetero- and self-hypnotic treatments (Dissertation). Dissertation Abstracts International, 37, 978-979.

This study investigated the use of self- and hetero-hypnosis with internal and external locus of control subjects. Fifty-eight subjects, matched on hypnotic susceptibility and internal-external locus of control, were randomly assigned to the self- or hetero-hypnotic treatments. Self reports of their hypnotic behavioral scores and hypnotic subjective responses were obtained for each subject. "The statistical analyses showed there were no significant differences between the internal and external locus of control groups or within groups in regard to self- and hetero-hypnosis total behavioral scores, "challenge" or "non-challenge" items, ... their reported subjective experiences. The results supported the similarity of hetero- and self- hypnosis. Various findings from past research in regard to I-E subjects were also challenged in terms of their generalizability to hypnotic settings" (pp. 978-979).

**1975**

Bean, Bruce W.; Duff, James L. (1975). The effects of video tape, and of situational and generalized locus of control, upon hypnotic susceptibility. American Journal of Clinical Hypnosis, 18 (1), 28-33.

This study examined the effects of mode of induction (video tape vs. live), general locus of control, and situational locus of control upon hypnotic susceptibility. A total of 62 student volunteers was hypnotized in eight small groups using the Harvard Group Scale of Hypnotic Susceptibility. Results confirmed that video taped inductions were as effective as live inductions. None of the other variables, singly or in interaction, significantly affected susceptibility scores. An analysis of variance was also performed upon subjects' subjective ratings of having experienced hypnosis. Results revealed that subjects with an external general locus of control (Rotter's I-E scale) rated themselves as having experienced hypnosis more fully. This was interpreted as a greater response to the demand characteristics of the hypnosis situation by externally controlled subjects. Discussion explores the potential flexibility provided by video tape hypnosis.

### **Medical**

**1994**

Bloom Peter (1994, October). Training boundaries that enhance responsible therapy: Using hypnosis creatively in one's own discipline. [Paper] Presented at the

annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Presented three cases that he elected not to treat, to illustrate the principle that we should only treat cases we would be professionally trained to treat without hypnosis. (1) a hemorrhoidectomy patient, where he elected not to do hypnosis because he is not trained specifically in anesthesiology and didn't know how to do anesthesia procedures; (2) conversion hysteria in 12 year old girl, because he isn't trained in child psychiatry and doesn't know child development; (3) to confirm the supposed existence of unidentified flying objects, or UFOs (when a woman tried to get him to hypnotize her so the "truth" would emerge). We must free ourselves from treatment of patients who retreat from reality, when we can't find commonality in goals.

1993

Attias, J.; Shemesh, Z.; Sohmer, H.; Gold, S.; Shoham, C.; Faraggi, D. (1993). Comparison between self-hypnosis, masking and attentiveness for alleviation of chronic tinnitus. Audiology, 32, 205-212.

A total of 45 male patients close in age with chronic tinnitus related to acoustic trauma were assigned to three matched subgroups: self-hypnosis (SH), masking (MA), and attentiveness to the patients' complaints (AT). The therapeutic stimuli in the SH and MA sessions, recorded on audio cassettes, were given to the patients for use when needed. SH significantly reduced the severity of tinnitus, AT partially relieved the tinnitus, and MA had no significant effect.

Bejenke, Christel J. (1993, October). A clinician's perspective. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Presents point of view of a private practice anesthesiologist in Santa Barbara, California. Used hypnosis for 20 years.

Use of hypnosis as hypnoanesthesia is rare since Esdaile, with brief resurgence in 50's, because surgery techniques advanced before anesthetics did in areas that were very risky. Now it is a matter of choice, and may be undertaken because of a patient's extreme fear of anesthesia, previous bad experience with anesthesia, fervent belief in holistic method, allergy, or previous experience with hypnosis. Still advised to use hypnosis for MRIs, radiation procedures, former drug addicts (who may have problems with drugs), burn patients, release of neck contractions, and medical procedures--especially with children--like lumbar puncture.

She disagrees with Kroger's estimate of only 10% of patients being able to use hypnoanesthesia; she does not believe it requires a lot of training, or profound muscle relaxation.

There is no indication of how many cases are actually done with hypnosis. Also, published cases are not representative of the quantity or complexity of cases; most published cases have a few extraordinary characteristics. The Irish surgeon Jack Gibson has done more than 4000 cases, some very complicated.

I have used it for D & Cs, and complex cases that were not published. Most of my patients elected to be alert during the hypnosis and conversed with their surgeons. The most common benefit is that recovery from anesthesia is not necessary; but these days with newer anesthetics recovery from anesthesia is rapid anyway. However, if as we suspect anesthesia affects immune function, that would be another reason to use hypnosis.

The most common benefit is that recovery from anesthesia is not necessary; but these days with newer anesthetics recovery from anesthesia is rapid anyway. However, if as we suspect anesthesia affects immune function, that would be another reason to use hypnosis.

Preparation for surgery may be of three types: 1. formal hypnosis techniques 2. "hypnoidal" techniques that aren't formal 3. unprepared patients in whom hypnosis is used at last moment.

Examples. 1. Formal hypnosis: This symposium deals with this type of approach. Three groups derive particular benefit -- those requiring prolonged artificial ventilation postoperatively (because otherwise sedation must be used, which leads to complications), where prepared patients tolerate interventions calmly and comfortably -- cancer patients, for whom this can be first experience of patient to see self as active participant in care rather than a victim of the illness and of complicated technology -- pediatric patients. 2. Hypnoidal (hypnosis like) techniques: This is the most important application. Time doesn't permit much discussion here. Patients are in an altered state when they come for surgery, highly suggestible, and suggestions appear to be as effective as during formal trance state. The doctor can elicit positive responses during "casual conversation" while seemingly giving information to the patient. (The reverse is true also, with inadvertent negative suggestions, to the detriment of the patient.) Scrupulous adherence to medical facts is important during this type of conversation.

Operating room fixtures are useful for focus of attention, and I have published this information in an article.

Recovery room also is place where case specific information and appropriate suggestions can be given. Patient can experience his ability to alter sensations, for the first time, following suggestions.

Remainder of the hospitalization offers opportunity for reinforcing case specific positive suggestions.

1992

Blankfield, Robert; Scheurman, Kathleen; Bittel, Sue; Alemagno, Sonia; Flocke, Sue; Zyzanski, Stephen (1992, October). Tapd therapeutic suggestions and tapd music as adjuncts in the care of coronary artery bypass graft patients. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

18 studies have explored the issue with an experimental design; half used tapes, half didn't; majority of studies found benefits; 2 were of heart surgery patients.

This study used taped suggestions with coronary bypass patients. Used tape recorder rather than person delivering suggestions because it was more convenient; used tape intra-surgery and post-operatively for more impact.

We hypothesized: shorter length of stay, less narcotic analgesia, less anxiety, faster recovery, more positive mental outlook, resume activities sooner, have less symptoms postoperatively, etc.

Used a prospective, randomized, single-blind trial in 2 community hospitals in Cleveland with coronary artery bypass graft surgery patients. Study was done between Dec 1989 - Feb 1992.

3 groups were involved: (1) Suggestion, (2) music, and (3) tape. Control subjects had a blank tape. Tapes were played continuously and repeatedly with headphones. Postoperatively, a different tape was played.

Excluded: Patients with emergent surgery, hearing impairment, poor comprehension of English, patients who died in hospital, patients whose hospital stay lasted longer than 14 days (3 of them). 5% of sample were eliminated for last 2 reasons.

Music: Herb Ernst, Dreamflight II. Suggestions: Music background, permissive, based on Evans & Richardson's study.

Outcome Measures: Nurse assessment of anxiety and progress post operatively, Symptom scale, Depression scale.

Mean age 62, 3/4 men, 92% white, 75% married. The groups were same on a variety of preoperative variables (status of heart and arteries). Length of stay was 6.5 in all 3 groups. No difference in narcotics use, in nurse assessment of anxiety or of progress; of depression scale, or activities of daily living.

Recategorized data into patients who said the tapes were helpful (both music and suggestion) N = 33 vs the other patients N = 62. No difference in the variables evaluated.

**Bierman, Steven F. (1989). Hypnosis in the emergency department. American Journal of Emergency Medicine, 7, 238-242.**

Five cases are presented wherein hypnosis was used by the emergency physician either as the primary mode of treatment or as an adjuvant to standard medical care. Common hypnotic phenomena (e.g. anesthesia, analgesia), as well as novel effects, are reported. The technique used for trance induction and utilization is briefly outlined, and criteria are set forth for the bedside recognition of hypnotic trance.

**1984**

**Brown, Erick L.; Kinsman, Robert A. (1984). Resolving intractable medical problems through psychological intervention: A clinical report. Psychotherapy, 21, 452-455.**

Treatment of chronic physical illness is often complicated by psychological factors that maintain and exacerbate the illness. Hypnotic techniques, coupled with insight-oriented psychotherapy comprised an effective strategy for favorably influencing medical outcome. A clinical report illustrates how psychological intervention initiated the resolution of severe medical problems in an asthmatic patient.

**1977**

**Albornoz-Ruiz, Jose M. (1977). Suggestibility as a factor in medical treatment. Maryland State Medical Journal, 26, 66-68.**

This paper presents the view that a physician must be aware of the great influence, direct and indirect, s/he has with the patient as a result of their relationship. "Here it should be remembered that the power of a suggestion, without the benefit of formalized hypnosis, is directly related to the intensity and nature of the emotional bond between the patient and the doctor, often colored by a marked transference unconscious component, where the doctor stands 'in loco parentis' vis-a-vis the patient, regardless of the age, education or intellectual sophistication of the latter. Whatever the nature of the perception that is eventually presented by the patient as a symptom or identified by the doctor as a sign of illness, such perception will be elaborated upon by the patient's fancy, in lonely reveries where he defines for himself causes, nature and possible course of his disorder, not always in keeping with those established by the doctor as he exposes the same set of phenomena to his learned medical judgment" (p. 68).

**Barber, Joseph (1977). Rapid induction analgesia: A clinical report. American Journal of Clinical Hypnosis, 19, 138-149.**

This is a report of clinical dental experience using a newly developed, hypnotic pain control procedure. Characteristics of the procedure are outlined, an explanation for its success is suggested, and the broader implications of this success are discussed. The unusually high incidence of clinical analgesia rapidly obtained with this procedure leads the author to question the meaning and relevance of the concept of 'hypnotic susceptibility' for the practical clinical application of hypnosis.

1975

Carli, G. (1975). Some evidence of analgesia during animal hypnosis [Abstract]. Experimental Brain Research, 23, 35.

The purpose of this study was to investigate the response to painful stimuli during animal hypnosis. The experiments were performed on unanesthetized, free-moving rabbits carrying implanted electrodes for recording the EEG and EMG activity and nerve stimulation. Injection of formaline into the dorsal region of the foot produced long lasting EEG desynchronization and motor pain reactions. In some rabbits a procedure of habituation was used to reduce hypnosis duration below 45 sec. Hypnosis was induced by inversion. The following results were obtained: 1) Polysynaptic reflexes elicited [sic] by electrical stimulation of cutaneous and muscle afferents were depressed during hypnosis. 2) Hypnosis transitorily suppressed all the painful manifestations due to formaline injection and was characterized by high [sic] voltage slow wave activity in the EEG, 3) In habituated rabbits, a significant increase in hypnotic duration and EEG synchronization was observed when hypnosis was preceded by formaline injection. Hypnosis duration was not potentiated by painful stimuli when Naloxone (5mg/Kg i.v.) was injected before hypnosis induction. 4) In habituated rabbits a recovery in hypnotic duration coupled to EEG synchronization was obtained, in absence of painful stimuli, following subanalgesic injection of Morphine (1mg/Kg). It has been previously shown that in the rabbit administration of 5-20 mg/Kg of Morphine produces EEG synchronization and strong reduction of pain reactions. It is suggested that, during animal hypnosis in a condition of continuous nociceptive stimulation, the pain response is blocked by a mechanism which exhibit [sic] similar effects of Morphine both at spinal cord (polysynaptic reflexes) and at cortical levels (EEG synchronization).

Bowers, Kenneth S.; Kelly, P. (1970). Stress, disease, psychotherapy, and hypnosis. Journal of Abnormal Psychology, 490-505.

Presents evidence for the importance of suggestion and hypnotic ability in the healing or amelioration of various somatic disorders. It is argued that even in some treatment interventions that are not explicitly hypnotic, suggestion and hypnotic ability may be hidden factors that help to promote successful healing. Consequently, hypnotic ability may be an individual difference variable that influences treatment outcome in a manner not heretofore recognized by many investigators and clinicians involved in helping the psychologically and physically ill.

promote successful healing. Consequently, hypnotic ability may be an individual difference variable that influences treatment outcome in a manner not heretofore recognized by many investigators and clinicians involved in helping the psychologically and physically ill.

1968

Bartlett, K. A. (1968). A rationale of the nature of hypnosis. American Journal of Clinical Hypnosis, 11, 112-118.

A rationale of the nature of hypnosis without formal trance induction is presented. Central to this viewpoint is meeting the needs of the patient in accord with his perception of them and in a manner based on patient-oriented treatment. Case material illustrates practical applications.

British Tuberculosis Association (1968). Hypnosis for asthma: A controlled trial: A report to the research committee of the British Tuberculosis Association. British Medical Journal, 71-76.

**Summary:** An investigation of hypnosis in asthma was made among patients aged 10 to 60 years with paroxysmal attacks of wheezing or tight chest capable of relief by bronchodilators. One group of patients was given hypnosis monthly and used autohypnosis daily for one year. Comparisons were made with a control group prescribed a specially devised set of breathing exercises aimed at progressive relaxation. Treatment was randomly allocated and patients were treated by physicians in nine centres. Results were assessed by daily diary recordings of wheezing and the use of bronchodilators, and by monthly recordings of F.E.V. and vital capacity. At the end of the year independent clinical assessments were made by physicians unaware of the patients' treatment.

There were 252 patients (127 hypnosis and 125 controls) accepted for analysis, but a number of them did not continue the prescribed treatment for the whole year: 28 hypnosis and 22 control patients failed to cooperate, left the district, or had family problems; one hypnosis and one control patient died. Seven hypnosis and 17 control patients were withdrawn as treatment failures, the difference between the two groups being statistically significant.

As judged by analyses based on the daily "score" of wheezing recorded in patients' diaries, by the number of times bronchodilators were used, and by independent clinical assessors, both treatment groups showed some improvement. Among men the assessments of wheezing score and use of bronchodilators showed similar improvement in the two treatment groups; among women, however, those treated by hypnosis showed improvement similar to that observed in the men, but those given breathing exercises made much less progress, the difference between the two treatment groups reaching statistical significance. Changes in F E.V. and V.C. between the control and hypnosis groups were closely similar.

Independent clinical assessors considered the asthma to be "much better" in 59% of the hypnosis group and in 43% of the control group, the difference being

significant. There was little difference between the sexes. Physicians with previous experience of hypnosis obtained significantly better results than did those without such experience.

Bernstein, Norman R. (1965). Observations on the use of hypnosis with burned children on a pediatric ward. International Journal of Clinical and Experimental Hypnosis, 13 (1), 1-10.

Several cases are described and observations made about the interplay of forces between staff, patient, and therapist, as well as the expectations of the patients to assess how these factors influenced the use of hypnosis. Hypnosis appears to be a particularly useful means for reaching isolated and depressed children with burns and for improving the morale of the staff team working with these children. The results may be along specific lines in terms of pain tolerance and improved eating, or in general improvement of cooperativeness and mood on the part of the child. Attar, A.; Muftic, M. (1964). Narcohypnosis in abdominal surgery. British Journal of Medical Hypnotism, 16 (1), 29-32.

Effectiveness of a relaxation technique to increase the comfort level of patients in their first postoperative attempt at getting out of bed was tested on 42 patients, aged 18 to 65, who were hospitalized for elective surgery. Study group patients were taught the relaxing technique; control group patients were not taught the technique. Each group had an equal distribution of cholecystectomy, herniorrhaphy, and hemorrhoidectomy patients. Blood pressure, pulse, and respiratory rates of subjects in both groups were compared prior to surgery and after the postoperative attempt to get out of bed. Subjects' reports of incisional pain and bodily distress were measured via a pain and distress scale after their attempt at getting out of bed. Amount of analgesics used in the first 24 hrs following surgery was examined. Mean differences in report of incisional pain and body distress, analgesic consumption, and respiratory rate changes were statistically significant, supporting the hypothesis that use of a relaxation technique to reduce muscular tension will lead to an increased comfort level of postoperative patients.

Cedercreutz, Claes (1961). Hypnosis in surgery. International Journal of Clinical and Experimental Hypnosis, 9, 93-95.

(Author's Summary) "It is possible to treat painful conditions and spasms in the alimentary canal by hypnosis. In the rehabilitation of patients with limb injuries and fractures, hypnosis has also proved useful. There is seldom reason to resort to this method of inducing anaesthesia in surgery" (p. 95).

**Meditation/Yoga**

2003

Holroyd, Jean (2003). The science of meditation and the state of hypnosis. American Journal of Clinical Hypnosis, 46 (2), 109-128.

Two aspects of Buddhist meditation -- concentration and mindfulness -- are discussed in relationship to hypnosis. Mindfulness training facilitates the investigation of subjective responses to hypnosis. Concentration practice leads to altered states similar to those in hypnosis, both phenomenologically and neurologically. The similarities and differences between hypnosis and meditation are used to shed light on perennial questions: (1) Does hypnosis involve an altered state of consciousness? (2) Does a hypnotic induction increase suggestibility? It is concluded that a model for hypnosis should include altered states as well as capacity for imaginative involvement and expectations.

1999 Wickramasekera, Ian (1999). How does biofeedback reduce clinical symptoms and do memories and beliefs have biological consequences? Toward a model of mind-body healing. Applied Psychophysiology and Biofeedback, 24 (2), 91-105.

Changes in the magnitude and direction of physiological measures (EMG, EEG, temperature, etc.) are not strongly related to the reduction of clinical symptoms in biofeedback therapy. Previously, nonspecified perceptual, cognitive, and emotional factors related to threat perception (Wickramasekera, 1979, 1988, 1998) may account for the bulk of the variance in the reduction of clinical symptoms. The mean magnitude of these previously nonspecified or placebo factors is closer to 70% when both the therapist and patient believe in the efficacy of the therapy. This powerful placebo effect is hypothesized to be an elicited conditioned response (Wickramasekera, 1977a, 1977c, 1980, 1985) based on the memory of prior healing. These memories of healing are more resistant to extinction if originally acquired on a partial rather than continuous reinforcement schedule. High and low hypnotic ability in interaction with threat perception (negative affect) is hypothesized to contribute to both the production and reduction of clinical symptoms. High and low hypnotic ability respectively are hypothesized to be related to dysregulation of the sympathetic and parasympathetic arms of the autonomic nervous system. Biofeedback is hypothesized to be the most effective for reducing clinical symptoms in people of low to moderate hypnotic ability. For people high in trait hypnotic ability, training in self-hypnosis or other instructional procedures (e.g., autogenic training, progressive muscle relaxation, meditation, CBT, etc.) will produce the most rapid reduction in clinical symptoms.

1998

Easterlin, Barbara L.; Cardena, Etzel (1998-99). Cognitive and emotional differences between short- and long-term Vipassana meditators. Imagination, Cognition and Personality, 18 (1), 69-81.

This study compared perceived stress and cognitive and emotional differences between two groups of Buddhist mindfulness [Vipassana] meditators. Nineteen beginning and twenty-four advanced meditators carried electronic pagers for five days and responded to daily random signals by completing an Experience Sampling form (ESF) containing items related to the dependent variables. As compared with beginners, advanced practitioners reported greater self-awareness, positive mood, and acceptance. Greater stress lowered mood and self-acceptance in both groups, but the deleterious effect of stress on acceptance was more marked for the beginners. These findings validate in a naturalistic setting some of the effects described in traditional Buddhist texts on mindfulness.

so precise that what was "I" is deconstructed into evanescent flux, into thoughts, images, emotions (like a movie with solitary frames); the yogi dissolves the self sense, but because of fixed concentration the separate self disappears and yogis feel like merging with larger Self.

So now for first time in history we can compare and map both similarities and differences. Now we have new possibilities for understanding and contrasting different practices. We can now differentiate the many states of consciousness that are available. But there are an awful lot of states. Can we find an over-arching framework? For the first time, we can say yes--due to the work of Ken Wilber. This is Developmental Structuralism (looking for common deep structures).

For example, you can identify millions of different faces, and they are surface structures; but they all have a common deep structure. Likewise, if we see that a Hindu creates images of [devas] and a Christian sees saints, they are seeing archetypal images. Likewise, Buddhists experience nirvana in which all phenomena disappear, and so does another group. This [sense of all phenomena disappearing] is common to both, but different from those who see archetypal images. We may be able to come up with a typology of altered states.

Wilber also says that these deep structures and corresponding states may develop in a developmental sequence, with common stages. Three transpersonal stages are subtle, causal, and non-dual. In meditation, first you learn how out of control the mind is, then gradually it quiets and you discover subtle experiences that you usually overlooked. Going further, all thoughts cease to arise, and there is only pure consciousness. Beyond that, images re-arise but are now recognized as projections of consciousness.

Subtle images may be formless (as in pure light, pure sound). The person may pay attention to more and more subtle sounds. Or the images may have form (as in shamanic power animals).

At the casual stage, the person may be aware of consciousness itself, only consciousness, with no objects: pure consciousness, void, the Atman of Vedanta, abyss of gnosticism.

At the non-dual stage, objects arise again: everything is recognized as expressions of consciousness--e.g., Zen's "one mind." Consciousness now has awoken and sees itself in all things, unbounded by space and time and limits because consciousness is what creates space, time, and limits. This is Moksha, Enlightenment, etc.

This is not the final task, because the final task is bringing the awakening to the world (Plato's re-entering the cave, to educate others; Zen oxherder entering the

marketplace with help-bestowing hands; Christianity's "fruitfulness of the soul"). For Joseph Campbell, this was the hero's return. Toynbee observed that each great contributor had withdrawn and then returned to the world to offer what they had found.

[It is a process of] transforming a peak into plateau experience; an altered state into a trait; stabilized into enduring understanding, and then bringing it back into the world.

Is there evidence for enlightenment? There now is analogical and laboratory support for this. Analogical support is lucid dreaming. Until 20 years ago, Western psychology thought lucid dreaming was impossible, but now LaBerge at Stanford University has shown physiological evidence. We know from every night's experience that we can create worlds and bodies on which our lives seem to depend. The claim of spiritual traditions is that there is a state of consciousness that bears a relationship to the ordinary [waking] state as lucid dreaming has to nonlucid dreaming. The Dalai Lama said they train yogis to be aware during dreams, not to lose awareness 24 hours a day; then to be aware of dreaming while in a waking period. A Tibetan dream yoga aim is the "great realization," that everything in existence is like a dream.

Laboratory studies have been done on enlightened people. The EEG data obtained while they are sleeping is consistent with lucidity during their dreams and between dreams. Rorschach tests have been done on advanced Buddhist meditators; at the penultimate of enlightenment, they show no evidence of conflicts around sexuality and aggression. The 2000 year old Buddhist texts say that at this stage these issues are resolved.

The implications for our usual state are that normality is not the peak of human development; normality is arrested development. The link between apes and civilization is us! We experience a consensus trance, a collective psychosis, society's hypnosis. We live in the biggest cult of all: CULTURE. The answer is, "Wake up."

A most important question is, if it is true that our conventional state of development is suboptimal, how do we develop other states? The classic answer is: take up a discipline, a practice (e.g., meditation, service, being in nature). One problem is that spiritual traditions are usually couched in archaic language, and have accumulated nonsense around them over the years. It is desirable to abstract out the essential elements. That is a recent thrust of transpersonal research.

There are six common elements: 1. Ethics: the moment you sit down to meditate, what emerges is all the unethical stuff you've done and what was done to you. Ethical behavior (not conventional morality) is a tool for mind training. 2. Attentional training: ordinarily we cannot sustain attention. (William James said the maximum is 3 seconds.) The aim is to be able to maintain attention on what one wants. It leads to the stabilization of mind, calming. 3. Emotional training: destroying negative emotions (well developed in Western psychology, maybe better than in the Eastern traditions, because we recognize the problem with repression); cultivating positive emotions (where contemplative practices do well, because they offer tools for unwavering, unconditional, and all-encompassing [positive regard]; what is known as *agape* in Christianity). 4. Redirection of motivation: changing what you want, etc. 5. Perceptual refinement: we mistake shadows for realities;

according to St. Paul we "see through a glass darkly." This enhances sensitivity, accuracy, and subtlety of perception. 6. Wisdom: actually the first element, playing a role all through the path. Initial motivation sees suffering of the world; provides motivation for realizing that there must be another way of living, culminates with deep insight into nature of the world, mind, consciousness, reality (prajna; Christian's gnosis). When the mind is trained, stabilized, and clarified, the mind has a heightened capacity for understanding.

So for the first time we can recognize the common elements in religions; we can see that the contemplative core contain practices and road maps. This approach recognizes multi-state psychologies and philosophies.

**APPLICATION.** Many areas of research are developing in transpersonal psychology. These studies have implications for the state of the world. It is only 25 years since the founding of transpersonal psychology. The world's population has developed to the extent that every four months we are losing as many people from malnutrition as from a Holocaust. Our problems are still solvable. The best population explosion control is to make education available to women in the Third World. The transpersonal vision gives a frame to recognize that we are all connected.

For a fuller account of transpersonal psychology, see R. Walsh & F. Vaughan (Eds). (1993) *\_Paths Beyond Ego: The Transpersonal Vision.\_* New York: Tarcher/Putnam.

Zika, William (1991, January). Hidden observer in psychotherapy. [Lecture] Seminar in the UCLA Department of Psychiatry and Biobehavioral Sciences.

Author has explored use of a "hidden observer" metaphor in psychotherapy. He distinguishes between two types of dissociation--that resulting from involvement in fantasy and imagery (separation from the Generalized Reality Orientation described by R. Shor) and that between the "I" and the Observer. He calls the latter nonattachment instead of dissociation, aligning it with meditation concepts. The observer, in the hypnotized patient, is objective and even more in touch with reality than the patient in the waking state. He likens the Observer to Erickson's Inner Self, noting that just as patients learn to allow the therapist to care for them, they can come to allow the Observer to care for them. During inductions he speaks of the Hidden Observer (H.O.) that always knows what is going on, giving a suggestion that the H.O. can be helpful. (This concept seemingly relates also to the observer in Multiple Personality Disorder, and to John Kihlstrom's discussion of William James and the self, as well as to amnesia/duality in age regression or duality (HO) in pain control.)

1990

Hughes, Dureen J.; Melville, Norbert T. (1990). Changes in brainwave activity during trance channeling: A pilot study. Journal of Transpersonal Psychology, 22, 175-189

Authors studied 10 people known trance channels--all had been channeling for more than one year. Used an anthropological field method. Electrode was placed only on left occipital (O1) area, referenced to left ear. Calculated difference between each S's pre- trance and trance EEG beta percentages, for alpha and theta percentages also.

Basically, the pre-trance versus trance sums of differences scores were greater than the post-trance versus trance sums of different scores for each of the three frequency bands--indicating a residual of the trance state. There were large, statistically significant increases in amount and percentage of beta, alpha and theta brainwave activity, and some suggestion of a pattern. The large amount of beta differentiates these Ss from what has been observed with meditators (increases in alpha and theta). Among the Subjects, large amounts of beta activity were recorded continuously throughout the trance period and were coupled with large amounts of high amplitude alpha and theta (relative to the pre- and post-trance states).

The authors compare these results to older hypnosis literature. They conclude that the trance channeling state may be a distinctive state characterized by a particular EEG profile that differs from that found in certain meditative states, hypnotic states, various pathological states, or the waking states of the trance channel Subjects who participated in the study. Authors also liken the differences seen between trance and non-trance states of these Subjects to the differences seen for different alter personalities among people diagnosed with Multiple Personality Disorder.

**DISCUSSION.** The foregoing research suggests that the trance channeling state, as measured in the current study, is characterized by large, statistically significant increases in amount and percentage of beta, alpha and theta brainwave activity. There appear to be definite neurophysiological correlates to the trance channeling state, and furthermore there is some evidence that these correlates may be patterned. This pattern might be provisionally compared to those associated with other altered states of consciousness.

both groups, but the deleterious effect of stress on acceptance was more marked for the beginners. These findings validate in a naturalistic setting some of the effects described in traditional Buddhist texts on mindfulness.

"Meditation can be defined as the deliberate deployment of mental attention to obtain a particular patterning of consciousness. The aim of such control may be the stabilization of the stream of thought, greater relaxation, the attainment of an altered state, or the development of insights into the nature of mind [12]. Mindfulness meditation has sometimes been contrasted with concentration meditation as one of two main forms of meditation practice [13, 14]. The usual distinction is that mindfulness involves opening awareness to all contents and processes of mind, whereas concentrative forms of meditation involve shutting out

all stimuli extraneous to a single object of attention" (p. 70). Long-term meditators averaged 103 months and 85 days of retreat training. They did not differ from short-term meditators on measures of absorption, neuroticism, trait anxiety, or cognitive style; however they evidenced greater self-awareness and acceptance. The short-term meditators actually had more than a year of meditation experience so that differences between groups are not likely to be due to self-selection. The authors conclude that "meditation brings about sustainable changes in people's lives, above and beyond relaxation. ... [and] that greater conscious awareness through mindfulness techniques such as Vipassana meditation, increases acceptance, positive mood, and the ability to dispassionately observe one's mental states. These results have implications for clinical issues such as pain management and psychotherapy, in which acceptance and awareness are necessary ingredients for therapeutic change" (p. 78). JH

Jana, Hrishikesh (1997). The development of hypnosis in India. [Unpublished manuscript]

Yoga (specially Meditative Yoga or Savasana) and Transcendental Meditation are integral parts of the cultural heritage of Indians. These and the state of hypnosis possess some of the characteristics in common and all these have been grouped under the heading 'Altered States of Consciousness' by the modern psychophysiological and biological researchers. Hindu saints used to clothe sparsely even in the midst of extreme environmental conditions and the lying down of some yogis on the nail-bed are examples of their super-human tolerance to cold, pain, etc." (p. 2). Author cites the pioneering work of Dr. James Esdaile using hypnosis for surgical anaesthesia at Hooghly Hospital (1845-1850). Despite India's culture and the record of Dr. Esdaile, hypnosis often was regarded with suspicion in India. In the early and mid-20th century, physicians (e.g. Dr. N.V. Mody, an obstetrician) had difficulty having their work accepted, but since the early 1970s Dr. Jana and others have contributed to a renaissance in the use of medical, dental, and psychological hypnosis. This paper chronicles the history of hypnosis in the late 20th century in India.

Reader, August L. (1994). The internal mystery plays: The role and physiology of the visual system in contemplative practices. ReVision: A Journal of Consciousness and Transformation, 17 (1).

Walsh, Roger (1994, August). Transpersonal psychology--the state of the art. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

Twenty-five years ago a group formed that was called transpersonal psychology, following after humanistic psychology (e.g. Maslow). Some of the humanistic psychologists came into transpersonal psychology. Maslow was interested in healthy people, and in peak experiences that were transpersonal in nature--experiences encompassing wider aspects of life, including mystical experiences.

Peak experiences were thought to be positive, but also overwhelming. When psychologists looked Eastward, they found that there were whole families of these types of experiences, and that they could be induced by will and could be stabilized into not only peak but plateau experiences. There was a reservoir of wisdom in the world's religions that could be drawn upon. This wisdom is being integrated with Western science to create the discipline of transpersonal psychology.

There is a broad spectrum of altered states of consciousness. Traditionally, altered states of consciousness were thought to be few in number, and usually pathological. Our society has been resistant toward studying them. For example, Esdaile's use of hypnosis in surgery was not welcomed, even though he was lowering morbidity and mortality because he controlled shock. His paper was turned down for publication. He amputated a leg in front of colleagues in Britain, who commented that he "must have hired a very hard rogue" to have his leg cut off under hypnosis.

Our culture is monophasic, deriving its world view almost exclusively from the waking state; other cultures are polyphasic and also draw their world view from dreams, meditative, or yogic contemplative states, etc. Recently we can apply more sophisticated analyses, to compare states of consciousness and map these out, phenomenologically. There are several key dimensions of experience for mapping the states: 1. Control 2. Awareness of Environment 3. Concentration 4. Mental Energy/Arousal 5. Emotion 6. Identity or Self Sense 7. Out-of-Body Experience 8. Content of Experience

Using these dimensions, we could compare shamanic, yogic, and Buddhist practices. A Nepalese shaman drums himself into a trance state, demonstrating: 1. Ability to enter and leave an altered state of consciousness and partly control experience 2. Decreased awareness of his environment 3. Increased concentration, fluid attention 4. Increased mental energy/arousal 5. Either pleasurable or not [pleasurable] emotion 6. Separate self sense: may be experienced as a non-physical "spirit" or "soul" 7. Controlled ecstasy (Out of Body experience)

Buddhist meditation is training awareness to examine experience as minutely as possible, in effect a heightened awareness (Vipassana).

A yogic practitioner engages in concentration, focusing on a fixed stimulus and holding it unwaveringly, till it dissolves a sense of separation into a unity with the object, ultimately with the Self.

[Author showed a slide comparing the three.] All three approaches have increased control and concentration. (The Yogi's is unshakable.) An awareness of the environment is increased for the Buddhist; the Yogi may lose awareness entirely. Others have ecstatic experience; the yogi has enstatic experience. Identity for the shaman is separate (a soul); for the Buddhist awareness is so precise that what was "I" is deconstructed into evanescent flux, into thoughts, images, emotions (like a movie with solitary frames); the yogi dissolves the self sense, but because of fixed

concentration the separate self disappears and yogis feel like merging with larger Self.

So now for first time in history we can compare and map both similarities and differences. Now we have new possibilities for understanding and contrasting different practices. We can now differentiate the many states of consciousness that are available. But there are an awful lot of states. Can we find an over-arching framework? For the first time, we can say yes--due to the work of Ken Wilber. This is Developmental Structuralism (looking for common deep structures).

For example, you can identify millions of different faces, and they are surface structures; but they all have a common deep structure. Likewise, if we see that a Hindu creates images of [devas] and a Christian sees saints, they are seeing archetypal images. Likewise, Buddhists experience nirvana in which all phenomena disappear, and so does another group. This [sense of all phenomena disappearing] is common to both, but different from those who see archetypal images. We may be able to come up with a typology of altered states.

Wilber also says that these deep structures and corresponding states may develop in a developmental sequence, with common stages. Three transpersonal stages are subtle, causal, and non-dual. In meditation, first you learn how out of control the mind is, then gradually it quiets and you discover subtle experiences that you usually overlooked. Going further, all thoughts cease to arise, and there is only pure consciousness. Beyond that, images re-arise but are now recognized as projections of consciousness.

Subtle images may be formless (as in pure light, pure sound). The person may pay attention to more and more subtle sounds. Or the images may have form (as in shamanic power animals).

At the casual stage, the person may be aware of consciousness itself, only consciousness, with no objects: pure consciousness, void, the Atman of Vedanta, abyss of gnosticism.

At the non-dual stage, objects arise again: everything is recognized as expressions of consciousness--e.g., Zen's "one mind." Consciousness now has awoken and sees itself in all things, unbounded by space and time and limits because consciousness is what creates space, time, and limits. This is Moksha, Enlightenment, etc.

This is not the final task, because the final task is bringing the awakening to the world (Plato's re-entering the cave, to educate others; Zen oxherder entering the marketplace with help-bestowing hands; Christianity's "fruitfulness of the soul"). For Joseph Campbell, this was the hero's return. Toynbee observed that each great contributor had withdrawn and then returned to the world to offer what they had found.

[It is a process of] transforming a peak into plateau experience; an altered state into a trait; stabilized into enduring understanding, and then bringing it back into the world.

Is there evidence for enlightenment? There now is analogical and laboratory support for this. Analogical support is lucid dreaming. Until 20 years ago, Western psychology thought lucid dreaming was impossible, but now LaBerge at Stanford University has shown physiological evidence. We know from every night's experience that we can create worlds and bodies on which our lives seem to depend.

The claim of spiritual traditions is that there is a state of consciousness that bears a relationship to the ordinary [waking] state as lucid dreaming has to nonlucid dreaming. The Dalai Lama said they train yogis to be aware during dreams, not to lose awareness 24 hours a day; then to be aware of dreaming while in a waking period. A Tibetan dream yoga aim is the "great realization," that everything in existence is like a dream.

Laboratory studies have been done on enlightened people. The EEG data obtained while they are sleeping is consistent with lucidity during their dreams and between dreams. Rorschach tests have been done on advanced Buddhist meditators; at the penultimate of enlightenment, they show no evidence of conflicts around sexuality and aggression. The 2000 year old Buddhist texts say that at this stage these issues are resolved.

The implications for our usual state are that normality is not the peak of human development; normality is arrested development. The link between apes and civilization is us! We experience a consensus trance, a collective psychosis, society's hypnosis. We live in the biggest cult of all: CULTURE. The answer is, "Wake up."

A most important question is, if it is true that our conventional state of development is suboptimal, how do we develop other states? The classic answer is: take up a discipline, a practice (e.g., meditation, service, being in nature). One problem is that spiritual traditions are usually couched in archaic language, and have accumulated nonsense around them over the years. It is desirable to abstract out the essential elements. That is a recent thrust of transpersonal research.

There are six common elements: 1. Ethics: the moment you sit down to meditate, what emerges is all the unethical stuff you've done and what was done to you. Ethical behavior (not conventional morality) is a tool for mind training. 2. Attentional training: ordinarily we cannot sustain attention. (William James said the maximum is 3 seconds.) The aim is to be able to maintain attention on what one wants. It leads to the stabilization of mind, calming. 3. Emotional training: destroying negative emotions (well developed in Western psychology, maybe better than in the Eastern traditions, because we recognize the problem with repression); cultivating positive emotions (where contemplative practices do well, because they offer tools for unwavering, unconditional, and all-encompassing [positive regard]; what is known as agape in Christianity). 4. Redirection of motivation: changing what you want, etc. 5. Perceptual refinement: we mistake shadows for realities; according to St. Paul we "see through a glass darkly." This enhances sensitivity, accuracy, and subtlety of perception. 6. Wisdom: actually the first element, playing a role all through the path. Initial motivation sees suffering of the world; provides motivation for realizing that there must be another way of living, culminates with deep insight into nature of the world, mind, consciousness, reality (prajna; Christian's gnosis). When the mind is trained, stabilized, and clarified, the mind has a heightened capacity for understanding.

So for the first time we can recognize the common elements in religions; we can see that the contemplative core contain practices and road maps. This approach recognizes multi-state psychologies and philosophies.

APPLICATION. Many areas of research are developing in transpersonal psychology. These studies have implications for the state of the world. It is only 25

years since the founding of transpersonal psychology. The world's population has developed to the extent that every four months we are losing as many people from malnutrition as from a Holocaust. Our problems are still solvable. The best population explosion control is to make education available to women in the Third World. The transpersonal vision gives a frame to recognize that we are all connected.

For a fuller account of transpersonal psychology, see R. Walsh & F. Vaughan (Eds). (1993) \_Paths Beyond Ego: The Transpersonal Vision.\_ New York: Tarcher/Putnam.

percentage of beta, alpha and theta brainwave activity. There appear to be definite neurophysiological correlates to the trance channeling state, and furthermore there is some evidence that these correlates may be patterned. This pattern might be provisionally compared to those associated with other altered states of consciousness.

1989

Eppley, Kenneth R.; Abrams, Allan I.; Shear, Jonathan (1989). Differential effects of relaxation techniques on trait anxiety: A meta-analysis. Journal of Clinical Psychology, 45, 957-974.

Conducted a meta-analysis of studies on the effects of relaxation techniques on trait anxiety. Effect sizes for the different treatments (e.g., progressive relaxation, biofeedback, meditation) were calculated. Most treatments produced similar effect sizes, although transcendental meditation (TM) produced a significantly larger effect size than other forms of meditation and relaxation. A comparison of the content of the treatments and their differential effects suggests that this may be due to the lesser amount of effort involved in TM. Meditation that involved concentration had a significantly smaller effect than progressive relaxation.

Soskis, D. A.; Orne, E. C.; Orne, M. T.; Dinges, D. F. (1989). Self-hypnosis and meditation for stress management: A brief communication. International Journal of Clinical and Experimental Hypnosis, 37, 285-289.

In a 6-month follow-up study, telephone interviews were conducted with 31 male executives who were taught either a self-hypnosis or meditation exercise as part of a stress-management program. Use of and problems with the 2 exercises were similar, with the percentage of Ss using the techniques falling over 6 months from 90% to 42%. The exercises were used primarily for physical relaxation, refreshing mental interludes, aiding sleep onset, and stress-reduction. Problems with the exercises chiefly involved difficulty in scheduling even brief uninterrupted practice times and discomfort with the techniques. The incorporation of these issues into the clinical teaching of self-hypnosis may be useful.

1985

Delmonte, Michael M. (1985). Meditation and anxiety reduction: A literature review. Clinical Psychology Review, 5 (2), 91-102.

Reviews the literature concerning the effects of meditation on self-reported anxiety levels, with emphasis on forms of meditation (e.g., transcendental and Zen meditation) in which a person's attention is focused. It is noted that meditation is increasingly being practiced as a therapeutic technique and that the effects of practice on psychometrically assessed anxiety levels have been extensively researched. Prospective meditators tend to report above average levels of anxiety. Methodological issues involving the measurement of anxiety levels are examined, and it is noted that reductions in self-reported anxiety are not always accompanied by decrements in behavioral or physiological measures of anxiety. In general, high anxiety levels predict a subsequent low frequency of practice. However, the evidence suggests that those who practice regularly tend to show significant decreases in anxiety. Meditation does not appear to be more effective than comparative interventions in reducing anxiety, but there is evidence to suggest that hypnotizability and expectancy may both play a role in reported anxiety decrements. It is concluded that individuals with a capacity to engage in autonomous, self-absorbed relaxation may benefit most from meditation

Kabat-Zinn, Jon; Lipworth, Leslie; Burney, Robert (1985). The clinical use of mindfulness meditation for the self-regulation of chronic pain. Journal of Behavioral Medicine, 8 (2), 163-190.

90 chronic pain patients were trained in mindfulness meditation in a 10-wk stress reduction and relaxation program. Self-report indices, including the McGill Pain Questionnaire, the Profile of Mood States, and the Hopkins Symptom Checklist, were administered to the Ss to assess multiple aspects of pain and certain pain-related behaviors. Results show statistically significant reductions in measures of present-moment pain, negative body image, inhibition of activity by pain, symptoms, mood disturbance, and psychological symptomatology, including anxiety and depression. Pain-related drug utilization decreased, and activity levels and feelings of self-esteem increased. Improvement appeared to be independent of gender, source of referral, and type of pain. A comparison group of 21 pain patients did not show significant improvement on these measures after traditional treatment protocols. At follow-up, the improvements observed during the meditation training were maintained up to 15 months postmeditation training for all measures except present-moment pain. The majority of Ss reported continued high compliance with the meditation practice as part of their daily lives.

1984

Holmes, David S. (1984). Meditation and somatic arousal evidence. American Psychologist, 39 (1), 1-10.

The conceptual and methodological issues associated with research on the effects of meditation are reviewed. A summary of the research in which the somatic arousal of meditating subjects was compared to the somatic arousal of resting subjects did not reveal any consistent differences between meditating and resting subjects on measures of heart rate, electrodermal activity, respiration rate, systolic blood pressure, diastolic blood pressure, skin temperature, oxygen consumption, EMG activity, blood flow, or various biochemical factors. Similarly, a review of the research on the effects of meditation in controlling arousal in threatening situations did not reveal any consistent differences between meditating and nonmeditating (no-treatment, antimediation, or relaxation) subjects. The implications of these findings for research and practice are discussed.

1983

Heide, F. J.; Borkovec, T. D. (1983). Relaxation-induced anxiety: Paradoxical anxiety enhancement due to relaxation training. Journal of Consulting and Clinical Psychology, 51, 171-182.

The present study was designed to document the occurrence of relaxation-induced anxiety. Fourteen subjects (7 male, 7 female) suffering from general tension and significant levels of anxiety were given one session of training in each of two relaxation methods, progressive relaxation and mantra meditation; order of presentation was counterbalanced. Four of the subjects plus one other who terminated prematurely displayed clinical evidence of an anxiety reaction during a preliminary practice period, while 30.8% of the total group under progressive relaxation and 53.8% under focused relaxation reported increased tension due to the relaxation session. Progressive relaxation produced greater reductions in subjective and physiological outcome measures and less evidence of relaxation-induced anxiety, and the phenomenon was not clearly evident from physiological measures and from subjective ratings even in this clinical population.

Progressive relaxation produced greater reductions in subjective and physiological outcome measures and less evidence of relaxation-induced anxiety, and the phenomenon was not clearly evident from physiological measures and from subjective ratings even in this clinical population.

Lehrer, Paul M. et al. (1983). Progressive relaxation and meditation: A study of psychophysiological and therapeutic differences between two techniques. Behaviour Research and Therapy, 21 (6), 651-662.

Collected physiological and self-report data on 50 anxious Ss (as determined by the IPAT Anxiety Scale) who participated in a study comparing progressive relaxation, meditation, and a waiting-list control. Data provide some support for the hypothesis of G. E. Schwartz et al that there are specific effects for different relaxation procedures, superimposed upon a generalized relaxation response. The similarities between techniques, however, were greater than the differences, both on physiological and self-report measures. Both techniques generated positive expectancies and produced decreases in a variety of self-reported symptoms and on EMG, but no skin conductance or frontal EEG effects were observed. Progressive relaxation produced bigger decreases in forearm EMG responsiveness to stressful simulation and a generally more powerful therapeutic effect than meditation. Meditation produced greater cardiac orienting responses to stressful stimuli, greater absorption in the task, and better motivation to practice than progressive relaxation; however, it also produced more reports of increased transient anxiety. No significant differences between conditions in the therapeutic expectancies they generated were found.

1982

Brown, Daniel P.; Forte, Michael; Rich, Philip; Epstein, Gerald (1982-83). Phenomenological differences among self hypnosis, mindfulness meditation, and imaging. Imagination, Cognition and Personality, 2 (4), 291-309.

A survey of 122 subjects was conducted to investigate the differences in the phenomenological quality of the experiences engendered by three types of awareness discipline: self-hypnosis (21 Ss), waking dreaming (49 Ss) and mindfulness meditation (25 Ss from a 2-week retreat, and another group of 27 Ss from a 2-day weekend retreat). A questionnaire, the profile of Trance, Imaging, and Meditation Experience (TIME) was used in the survey. Discriminant analyses were used to construct models of the differences in the phenomenological quality of the experiences among the three groups. A number of phenomenological dimensions, in the major areas of attention, thinking, memory, imagery, body sensations, emotions, time sense, reality sense, and sense of self, were found which could accurately distinguish among the experiences of practitioners of the three types of awareness training. Results show that while self hypnosis involves self-referential thinking, memory changes, and intense emotions, waking dreaming emphasizes the immediate impact of emerging images, which unfold in a thematic manner and have a sense of their own reality. Mindfulness meditators have difficulty managing distractions, but with experience learn greater awareness of bodily processes, and experience changes in the perception of time and self; mental processes seem to slow down, and awareness assumes an impersonal quality. No attributions as to the causes or sources of these phenomenological differences are made, as the survey was

not large enough to provide comparison groups, subject matching, or other statistical controls necessary for causal analyses.

**Credidio, Steven G. (1982). Comparative effectiveness of patterned biofeedback vs meditation training on EMG and skin temperature changes. Behaviour Research and Therapy, 20, 233-241.**

Examined whether a low arousal, relaxation pattern of frontalis EMG decreases and peripheral skin temperature increases could be attained more effectively through biofeedback or meditation training. 30 21-59 yr old females were randomly assigned to 1 of 3 groups: patterned biofeedback, clinically standardized meditation, or control. Prior to training, Ss were administered the Eysenck Personality Inventory. Each S was seen weekly for 7 sessions. Subjective experiences and time spent practicing at home were also recorded. Results indicate that the meditation group showed significantly lower EMG levels at the end of treatment than did the control group. The biofeedback group had difficulty in patterning the 2 feedback signals simultaneously. Extraverts in the control group had the highest EMG levels. The most positive subjective reports came from Ss in the meditation group. It is suggested that meditation offers a viable alternative as a relaxation procedure, requiring little time to learn and devoid of any performance criteria levels.

**Larbig, W.; Elbert, T.; Lutzenberger W.; Rockstroh, B.; Schnerr, G.; Birbaumer, N. (1982). EEG and slow brain potentials during anticipation and control of painful stimulation. Electroencephalography and Clinical Neurophysiology, 53, 298-309.**

Cerebral responses in anticipation of painful stimulation and while coping with it were investigated in a 'fakir' and 12 male volunteers. Experiment 1 consisted of 3 periods of 40 trials each. During period 1, subjects heard one of two acoustic warning stimuli of 6 sec duration signaling that either an aversive noise or a neutral tone would be presented at S1 offset. During period 2, subjects were asked to use any technique for coping with pain that they had ever found to be successful. During period 3, the neutral S2 was presented simultaneously with a weak electric shock and the aversive noise was presented simultaneously with a strong, painful shock, again under pain coping instructions. EEG activity within the theta band increased in anticipation of aversive events. Theta peak was most prominent in the fakir's EEG. A negative slow potential shift during the S1-S2 interval was generally more pronounced in anticipation of the aversive events than the neutral ones, even though no overt motor response was required. Negativity tended to increase across the

three periods, opposite to the usually observed diminution. In Experiment 2, all subjects self-administered 21 strong shock-noise presentations. The fakir again showed more theta power and more pronounced EEG negativity after stimulus delivery compared with control subjects. Contrary to the controls, self-administration of shocks evoked a larger skin conductance response in the fakir than warned external application.

A published case study by Pelletier (1977) reported EEG theta enhancement during pain control states, which were maintained by EEG feedback of alpha and theta bands. That author concluded that EEG theta was necessary for the control of pain psychologically.

The authors of this article measured slow brain potentials (SBPs) and vertical eye movements (VEMs). Principal components analysis of the EEG wave forms found three components: theta (4-5.6 c/sec), alpha band (9-10 c/sec) and high frequencies (above 14.4 c/sec) plus harmonics loading in frequencies of 3.2-4.5 c/sec, 7.5-9, and above 15 c/sec.

Alpha "decreased over periods in the parietal record and was virtually absent in the fakir's EEG during period 3" (p. 301). The fakir had a lot of non-sinusoidal, especially square wave, activity.

"Very pronounced negativity was recorded preceding the aversive S2, greater than under neutral stimulus conditions .... This difference was most pronounced at the vertex ... The late negativity increased over periods in control subjects ... especially in anticipation of the aversive S2 ... . This contrasts with the usually observed decrease of SBP components over trials. As is shown in Figure 2, the PCA [principal components analysis] yielded two components for the 2.0 sec S2 interval, a positive deflection, which can be assigned to the P300 complex (here not reported), and a negative deflection, labeled post- imperative negative variation. ... This negative component increased over periods, being more pronounced in response to the aversive stimulation ... with increasing differentiation over period ..." (p. 302-303).

The fakir undertook an elaborate self hypnosis or trance induction to achieve analgesia that he had previously demonstrated in the laboratory (thrusting 4 unsterilized metal spikes into his abdomen, tongue, and neck without bleeding). This included "long- continued fixation on a point above the eye-brows. Blank facial expression, staring eyes, and a very low rate of eye-blinks indicated a trance-like state (periods without eye-blinks more than 30 min)" (p. 299). During the experiment itself, the fakir showed few ocular movements during the second and third periods. He also demonstrated large skin conductance responses, recorded from the second phalanges of the index and middle fingers of the left hand, to the aversive S1.

Experiment 2 was designed to emulate the self-administered aversive stimulation that the fakir routinely undertook, by having the volunteer Ss hold a switch that they pressed twice/minute, giving themselves a mild shock and an aversive noise. (These were the same aversive stimuli as were used in Experiment 1.) There were 21 self-paced button presses.

Three additional measures were taken: 1. Bereitschaftspotential (BP) - the mean negative shift during the 0.3 sec interval prior to the motor response of pressing the

switch 2. Postimperative component (PINV) - the mean negative shift 0.9 to 1.9 sec after stimulus onset, i.e. elicited by closing the microswitch 3. Skin conductance response (SCR) - maximum change in skin conductance level during five second interval after the motor response of pressing the switch.

The fakir, but not the control Ss, showed a pronounced precentral PINV on each single trial of Experiment 2. He also showed pronounced SCRs (indicating autonomic arousal), which was even greater than the SCRs of control Ss. His subjective pain rating was 1 in Experiment 1 (compared with 6.4 for controls) but 8 during Experiment 2 (compared with 5.7 for controls), on a scale of 1 to 10 maximum. Thus the fakir's pain increased from Experiment 1 to 2, while for many volunteer Ss it decreased 2 or 3 points. When interviewed, he said that "intention and motor commands prevented the fakir from getting into 'trance' satisfactorily. Consequently, he reported to have experienced the aversive stimuli as more painful than in experiment 1. Thus it might be that the observed PINV indicates the noncontingency between the demand for coping and the failure to cope or the discrepancy between expected control and presently experienced control" (p. 307).

In their Discussion, the authors speculate that control of pain such as can be achieved by the fakir may involve dissociation of higher (possibly thalamic and cortical) and lower (reticular formation) arousal structures. Their observation of slow brain potentials (theta) recorded in anticipation of painful or aversive stimuli is in agreement with earlier published studies. However their observation of increasing negativity in anticipation of aversive stimuli is in contrast to previous research findings, in which diminution of negativity is generally observed.

Both the fakir and subjects showed a post-stimulus negative shift in response to the S2; this has been "observed in normal subjects under conditions of change from controllable to uncontrollable aversive stimuli... and/or from obvious response-consequence contingencies to unpredictable control over the S2... PINVs were associated with an unexpected change in contingency or the inability to resolve ambiguity. Since a relationship was found between PINV amplitude and subjective ratings or experienced aversiveness of the painful stimulation, it may be speculated that obvious failure in coping with pain (i.e. more experienced pain) together with the requirement to cope (induced by instructions and experimental setting, giving rise to increased expectancy for control), produced a PINV (and probably feelings of uncontrollability together with a state of reactance and frustration) in the present experiments. In accordance with this point of view, it is of particular interest that only the fakir showed a more pronounced PINV in experiment 2, in which subjects delivered the painful stimuli to themselves. A postexperimental interview revealed that intention and motor commands prevented the fakir from getting into 'trance' satisfactorily" (p. 307).

Meares, Ainslie (1982-83). A form of intensive meditation associated with the regression of cancer. American Journal of Clinical Hypnosis, 25 (2-3), 114-121.

Elsewhere I have reported a number of cases of regression of cancer following intensive meditation. This type of meditation is characterized by extreme simplicity and stillness of the mind, and so differs from other forms using a mantra, awareness

of breathing or visualization of the healing process. Any logical verbal communication by the therapist stimulates intellectual activity in the patient. So communication is by un verbalized phonation, reassuring words and phrases, and most important, by touch. There follows a profound reduction in the patient's level of anxiety which flows on into his daily life. The non-verbal nature of the meditative experience initiates a non-verbal philosophical understanding of other areas of life.

Shapiro, Deane H. (1982). Overview: Clinical and physiological comparison of meditation with other self-control strategies. American Journal of Psychiatry, 139 (3), 267-274.

In 1977, the American Psychiatric Association called for a critical examination of the clinical effectiveness of meditation. The present author reviews the pertinent literature and defines meditation as a family of techniques that attempt to focus attention in a nonanalytical way and attempt not to dwell on discursive, ruminating thought. Meditation is then compared with such self-regulation strategies as biofeedback, hypnosis, and progressive relaxation. Particular attention is given to the "uniqueness" of meditation as a clinical intervention strategy as well as the adverse effects of meditation. Future research should deal with the context of meditation, a component analysis, refinement of the dependent variable, S variables, and the phenomenology of meditation.

Stoyva, J. M.; Anderson, C. (1982). A coping-rest model of relaxation and stress management. In Goldberger, L.; Breznitz, S. (Ed.), Handbook of stress: Theoretical and clinical aspects (pp. 745-763). New York: The Free Press.

"Patients with psychosomatic or stress linked disorders are likely to show signs of high physiological arousal, and they are likely, under stress, to react strongly in the symptomatic system and to show evidence of being deficient in the ability to shift from the coping to the rest mode (e.g., slowness of habituation to, and recovery from, stressful stimulation). A corollary inference is that such patients ... show activity in the symptomatic system for a higher percentage of the time that [sic] do normal subjects. We suggest that this defect in the capacity to shift to a rest condition is the principal reason that various relaxation procedures have so often proved successful in the alleviation of stress related symptoms" (p. 748).

The authors refer to a number of different stress management procedures. Among those associated with primary focus on the rest phase they include: Relaxation training (progressive relaxation, autogenic training, EMG feedback, meditation [Zen, TM]), Specific biofeedback (hand temperature, electrodermal response [EDR], EMG from particular muscle group), and Systematic desensitization. Among those associated with primary focus on coping phase are: Assertiveness training, Social skills retraining and motor skills retraining, Self-statements, Imagery (Guided waking imagery, autogenic abreaction, covert reinforcement and covert sensitization, behavior rehearsal). These various procedures may reflect three dimensions or aspects of the stress response, with some addressing physiology and others addressing cognition or behavior change.

**"Rachman (1978) ... found it useful to divide the phenomenon of fear into physiological, cognitive, and behavioral components. Similarly, Davidson and Schwartz (1976) conceptualized relaxation as consisting of somatic, cognitive, and attentional components. Phillips (1977) argued that pain, such as headache pain, can be viewed as consisting of cognitive, behavioral, and physiological aspects (and that, consequently, we should not expect high correlations between headache pain and a particular physiological measure such as forehead EMG level). ...**

**"... In discussing contemporary studies of dreaming, they [Stoyva and Kamiya (1968)] proposed that there is no single, totally valid indicator of dreaming as a mental experience. Instead, there are several imperfect indicators of the dream experience--verbal report, rapid eye movements, and certain electroencephalographic (EEG) stages. ... Discrepancies among the indicators can serve to generate hypotheses" (p. 749).**

**The authors discuss different ways of retraining the capacity to rest: relaxation training (including biofeedback, etc.), systematic desensitization; and of reshaping the coping response: assertiveness training, social skills and motor skills retraining, self- statements, imagery techniques; and discuss controllability. These notes cover only a very small part of their extensive review, the material most relevant to hypnosis and suggestion.**

**"Although imagery techniques are often employed by stress management therapists, one approaches this area with ambivalence. In part, this uneasiness springs from the unsettling awareness that imagery techniques have been embraced by a freewheeling assortment of lay psychologists such as Emil Coue, Dale Carnegie, and Norman Vincent Peale, not to mention a diverse throng of contemporary 'mind controllers' and self-styled healers. A more serious source of uneasiness is ignorance of the specific processes at work. What are the mechanisms by which imagery affects the stress response?" (p. 756).**

**"There is intriguing recent evidence that simply the illusion of control may exert beneficial effects. Stern, Miller, Ewy, and Grant (1980) noted that subjects who were led to believe by means of bogus information feedback that they were successfully lowering their heart rates showed a reduction in stress type symptoms, especially those of a cardiovascular nature. It seems possible that the feeling of control may be an important part of what we have called 'placebo responding.' Stoyva (1979b) suggested that this phenomenon is probably not a unitary entity but, rather, a cluster of processes, of which the feeling of developing control over factors affecting one's disorder is an important and potentially manipulable component of therapeutic interventions" (p. 758).**

**change.**

**"Rachman (1978) ... found it useful to divide the phenomenon of fear into physiological, cognitive, and behavioral components. Similarly, Davidson and Schwartz (1976) conceptualized relaxation as consisting of somatic, cognitive, and attentional components. Phillips (1977) argued that pain, such as headache pain, can be viewed as consisting of cognitive, behavioral, and physiological aspects (and that, consequently, we should not expect high correlations between headache pain and a particular physiological measure such as forehead EMG level). ...**

Throll, D. A. (1982). Transcendental meditation and progressive relaxation: Their physiological effects. Journal of Clinical Psychology, 38 (3), 522-530.

Measured oxygen consumption, tidal volume, respiration rate, heart rate, systolic and diastolic blood pressure before the Ss learned Transcendental Relaxation Meditation (Transcendental meditation: N = 21) or Jacobson's Progressive Relaxation (PR: N = 18). Ss were tested immediately after learning either technique and again 5, 10, and 15 weeks later. While there were no significant differences between groups for any of the physiological variables at pretest, the Transcendental meditation group displayed more significant decreases during meditation and during activity than did the Psychological Review group. Both groups displayed significantly lowered metabolic rates during Transcendental meditation or PR. The generally more significant and comprehensive results for meditators were explained primarily in terms of the greater amount of time the Transcendental meditation

group spent on their technique, plus the differences in the two techniques themselves. Several avenues for future research are discussed.

amount of time the Transcendental meditation group spent on their technique, plus the differences in the two techniques themselves. Several avenues for future research are discussed.

Woolfolk, Robert L.; Lehrer, Paul M.; McCann, Barbara S.; Rooney, Anthony J. (1982). Effects of progressive relaxation and meditation on cognitive and somatic manifestations of daily stress. Behaviour Research and Therapy, 20 (5), 461-467.

Compared meditation and progressive relaxation with self-monitoring control as treatments for symptoms of stress. 34 Ss were assigned to either the progressive relaxation, the meditation, or the self-monitoring control group and were given 5 sessions of training. All Ss self-monitored stress symptoms throughout the study and had their behavior rated weekly by a spouse/roommate. Results show that the progressive relaxation and mediation treatments significantly reduced stress symptomatology over time.

1981

Fling, Sheila; Thomas, Anne; Gallaher, Michael (1981). Participant characteristics and the effects of two types of meditation vs. quiet sitting. Journal of Clinical Psychology, 37 (4), 784-790.

Randomly assigned 61 undergraduate volunteers to Clinically Standardized Meditation (CSM), quiet sitting (SIT), or wait list1 and 19 others to Open Focus (OF) or wait list2. Ss were tested before training and again 8 weeks later. All groups but wait list2 decreased significantly on Spielberger's trait anxiety. All groups became nonsignificantly more internal on Rotter's locus of control. On the Myers-Briggs Type Indicator, meditation volunteers were more introverted than extraverted, intuitive than sensing, feeling than thinking, and perceiving than judging. All groups became more intuitive, approaching significance for CSM only. OF became significantly more extraverted than both CSM and SIT, and CSM significantly more so than wait list1. Practice time correlated with anxiety reduction for the combined treatment groups. More evidence was found for correlations of practice time and outcome with growth motivation than with either new experience motivation or expectancy of benefit

Throll, D. A. (1981). Transcendental meditation and progressive relaxation: Their psychological effects. Journal of Clinical Psychology, 37 (4), 776-781.

Administered the Eysenck Personality Inventory, the State-Trait-Anxiety Inventory, and two questionnaires on health and drug usage to 39 Ss before they learned Transcendental Meditation (TM) or Progressive Relaxation (PR). All Ss were tested immediately after they had learned either technique and then retested 5, 10, and 15 weeks later. There were no significant differences between groups for any of the

psychological variables at pretest. However, at posttest the TM group displayed more significant and comprehensive results (decreases in Neuroticism/Stability, Extroversion/Introversion, and drug use) than did the PR group. Both groups demonstrated significant decreases in State and Trait Anxiety. The more pronounced results for meditators were explained primarily in terms of the greater amount of time that they spent on their technique, plus the differences between the two techniques themselves.

Heide, Frederick J.; Wadlington, W. L.; Lundy, Richard M. (1980). Hypnotic responsivity as a predictor of outcome in meditation. International Journal of Clinical and Experimental Hypnosis, 28 (4), 358-385.

Hypnosis, 28 (4), 358-385.

This study tested the hypothesis that measures of hypnotic responsivity would predict outcome from brief meditation training. 58 Ss were matched on hypnotic responsivity and randomly assigned to meditation and control conditions. The Ss in the meditation group displayed significantly greater decreases in trait anxiety than control Ss following a 1-week treatment period. The Ss highest in hypnotic responsivity showed the most substantial decrements in anxiety. It is concluded that hypnotic responsivity is moderately predictive of outcome in meditation. Findings were also consistent with reports that hypnotic responsivity is not increased by practice in meditation.

Lehrer, Paul M.; Schoicket, Sandra; Carrington, Patricia; Woolfolk, Robert L. (1980). Psychophysiological and cognitive responses to stressful stimuli in subjects practicing progressive relaxation and clinically standardized meditation. Behaviour Research and Therapy, 18 (4), 293-303.

32 Ss were assigned to either progressive relaxation (PR), clinically standardized meditation (SM), or a waiting list control group, which was asked to relax daily without specific instruction. Ss were given paper and pencil tests 2 times/separated by 5 wks, during which time the 2 treatment groups received 4 weekly sessions of group training. At the end of the 5-wk period, all Ss were exposed to 5 very loud tones. While relaxing as deeply as possible and anticipating the loud tones, SMs exhibited higher heart rates and higher integrated frontalis EMG activity, but they also showed greater cardiac decelerations following each tone, more frontal alpha, and fewer symptoms of cognitive anxiety than the other 2 groups. PRs reported more sensations of muscular relaxation than the other groups but also some symptoms of hyperventilation. Results suggest that frontal EEG alpha may be a physiological marker for the absence of cognitive anxiety. Physiological findings also support D. J. Goleman and G. E. Schwartz's suggestion that meditation prepares people to cope with stress.

Lundy, Richard M.; Heide, Frederick J.; Wadlington, W. L. (1980). Hypnotic responsivity as a predictor of outcome in meditation. International Journal of Clinical and Experimental Hypnosis, 28 (4), 358-366.

TM reportedly diminishes Trait Anxiety (not State Anxiety). Spielberger's Anxiety Scale was administered. Non-analytical attention is increased in TM. Spanos, et al. found a relationship between sustained attention in a meditation task and hypnotizability. Both load on the same factor.

Used Control and Experimental groups pretested on a scale of hypnotizability (Harvard Scale?): Lows = 1-4; Mediums = 5-7; Highs = 8-12.

Subjects were given instructions for modified TM, including a lecture on physiological benefits. "Let the sound 'OM' repeat itself; let that sound pass through and return to the mantra." Subjects logged practice on their 20 minute meditation twice a day, for 7 days. They were given pre- and posthypnotic tests of State and Trait anxiety.

**RESULTS.** Meditators decreased Trait anxiety but not State anxiety. But anxiety was reduced more for high hypnotizables than for other levels. There was greater change in anxiety for High hypnotizables who practiced meditation . No difference in pre- and posthypnotic test on Harvard, confirming Spanos, et al.

**CONCLUSIONS.**

This provides more evidence that the skill of hypnotizability has more utility than we had thought, in therapy. Spanos, et al. also found that improvement in meditation was correlated with hypnotizability (in terms of number of intrusions) and Benson, Frankel, et al., found Lows benefit less in blood pressure change with either meditation or hypnosis on Harvard, confirming Spanos, et al.

Puente, Antonio E.; Beiman, Irving (1980). The effects of behavior therapy, self-relaxation, and transcendental meditation on cardiovascular stress response. Journal of Clinical Psychology, 26 (1), 291-295.

Compared Behavior Therapy (BT), self-relaxation (SR), transcendental meditation (TM), and a waiting-list control group (WL) on measures of cardiovascular and subjective stress response. Male and female respondents (N = 60) to an ad for therapy were evaluated in assessment sessions before and after treatment. The results indicate that BT and SR were more effective than either TM or WL in reducing cardiovascular stress response. These data were interpreted as resulting from therapeutic suggestion and positively reinforced client progress.

Schuman, Marjorie (1980). The psychophysiological model of meditation and altered states of consciousness: A critical review. In Davidson, J. M.; Davidson, R. J. (Ed.), The psychobiology of consciousness (pp. 333-378). New York: Plenum Press.

Psychophysiological changes have been found to occur as correlates of meditation. Major emphasis has been placed on changes in alpha brainwave activity and on changes in alpha blocking response to sensory stimuli. Taken together, these

changes in baseline EEG and electrocortical responsiveness to sensory stimulation have been interpreted to be evidence of a unique meditative state of consciousness. The literature on the psychophysiology of meditation, including EEG and autonomic changes, is reviewed with careful attention to different types of meditation practice and various physiological measures of arousal and attentional set. The phenomenology of meditative states and their relationship to trance states is also considered. It is concluded that EEG and autonomic data cannot be used to define states of consciousness; the state of consciousness must be known before the significance of physiological changes can be inferred.

Spanos, Nicholas P.; Stam, Henderikus J.; Rivers, Stephen M.; Radtke, H. Lorraine (1980). Meditation, expectation and performance on indices of nonanalytic attending. International Journal of Clinical and Experimental Hypnosis, 28 (3), 244-251.

Following pretests on the Eysenck personality inventory (H. J. Eysenck & S. B. Eysenck, 1963) and hypnotic susceptibility as measured by the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962), 2 groups of Ss attended nonanalytically for 20, 15-minute sessions and were then posttested. Sessions were defined as meditation for 1 group and as a study in attention style for the other. Meditators and attenders did not differ in their rate of signalling intrusions into their attending, and neither treatment affected hypnotic susceptibility or personality dimension scores. The Ss who were defined as motivated to participate in the study, and those Ss who were unmotivated did not differ initially in rate of intrusions. At the end of the study, however, motivated Ss reported fewer intrusions than unmotivated ones. Intrusion rate correlated significantly with hypnotic susceptibility.

The Harvard Scale (HGSHS:A) scores correlated  $-.41$  with Mean number of intrusions. The meditation training consisted of one hour of training in transcendental meditation (TM) followed by 20 15-minute sessions spread across 4 or 5 weeks. In their Discussion section, the authors state, "The present finding that intrusion rate correlated significantly with hypnotic susceptibility replicated the results of Van Nuys (1972) and Spanos et al. (1978). In both the present study and that of Spanos et al. [Spanos, Gottlieb, & Rivers, The effects of short term meditation practice on hypnotic responsivity. Unpublished manuscript, Carleton University, 1978] meditation practice failed to produce either an overall reduction in rate of intrusions or an increment in hypnotic susceptibility. Thus, in these studies, the failure of meditation to enhance susceptibility can be accounted for in terms of its failure to increase proficiency at nonanalytic attending. Such an explanation cannot account for Spanos et al.'s (1979) results, however. These investigators, it will be recalled, found that experienced meditators who reported very few intrusions and unselected novice meditators with a relatively high intrusion rate, failed to differ from each other in susceptibility. The empirical interrelationships among meditation practice, intrusions into attending, and hypnotic susceptibility will have to be clarified if a theoretical integration of meditation and hypnotic phenomena is to be accomplished" (p. 249).

1979

Barmark, Susanne M.; Gaunitz, Samuel C. B. (1979). Transcendental meditation and heterohypnosis as altered states of consciousness. International Journal of Clinical and Experimental Hypnosis, 27 (3), 227-239.

The effects of transcendental meditation and relaxation-heterohypnosis on subjective phenomena and physiological arousal were examined. One group of Ss, who were experienced meditators, participated in meditation, and a second group of Ss, who were highly susceptible to hypnosis but with little hypnotic experience, were exposed to hypnosis. A period of quiet sitting served as control for Ss in each group. Neither heterohypnosis nor transcendental meditation were identified as low-arousal states. They were assumed to be similar phenomenologically altered states of consciousness, mainly characterized by changes in the distribution of attention and in body image.

Di Nardo, Peter A.; Raymond, Jayne B. (1979). Locus of control and attention during meditation. Journal of Consulting and Clinical Psychology, 47 (6), 1136-1137.

Undergraduates were assigned to an internal or external group on the basis of their locus of control scores. A meditation task required subjects to focus their attention on an actual stimulus or an imagined stimulus while recording intruding thoughts by pressing a button on a counter. Results showed that an internal locus of control was related to fewer intrusions than was an external locus and that the actual stimulus resulted in fewer intrusions than did the imagined stimulus. These results suggest that performance in meditation, and possibly in other self-control procedures, may be influenced by individual differences in deployment of attention.

Spanos, Nicholas P.; Steggle, Shawn; Radtke-Bodorik, H. Lorraine; Rivers, Stephen M. (1979). Nonanalytic attending, hypnotic susceptibility, and psychological well-being in trained meditators and nonmeditators. Journal of Abnormal Psychology, 88 (1), 85-87.

Four groups of trained meditators differing in amount of meditation practice and a group of nonmeditators attended nonanalytically to a mantra in two meditation sessions. Subjects signaled intrusions into their attending, and were also assessed on several person variables. The four trained meditator groups differed from one another only in terms of self-esteem. When combined into a single group, meditators signaled fewer intrusions and reported "deeper" levels of meditating than nonmeditators. However, meditators and nonmeditators did not differ on hypnotic susceptibility, absorption, or indices of psychopathology.

Benson, Herbert; Frankel, Fred H.; Apfel, Roberta; Daniels, Michael D.; Schniewind, Henry E.; Nemiah, John C.; Sifneos, Peter E.; Crassweller, Karen D.; Greenwood, Martha M.; Kotch, Jamie B.; Arns, Patricia A.; Rosner, Bernard

(1978). Treatment of anxiety: A comparison of the usefulness of self-hypnosis and a meditational relaxation technique. Psychotherapy and Psychosomatics, 30, 229-242.

We have investigated prospectively the efficacy of two nonpharmacologic relaxation techniques in the therapy of anxiety. A simple, meditational relaxation technique (MT) that elicits the changes of decreased sympathetic nervous system activity was compared to a self-hypnosis technique (HT) in which relaxation, with or without altered perceptions, was suggested. 32 patients with anxiety neurosis were divided into 2 groups on the basis of their responsivity to hypnosis: moderate-high and low responsivity. The NIT or HT was then randomly assigned separately to each member of the two responsivity groups. Thus, 4 treatment groups were studied: moderate-high responsivity MT; low responsivity MT; moderate-high responsivity HT; and low responsivity HT. The low responsivity HT group, by definition largely incapable of achieving the altered perceptions essential to hypnosis, was designed as the control group. Patients were instructed to practice the assigned technique daily for 8 weeks. Change in anxiety was determined by three types of evaluation: psychiatric assessment; physiologic testing; and self-assessment. There was essentially no difference between the two techniques in therapeutic efficacy according to these evaluations. Psychiatric assessment revealed overall improvement in 34% of the patients and the self-rating assessment indicated improvement in 63% of the population. Patients who had moderate- high hypnotic responsivity, independent of the technique used, significantly improved on psychiatric assessment ( $p = 0.05$ ) and decreased average systolic blood pressure from 126.1 to 122.5 mm Hg over the 8-week period ( $p = 0.048$ ). The responsivity scores at the higher end of the hypnotic responsivity spectrum were proportionately correlated to greater decreases in systolic blood pressure ( $p = 0.075$ ) and to improvement by psychiatric assessment ( $p = 0.003$ ). There was, however, no consistent relation between hypnotic responsivity and the other assessments made, such as diastolic blood pressure, oxygen consumption, heart rate and the self-rating questionnaires. The meditational and self- hypnosis techniques employed in this investigation are simple to use and effective in the therapy of anxiety.

Significantly improved on psychiatric assessment ( $p = 0.05$ ) and decreased average systolic blood pressure from 126.1 to 122.5 mm Hg over the 8-week period ( $p = 0.048$ ). The responsivity scores at the higher end of the hypnotic responsivity spectrum were proportionately correlated to greater decreases in systolic blood pressure ( $p = 0.075$ ) and to improvement by psychiatric assessment ( $p = 0.003$ ). There was, however, no consistent relation between hypnotic responsivity and the other assessments made, such as diastolic blood pressure, oxygen consumption, heart rate and the self-rating questionnaires. The meditational and self- hypnosis techniques employed in this investigation are simple to use and effective in the therapy of anxiety.

Parker, Jerry C.; Gilbert, Gary S.; Thoreson, Richard W. (1978). Reduction of autonomic arousal in alcoholics: A comparison of relaxation and meditation techniques. Journal of Consulting and Clinical Psychology, 46 (5), 879-886.

To investigate and compare the effects of progressive relaxation training and meditation training on autonomic arousal in alcoholics, 30 subjects were selected from a population of alcoholics in a Veterans Administration hospital substance-abuse program. The subjects were randomly assigned to one of the following three experimental conditions: (a) progressive relaxation training group, (b) meditation training group, or (c) quiet rest control group. All groups met for 3 weeks during which state anxiety, blood pressure, heart rate, and spontaneous galvanic skin responses were measured. The measures were designed to assess the treatment effects following the first training session and at the end of the total training period. The results indicate that both progressive relaxation training and meditation training are useful for reducing blood pressure in alcoholics. In addition, significant differences between the groups in the effectiveness of the relaxation procedures were found. Meditation training induced blood pressure decreases at an earlier point in the 3-week training period and affected decreases in systolic blood pressure that progressive relaxation training did not. These results support the idea of considerable specificity of response to relaxation techniques.

Reed, Henry (1978). Improved dream recall associated with meditation. Journal of Clinical Psychology, 34 (1), 150-156.

Analyzed the effect of meditation on the completeness and vividness of intentional dream recall by use of data protocols obtained from an experimental home-study dream research project that involved Ss who recorded dream recall for 28 consecutive days. It was found that when a S had meditated the day before, there was significantly greater completeness of dream recall on the following morning. A significant interaction effect also was found between the regularity of the S's meditation and whether such meditation was associated with improved dream recall. The results were discussed in terms of Cayce's attunement model of meditation, which predicts more observable effects of meditation when it is practiced regularly

Schwartz, G. E.; Davidson, R. J.; Goleman, D. J. (1978). Patterning of cognitive and somatic processes in the self-regulation of anxiety: Effects of meditation versus exercise. Psychosomatic Medicine, 40, 321-328

Spanos, Nicholas P.; Rivers, Stephen M.; Gottlieb, Jack (1978). Hypnotic responsivity, meditation, and laterality of eye movements. Journal of Abnormal Psychology, 87 (5), 566-569.

Right-handed male subjects were pretested on a number of person variables; they then meditated for eight sessions. Measures of hypnotic responsivity, meditating skill, imaginal abilities, and attitudes toward hypnosis loaded on a common factor that was labeled sustained nonanalytic attending. However, laterality of eye

movement (left moving) failed to load on this factor. The implications of these findings for current theorizing concerning hypnosis and meditation are discussed.

Zuroff, David C.; Schwarz, J. Conrad (1978). Effects of transcendental meditation and muscle relaxation on trait anxiety, maladjustment, locus of control, and drug use. Journal of Consulting and Clinical Psychology, 46 (2), 264-271

Sixty undergraduate volunteers were randomly assigned to receive training in transcendental meditation (Transcendental meditation), training in a muscle relaxation technique, or no treatment. The training in muscle relaxation was designed to be maximally similar in structure and atmosphere to training in Transcendental meditation. Measures of trait anxiety, locus of control, maladjustment, and drug use were collected before and after the 9-week treatment period. On a behavioral measure of trait anxiety, the scores of all three groups decreased equally, but on a self-report measure the Transcendental meditation subjects reported steady decreases in anxiety, whereas the scores of the other two groups remained unchanged. There were no differences in maladjustment, locus of control, or drug use as a function of treatment. Although Transcendental meditation subjects held higher expectancies for benefits, and were slightly more regular in practicing their technique, individual differences in expectancy and frequency of practice were not correlated with degree of reported anxiety reduction. It is concluded that Transcendental meditation may reduce trait anxiety, but it has not been shown to be of value in inducing general personality change.

1977

Avila, Donald; Nummela, Renate (1977). Transcendental meditation: A psychological interpretation. Journal of Clinical Psychology, 33 (3), 842-844.

The authors suggest that Transcendental Meditation offers a great deal of promise for use in helping relationships. They also suggest that the technique might receive wider acceptance if it could be explained in other than a purely philosophical or mystical way. For that reason, in their article they offer a psychological interpretation of the TM process.

- X. The meditative states**
- XI. Personality differences and meditation**
- XII. Affective and cognitive change in meditation**
- XIII. Ordinary Buddhist meditation, concentration, and insight meditation**
- XIV. The variety of Buddhist meditation traditions**

**Brown, Daniel P. (1977). A model for the levels of concentrative meditation. International Journal of Clinical and Experimental Hypnosis, 25 (4), 236-273.**

Classical Tibetan meditation texts are used to specify the most important variables in meditation that can be subjected to empirical test. There are 3 kinds of variables: (a) nonspecific variables, common to all meditation systems; (b) specific variables, limited to specific types of meditation practice; and (c) time-dependent variables, changing over the course of meditation practice. The latter, time-dependent variables, comprise the majority of meditation variables. One set of time-dependent variables for classical concentrative meditation is explored. Using the semantic-field method of translating, technical terms most important in each level of the entire phenomenology of concentrative meditation are discussed. These terms are translated into hypotheses, which are worded in terms of traditional constructs from cognitive psychology. Supporting empirical research is presented and suggestions for further research are made. Certain similarities are noted between the Yogic texts and the constructivist theories of perception, information-processing, and affect. The overall direction of change in concentrative meditation follows an invariant sequence of levels of consciousness.

**Cauthen, Nelson R.; Prymak, Carole A. (1977). Meditation versus relaxation: An examination of the physiological effects of relaxation training and of different levels of experience with transcendental meditation. Journal of Consulting and Clinical Psychology, 45 (3), 496-497.**

Three groups of meditators with varying amounts of experience, a group trained in relaxation, and a pseudomeditation group were tested for changes in heart rate, respiration, skin temperature, and skin conductance during meditation or relaxation. The two more experienced groups of meditators showed decreases in heart rate during meditation while the relaxation group showed decreases after relaxing. The group trained in relaxation and the least experienced meditators showed increases in skin temperature. There were no significant changes in skin conductance or respiration before, during, or after the meditation or relaxation periods.

**Davidson, R. J.; Goleman, D. J. (1977). The role of attention in meditation and hypnosis: A psychobiological perspective on transformations of consciousness. International Journal of Clinical and Experimental Hypnosis, 25, 291-308.**

A temporally based scheme for investigation of changes in consciousness, applicable to areas such as meditation and hypnosis, is proposed and is divided into 3 basic epochs: before -- predispositional variables that affect response to consciousness altering techniques; during -- the state effects of the particular technique; and after -- the trait effects of the practice. Research is surveyed which indicates the role of attentional processes during each of these 3 basic epochs in both meditation and hypnosis. Attentional flexibility is a predispositional variable affecting response to both meditation and hypnosis. The state effects of concentrative meditation involve alterations in stimulus set while the state effects of hypnosis may reflect primarily response set. The trait effects elicited by meditation depend critically on the psychobiological systems which are called into play. Evidence is discussed which suggests that concentrative meditation shares with relaxation an autonomic quiescence, but in addition enhances some attentional skills. A mindfulness technique involving the adoption of a particular attentional stance toward all objects of awareness appears to enhance cortical specificity, but a concentration technique does not. Some implications of attentional self-regulation are discussed.

Dillbeck, Michael C. (1977). The effect of the transcendental meditation technique on anxiety level. Journal of Clinical Psychology, 33 (4), 1076-1078.

Two weeks of twice-daily practice of the Transcendental Meditation (Transcendental meditation) technique was compared with 2 weeks of twice-daily practice of passive relaxation as a means of reduction of anxiety, as measured by the Trait scale of the State-Trait Anxiety Inventory. Thirty-three graduate and undergraduate students were assigned randomly to a relaxation group and a Transcendental meditation group. After a 2-week experimental interval, the relaxation Ss began Transcendental meditation. As hypothesized, in the comparison between the relaxation and meditation Ss, as well as between conditions of the relaxation-meditation group, Transcendental meditation was significantly more effective in reducing anxiety level. Thus, the anxiety-reducing effect of the practice of Transcendental meditation cannot be attributed merely to sitting quietly twice daily, although additional research must determine the extent to which S expectations for change contributed to this effect.

Fromm, Erika (1977). An ego-psychological theory of altered states of consciousness. International Journal of Clinical and Experimental Hypnosis, 25, 372-387.

In this paper a new ego-psychological theory is proposed for the understanding of altered states of consciousness. The dichotomies of primary and secondary process, ego activity and ego receptivity, and automatization and de-automatization of ego functions in daydreaming, in the inspirational phase of creativity, in hypnosis, in psychedelic states, and in meditation are discussed; so are the roles of fantasy, imagery, and various forms of attention.

The author provides a table titled "Typology of Waking State and Several Altered States of Consciousness by Attention Mode." The states listed in the table are: Waking, normally alert, and concentrated; Waking, fascinated, entranced; Free association; Daydreaming; Dreaming; Psychedelic drugs; Hypnosis; Self-hypnosis; Biofeedback; Transcendental meditation; Concentrative meditation; Satipatthana [mindfulness of body, feelings, mind, and mental events]; Classical vipasyana [Clear intuitive insight into physical and mental phenomena as they arise and disappear, seeing them for what they actually are]. She summarizes, "In general, the present author strongly feels that the advantage of hypnotherapy over therapy in the waking state is that hypnosis allows the therapist to help patients work with more primary process thinking, more fantasy, more imagery, more ego receptivity than they would employ in the waking state" (p. 385). "What helps the therapy is not the depth itself; it is that in the hypnotic state there is greater mobility, a greater ability to dip into the unconscious and to bring the unconscious material back into the waking state of consciousness" (p. 385).

and concentrated; Waking, fascinated, entranced; Free association; Daydreaming; Dreaming; Psychedelic drugs; Hypnosis; Self-hypnosis; Biofeedback; Transcendental meditation; Concentrative meditation; Satipatthana [mindfulness of body, feelings, mind, and mental events]; Classical vipasyana [Clear intuitive insight into physical and mental phenomena as they arise and disappear, seeing them for what they actually are]. She summarizes, "In general, the present author strongly feels that the advantage of hypnotherapy over therapy in the waking state is that hypnosis allows the therapist to help patients work with more primary process thinking, more fantasy, more imagery, more ego receptivity than they would employ in the waking state" (p. 385). "What helps the therapy is not the depth itself; it is that in the hypnotic state there is greater mobility, a greater ability to dip into the unconscious and to bring the unconscious material back into the waking state of consciousness" (p. 385).

Sacerdote, Paul (1977). Application of hypnotically elicited mystical states to the treatment of physical and emotional pain. International Journal of Clinical and Experimental Hypnosis, 25, 309-324.

Mystical states by-pass usual sensory perception and logical thinking. They often represent the ultimate goal of long apprenticeships in Eastern or Western monastic practices which stress self-discipline and meditation; or they correlate with sudden religious conversions. While interest has also been revived in mystical experiences stimulated by hallucinogens within the appropriate physical, intellectual, and emotional environment, less attention has been paid to those mystical experiences which appear spontaneously during hypnosis and Transcendental Meditation. The present author facilitates the unleashing of mystical experiences by using hypnotic approaches specifically aimed at altering space and time perceptions. Case presentations illustrate the methodologies for guiding receptive subjects to mystical states with the aim of relieving or correcting organic and functional painful syndromes unresponsive to other interventions. The probable biopsychological processes are discussed.

1976

Goleman, Daniel J.; Schwartz, Gary E. (1976). Meditation as an intervention in stress reactivity. Journal of Consulting and Clinical Psychology, 44 (3), 456-466.

Meditation and relaxation were compared for ability to reduce stress reactions in a laboratory threat situation. Thirty experienced meditators and 30 controls either meditated or relaxed with eyes closed or with eyes open and then watched a stressor film. Stress response was assessed by phasic skin conductance, heart rate, self-report, and personality scales. Meditators and the meditation condition habituated heart rate and phasic skin conductance responses more quickly to the stressor impact and experienced less subjective anxiety. Meditation can produce a psychophysiological configuration in stress situations opposite to that seen in stress-related syndromes. Research is indicated on clinical applications and on the process whereby meditation state effects may become meditator traits.

Smith, Jonathan C. (1976). Psychotherapeutic effects of transcendental meditation with controls for expectation of relief and daily sitting. Journal of Consulting and Clinical Psychology, 44 (4), 630-637.

Two experiments were conducted to isolate the trait-anxiety-reducing effects of transcendental meditation (TM) from expectation of relief and the concomitant ritual of sitting twice daily. Experiment I was a double-blind study in which 49 anxious college student volunteers were assigned to TM and 51 to a control treatment, "periodic somatic inactivity" (PSI). PSI was carefully designed to match the form, complexity, and expectation-fostering aspects of TM but incorporated a daily exercise that involved sitting twice daily rather than sitting and meditating. In Experiment 2 two parallel treatments were compared, both called "cortically mediated stabilization" (CMS). Twenty-seven volunteers were taught CMS1, a treatment that incorporated a TM-like meditation exercise, and 27, CMS2, an exercise designed to be the near antithesis of meditation. Results show 6 months of TM and PSI to be equally effective and 11 weeks of CMS1 and CMS2 to be equally effective. Differences between groups did not approach significance ( $p > .6$ ). The results strongly support the conclusion that the crucial therapeutic component of TM is not the TM exercise.

1972

Meares, Ainslie (1972). Group relaxing hypnosis. Journal of the American Society of Psychosomatic Dentistry and Medicine, 19, 137-141.

The paper is reprinted from Med. J. Aust., 1971, 2, 675-676 with permission of Editor. The author discusses theoretical concepts, techniques and patient selection for this method. "I avoid all logical communication, as this would only keep the patient alert, and so prevent the atavistic regression which is the essential factor in

hypnosis" (p. 139). He moves from patient to patient, saying little except "Good--easy--natural" etc. and he uses touch to reinforce their development of hypnotic state. To ratify the trance and make sure they are hypnotized, not just relaxed, he places a clip on forearm skin for a few moments. "This potentially painful stimulus has the effect of further deepening hypnosis" (p. 139). After about 35-40 minutes he alerts the group. Patients are taught self hypnosis to extend the results into daily life.

**1968**

Meares, Ainslie (1968). Hypnotherapy without the phenomena of hypnosis. International Journal of Clinical and Experimental Hypnosis, 16, 211-214

A clear distinction must be drawn between the phenomena of hypnosis and the hypnotic state itself. Hypnosis is a state of mind characterized by regression to atavistic mental functioning. The phenomena are produced as a result of this regression. The production of phenomena in either the induction or the therapeutic process is generally undesirable. Hypnosis may be used for reduction of anxiety or as a therapeutic experience without the production of any hypnotic phenomena. 1963 Das, J. P. (1963). Yoga and hypnosis. International Journal of Clinical and Experimental Hypnosis, 11, 31-38.

The nature of Yoga and Samadhi (concentration) was described. A comparison with hypnosis revealed widely differing objectives, but many points of functional and methodological similarity. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Yoga methods (with introduction by W. Grey Walter). International Journal of Parapsychology, 5, 25-41.

1960 Meares, Ainsley (1960). The Y-state: An hypnotic variant. International Journal of Clinical and Experimental Hypnosis, 8 (4), 237-242.

(Author's Summary) "Two different forms or manifestations of hypnosis are commonly used in clinical practice. These are hypnotic sleep, and hypnotic activity. Hypnotic sleep is used for giving therapeutic suggestions, and for resting the patient. In this form, the patient is utterly passive. Hypnotic activity is used in abreaction, and in all the various techniques of hypnoanalysis. In this form the activity, whether it is verbal, emotional or motor, is uncontrolled. An hypnotic variant can be induced which materially differs from both hypnotic sleep and hypnotic activity. It is a Yoga-like trance, and for convenience is referred to as the Y-state. It is a state of calm abstraction. It is distinguished from hypnotic sleep by the intense cerebration, and from ordinary hypnotic activity by the fact that activity is subjective and is actively controlled. Y-state has been used with encouraging results in certain cases of chronic anxiety" (p. 241).

**"In contrast to hypnotic sleep, there is another variety of the hypnotic state which involves quite a different state of consciousness. For convenience, we will refer to it as the state of hypnotic activity. In it, the patient talks spontaneously and moves spontaneously. He may express himself by graphic or plastic means if he is given suitable materials. In hypnotherapy, this state of hypnotic activity is used in abreaction and in the uncovering techniques of hypno-analysis. In this state, the activity is essentially uncontrolled, and unrelated to present reality" (p. 237).**

**Sukhakarn, Khun Vichit (1960/1962). Extra ocular vision [Letter]. British Journal of Medical Hypnotism, 14 (2), 41-47.**

**The article is in the original form of a letter to Herbert Spiegel, M.D. The author describes experiences training subjects, both blind and with normal vision, to 'see' through the skin of their cheeks. Training involved concentrative meditation (Buddhist) and hypnosis. Simple tests were performed, apparently independently, by two other scientists.**

**"From information available from our subjects, the Extra Ocular Vision gained through the cheek-skin is different from those through the eyes as best explained here below:-- (1) The vision through the cheek-skin first takes a form of a series of spots somewhat like the image of coarse grain prints. Only after further training the spots are transformed into a clear object, so clear that needle threading is possible. (2) Objects seen through the cheek-skin are as clear as through the eyes. Distant objects can be magnified by the subject's wish, just like looking through an opera glass. (3) The vision gained through the cheek-skin is first 'seen' in black and white, and the 'colour picture' is achieved only after further training. But the colour 'seen' through the cheek is more intense than those through the eyes. (4) The field of vision 'seen' through each side of the cheek is more narrow than those seen through each eye. (5) There is a sign indicating that the vision through the cheek is only two-dimensional, the subjects find it difficult at first to stand the finger to another finger test" (p. 42).**

## **MEMORY**

**1995**

**Eisen, Mitchell L.; Henn-Haase, Clare (1995, November). Memory and suggestibility for events occurring in and out of hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.**

**Resistance to misinformation uses two paradigms: 1. Elizabeth Loftus - expose Subject to slides or videotape, give misinformation with leading or misleading questions 2. Martin Orne - pseudomemory, i.e. age regress people in hypnosis and suggest events occurred.**

**Each approach yields mixed results. Misinformation is accepted more readily in context of hypnosis; but there is no relationship to hypnotizability. Spanos found**

that highs were more responsive to social pressure. In general, in the absence of social pressure, when presented subtly and outside the context of hypnosis, the relationship diminishes. Other factors play a more prominent role: source of information, type of information, salience of information, etc.

They examined whether events occurring in context of hypnosis were more prone to distortion when assessed in biased fashion with use of misleading information, than outside hypnosis. Also, form of questions (dichotomous or with 'I don't remember' option).

They gave the Harvard and asked afterwards 3 misleading items (e.g. did you clench your fist, when they didn't do it). Also asked them to circle items if they had no memory of it. Tellegen Absorption Scale and Dissociation scale (DES) were administered a week later. Also a week later asked about events that occurred, including confederate items. Half of Ss had 2 choices, half had also 'I don't remember' as a third option.

In a previous study, resistance to misleading information was related to the strength of the initial memory and not to hypnotizability (article published in AJCH).

**RESULTS.** When given 3 choices, the number of misleading items endorsed dropped from .7 to 0.4 which is the most robust finding in the study and affects the rest of the study. Many Ss who endorsed the items reported minutes later that they had no memory for the event (on the check list). While many Ss given only two choices wrote in the margin that the event had never occurred.

Offering an 'I don't know' third option decreased endorsement of the Harvard items also, from 6.4 to 5.2 which is significant. The relationship between hypnotizability and endorsement of misleading items became much weaker when accounting for this.

Scoring high on DES is significantly related to accepting misinformation. Tellegen Absorption Scale also related to accepting misleading information. Harvard Hypnotizability Scale was not related to accepting misinformation.

Total memory on the Harvard (before cue plus after cue) did not correlate with resistance to misleading information. History of abuse was related to hypnotizability. Have to evaluate whether it was traumatizing, multiple abuse, etc.

Memory

1995

Bowers, Kenneth S. (1995, November). Revisiting a Century-Old Freudian Slip -- from Suggestion Disavowed to the Truth Repressed. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

Cites J. Herman, Mason, and Miller who accused Freud of retreating from trauma theory to save his theory. Feminists view the Oedipal theory as a coverup for the

denial of child sexual abuse. This moral position fuels trauma theory and practice. It is the moral dimension of this debate that gives so many problems for the investigation of traumatic memory.

The intellectual origins of repressed trauma are examined here. Freud's early trauma theory, his later conflict theory.

Etiology of Hysteria (1896) presents Freud's argument, based on 18 patients: child is passive victim of experience imposed on them; memory is repressed and hysterical symptoms are derivatives of these repressed memories; when memories return as pictures the task of therapy is easier than if returning as thoughts. Bartlett's memory research showed visual image is followed by sense of confidence that surpasses what should be there.

The fact that patients had to be compelled to remember was offered by Freud as evidence against the idea that the memories were suggested. The patients initially would deny the reality of their memories, which Freud used in saying that we should not think that patients would falsely accuse themselves. In letter to Fleiss, he presented the conflict theory, which he presented in 1905 in Three Essays on Sexuality and later in My Views...on Etiology of Neurosis.

In 1905 Freud indicated he was unable to distinguish fantasy from true reports (and did not deny the existence of the latter). Freud often reconstructed the "memories" from dreams, transference, signs, symptoms, fantasies, etc. They were not produced as conscious memories, and it was Freud who inferred the sexual abuse. From signs of distress he took evidence of proof.

Freud presented his theory to his patients and then sought confirmation.

Freud asks us to abandon historical for narrative truth. The problems with Freud's first theory became worse with his second theory. In Introductory Lectures Freud states that opponents say his treatment talks patients into confirming his theories. He relies on the patient's inner reality confirming the theoretical ideas given to him. Success depends on overcoming internal resistance, however. The danger in leading a patient astray by suggestion has been exaggerated, because the analyst would have had to not allow the patient to "have his say." Freud denied strongly ever having done this.

Incorrect interpretations would not be accepted by the patients, and if believed would be suggestion. Brunbaum, another writer, said that this doesn't mean acceptance of a faulty idea won't occur. Both Milton Erickson and especially Pierre Janet reported cases in which suggestions were used to give benign memories to replace malignant ones.

Freud also viewed patient resistance to his interpretations as evidence that the interpretations were correct. Thus both resistance and acquiescence were thought to be validating. Popper's critiques using philosophy of science note that this makes his theory untestable.

Freud could not distinguish between the patient's reluctant acceptance of the truth and reluctant acceptance of a suggestion.

Contemporary theorists struggle less than Freud did with the problem of suggestion and suggestibility (and Freud did not have available the research on those areas!) Emotional upheaval that accompanies "insight" is readily taken to be validating. It

may be true that bad memories are repressed, but that doesn't mean that all bad memories are true.

Treatment groups focus on recalling memories and sharing memories with others in the group, not on current relationships. Hermann states that the group provides powerful stimulus for remembering. The group, of course, is reinforced by others remembering. Repeatedly considering the possibility of abuse can increase the sense of familiarity.

Current views expressed by some clinicians that certain symptoms and syndromes (eating disorders, etc.) indicate early sexual trauma are similar to Freud's theory of hysteria. In these proposals, the inability to recall abuse becomes evidence that it occurred; and it tallies with the patient not having a sense of remembering.

Because some believe it is necessary to bring memory to light for cure to occur, there is a tendency to believe the reports of early childhood abuse.

Recognizing that some "memories" may have been a product of a therapist's suggestion helps prevent untoward effects. Modern therapists recapitulate Freud's "slip" when they do not acknowledge the role of suggestion.

Endorsing repression does not commit us to a belief that recovered memories must be accurate in all particulars. A memory that is repressed does not escape the usual kinds of degradation of memory.

And just because the material comes from unconscious sources, or has emotional accompaniments, it doesn't mean it is true. (Bowers gave an example of his dream that Israel and Venezuela shared a common border, which was rectified by his waking awareness of the Atlantic Ocean and the Mediterranean. He noted that nothing like the Atlantic can be called upon if the dream is that one's parent molested oneself at the age of six.)

Ian Hacking, in *Rewriting the Soul*, labels a more fundamental indeterminacy (for the historical past itself). Bathing rituals in childhood can be redescribed as abuse, which determines the historical past rather than describing it. It is thus easier to justify abuse if the event is something that can be reinterpreted. For example, the conflicts of adolescents with their parents, may be reinterpreted later if personality problems continue. If in adulthood one concludes that abuse occurred, then bathing rituals can be reinterpreted as if it were earlier abuse, as if the abuse has continued for years

Our study looked at suggestibility and resistance to suggestion. During 5-day hospitalization for investigation of child abuse. The first day patient gets physical exam; 2nd day a genital exam, heart arousal, stress arousal; a later day had mental status, emotional functioning, cognitive functioning--and gross screen of IQ for age 5 and up and the digit span for 6 and up, plus rating of global functioning and provisional diagnosis. On Day 5 each child was given structured interview that included questions about the anal- genital exam, with some misleading questions included.

35 minutes after the psychological examination they were given questions about the exam, for brief memory. Next exam was forensic examination of memory for abuse. Gave memory for sentences, perceptual alterations scale (PAS), adolescent version of Dissociative Experiences Scale (A-DES); gave questionnaire to parents.

**Hypotheses: suggestibility would be negatively related to age (more errors when younger). Sexually and physically abused children would show more dissociation or psychopathology. Dissociation or psychopathology should be inversely related to memory ability. IQ should be related to memory and resistance to misinformation. Wanted to reconcile two models of post traumatic stress disorder (PTSD): one says they have poorer memory, and the other says they are hypervigilant.**

**Over 100 children in the 200 received the questionnaire on Day 5. 39% were 3-5 years old, 41% 6-10 years old. 76% were African American. 22% had no documented abuse or neglect; 13% had experienced physical abuse; 30% sex abuse; 12% both types of abuse; 15% neglect; 8% parental addiction.**

**Measuring dissociation in kids is problematic. The concept is used to describe a huge range of phenomena. Scores on the DES are more highly correlated with the F Scale on the MMPI than with any other measure (Michael Nash's research). So the DES measures psychopathology. Also, children have healthy kinds of dissociation--daydreaming, etc. Josephine Hilgard noted that young kids are naturally involved in imagination. Early traumas may lead to this dissociative style. How do we sort out the healthy imaginal involvements of children from the psychopathology? There is not sufficient data at this time.**

**Available measures are not validated well. The CDC indicates behavior problems in children. The C-PAS conceptualizes dissociation as relating to eating disorders; the A-DES is a self report measure that related to psychopathology.**

**CDC scores increase, in 3-5 year olds, as the amount of abuse increases. This looks like general psychopathology, and it is a parental rating. The A-DES and C-PAS were not related to abuse or neglect. In the older groups the CDC related to poor performance on memory tests; but only for the 6-10 year olds. (Poorer memories in younger children could have masked the effect in them.)**

**The main finding for the study was clinician's estimate of Global Adaptive Functioning was significantly related to Resistance to Misleading Information. The effect did not show for the 3-5 yr old group, perhaps because their memory functioning is poor anyway. Also age was related to memory and suggestibility.**

**Frischholz, Edward J. (1995, November). A critical evaluation of the 1985 AMA Report on hypnosis and memory. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.**

**JAMA 1985 concluded that hypnotically refreshed memories are less reliable than nonhypnotic recall. There are two problems with their conclusion: 1. No consensually validated definition of 'hypnosis' is identified. They talk about administration of induction, and differences in hypnotic susceptibility. 2. Empirical criteria for discriminating the unique and/or moderating effects attributable to hypnosis are not specified.**

**For example Loftus showed that memory errors can be created without hypnosis. You should not just add hypnosis to that model.**

**The criticisms have not led to remedial practices. No research has been done to show how to minimize errors or how to facilitate accuracy.**

'What is Hypnosis?' Something that is done vs. something that happens? A procedure or responsivity? Questions like this are relevant to research on whether hypnotically refreshed memories are less reliable than ordinary recall.

Hypnosis is not a 'valid therapeutic modality' (i.e., 'hypnotherapy' is a misnomer). Hypnosis can be used adjunctively with many different types of therapeutic modalities: --psychodynamic therapies --behavior modification treatments --cognitive restructuring strategies --systematic desensitization --flooding --direct suggestion

There is a specious communality: hypnosis is used in a different kind of way with each approach.

If hypnosis is defined in terms of whether an hypnotic induction procedure was administered to the subject, then hypnosis is a universal phenomenon (i.e., everyone can be administered an hypnotic induction procedure). This, in the AMA report, permitted the courts to define it this way, which leads to a number of ridiculous results.

We need to highlight 'What are the variables that are the source of the errors?' The sources are not hypnosis. We can minimize the sources by the way we ask questions, instruct the subjects, etc.

If hypnosis is defined in terms of the nature of the subjects' response to the procedures, then hypnosis is not a universal phenomenon (i.e., there are wide individual differences in hypnotic responsivity). I have shown that it is possible to alter memories, using the Loftus model, in people who are both low and high hypnotizable.

We need to take into account induction procedure, hypnotizability, type of memory, and the retrieval/influence procedure. The demand characteristics re forced responding, expectancies about memory (e.g. video recorder model), expectancies about hypnosis (e.g., everyone remembers) must be accounted for.

Dependent variables in this type of research include memory accuracy, memory errors, and subjective confidence.

Laurence, Jean-Roch; Gendron, Marie-Josée (1995, November). Pay attention, it may happen by itself. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

Aronoff, J.; Green, J. P.; Malinoski, P.; Zelikovsky, N.; Lynn, S. J. (1994, October). Hypnosis and autobiographical memories: The impact of contextual factors. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco

We examined the individual differences in recall for early memories, in a college population, using the Autobiographical Memory Scale (AMS) along with other scales and with a hypnotizability scale (measured in same and different contexts). 75 male and 171 females subjects participated.

Presented as two separate experiments, so Ss would not make an explicit link between autobiographical memories and things measured in the second study.

**Exper 1. Administered AMS which indicates we are interested in their memories of events, and not what they were later told about the events. First 5 birthdays, first day of school, etc. Rate the detail, vividness, and accuracy.**

**Exper 2. Administered Fantasy Proneness (Wilson & Barber), Cognition, Imagery Control Scale, Derogotis, SAC (Brier's symptoms of child abuse), and Dissociative Experiences Scale.**

**Final sample of 247 Ss.**

**Earliest memory was 3.8 years.**

**Ss ratings of details, vividness, and accuracy were highly correlated. These were negatively correlated with age of first memory.**

**Bloom, Peter B. (1994). Clinical guidelines in using hypnosis in uncovering memories of sexual abuse: A master class commentary. International Journal of Clinical and Experimental Hypnosis, 42 (3), 173-178.**

**"Joan," a clinical psychologist, requested a psychiatric consultation to determine whether hypnosis could recover accurate memories of suspected child abuse by her still living father. Are there clinical guidelines in using hypnosis in uncovering such possible memories of sexual abuse? We asked Dr. Peter B. Bloom to share his views with us.**

#### **NOTES**

**Gives case example and clinical guidelines for using hypnosis in uncovering memories of sexual abuse. 1. In medical practice, "Primum non nocere," i.e. "First do no harm." 2. "No therapist should ever, either directly or indirectly, suggest abuse outside of a specific therapeutic context--certainly not to a client who is on the phone making a first appointment!" 3. "A therapist must not jump quickly to the conclusion that abuse occurred simply because it is plausible." 4. "A therapist should never simply assume that a client who cannot remember much from childhood is repressing traumatic memories or is in denial." 5. "Remember 'a client is most vulnerable to suggestion and the untoward influence of leading questions when therapy begins to delve into painful life situations from the past, particularly from childhood.'" 6. "Therapists ... should be cautious about suggesting that clients cut off communication with their families." 7. "Therapists should reconsider the 'no pain, no gain' philosophy of treatment." 8. "The context of therapy is as important as the content." 9. "Tolerate ambiguity." (Sincerity and conviction on the part of the patient reporting abuse are not in and of themselves reason to believe the material.) 10. "Respect the current science of memory." 11. "Maintain responsibility for making the diagnosis and choosing the treatment." 12. "Pursue alternative diagnoses to account for the symptoms." 13. "Historical and narrative truth: Understand the difference."**

**COMMENT: The tenet that insight is necessary for change and growth is not true. Change can occur without insight, although insight may be helpful in maintaining change once it has occurred.**

**SUMMARY:** These guidelines are presented to enhance safe practice, however, clinicians should use their own judgement to determine the best path to follow with each patient.

**NOTE:** Guidelines 1, 8, 9, 10, 11, 12, and 13 are those of Peter B. Bloom. Those labeled as Guidelines 2, 3, 4, 5, 6, and 7 were taken with permission from Yapko, M. (1993 September/October). "The seductions of memory. The false memory debate." *Family Therapy Networker*, 17, pp. 30-37. All discussions, however, are those of Peter B. Bloom.

Bowers, Kenneth S. (1994, October). Bringing balance to controversy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Skeptics argue that concept of "repression" has no scientific merit, though even if a valid concept, it wouldn't validate all memories recovered. Skeptics regard laboratory evidence as essential, while clinicians are impressed by case reports. See Polonyi, Personal Knowledge.

It is not reasonable to say there is no evidence for fugue states, when seeing one, if it has not been demonstrated in the laboratory. But you can investigate some of the phenomena in the laboratory.

Most of the time it is an affectively loaded idea that is repressed; in contrast, trauma usually lead to intrusions into consciousness. So repression of a traumatic event may be a rare way to deal with the event.

Claims for repression and ESP differ in that there are probably observable mechanisms in the former (e.g. thought avoidance). If a person ejects thoughts about a topic frequently enough, the ejections become automatic. Freud's original description of repression used the word "intentional" and it was a footnote that took out that idea. (See Erdelyi's publications).

Recent research we conducted on intuition and on problem solving is relevant to this problem.

[The remainder of Bowers' presentation is not summarized here.]

1994

Farvolden, Peter; Bowers, Kenneth. S.; Woody, Erik Z. (1994, October). Hypnotic amnesia: Avoiding the intentional loop. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Social-cognitive position is that suggestions for amnesia lead to motivated attempts to forget, and the sense of nonvolition is due to attributional error. Neo-dissociation position is that post-hypnotic amnesia is activated by suggestions, and material is not available to consciousness. Ss may mistakenly attribute their amnesia to their own efforts, or to their imaginings. (See their analgesia studies.)

Used a recall organization paradigm. Ss learn 16 item categorized word list, then are given suggestion to forget one category. After suggestion is canceled, Ss are told to report again. In their heart rate study, highs were amnesic and recalled words not targeted for amnesia. Highs weren't trying to forget, even though they were experiencing things happening cognitively during the waiting period.

Study II. One group of highs engaged in a distraction task, which would prevent their participating in task relevant practice. Ss in the distraction condition recalled fewer words, just as in the standard hypnosis condition. However, their subjective report indicated they had even a stronger feeling that something had happened beyond their volition or control than did Ss in the standard hypnotic condition.

It appears that task relevant thoughts and imagery reported by Highs are not necessary. They are co-suggestion effects. See Hargedon, Bowers, & Woody in similar work, on analgesia. However, during the recall period Highs did not work as hard as the Lows in trying to remember according to both their self-reports and the heart rate measure.

standard hypnosis condition. However, their subjective report indicated they had even a stronger feeling that something had happened beyond their volition or control than did Ss in the standard hypnotic condition.

It appears that task relevant thoughts and imagery reported by Highs are not necessary. They are co-suggestion effects. See Hargedon, Bowers, & Woody in similar work, on analgesia. However, during the recall period Highs did not work as hard as the Lows in trying to remember according to both their self-reports and the heart rate measure

Frankel, Fred H. (1994, October). On patients remembering abuse when it in fact may not have occurred. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

The concept of hidden memories has supported the profession of psychotherapy for a century. This process can only occur if there is a mechanism to support it. Bowers says, if memory is not reliably accurate, it is not reliably inaccurate either.

"Ideas passing as descriptions lead us to equate the tentative with [the factual]" - Gould.

Three studies purporting to establish repression: 1. Briere & Comte sampled 450 adults who reported abuse. They asked, "Was there ever a time when you couldn't remember the forced experience?" How does respondent understand the question?

Clients were all in therapy. 2. Herman and Schatzow (1989) "verification of abuse" study. 53 Ss in a survivor's group. Reports percentages who had no or little recall. Authors don't acknowledge that the group discussion and the attitude of therapist may have shaped the response. It is also not clear how many Ss who claimed to have "verified" their accounts were among those who had severe amnesia for the event. They could be Ss who had never lost the memory in the first place. 3. Williams interviewed women who earlier were in Emergency Rooms because of abuse being suspected. 38% did not report childhood abuse when questioned, and author concluded it was due to repression. Significant numbers of adults cannot remember things even past the age of 5.

Problem with wording of questions. Some of the women interviewed might have preferred not to report the event. This was not investigated in the study.

Freyd, Jennifer J. (1994). Betrayal-trauma: Traumatic amnesia as an adaptive response to childhood abuse. Ethics and Behavior, 4.

Betrayal-trauma theory suggests that psychogenic amnesia is an adaptive response to childhood abuse. When a parent or other powerful figure violates a fundamental ethic of human relationships, victims may need to remain unaware of the trauma not to reduce suffering but rather to promote survival. Amnesia enables the child to maintain an attachment with a figure vital to survival, development, and thriving. Analysis of evolutionary pressures, mental modules, social cognitions, and developmental needs suggests that the degree to which the most fundamental human ethics are violated can influence the nature, form, processes, and responses to trauma.

A logical extension of this research direction, based on a strategy that has been very effective in cognitive neuroscience, would be to look for neuroanatomical underpinnings of the cognitive mechanisms implicated in dissociation. ... For instance, the ability to dissociate current experience may depend partly on representational structures that support spontaneous perceptual transformations of incoming events. One possible perceptual transformation that is amenable to scientific investigation, would be the creation of spatial representations in which the mental 'observer' is spatially distinct from the real body of that observer. Such a representation would fit patient descriptions of 'leaving their body' during a traumatic episode and viewing the scene as if from afar. Additionally one could investigate the role of mental recoding and restructuring during memory 'recovery' and psychotherapy" (pp. 19-20).

to scientific investigation, would be the creation of spatial representations in which the mental 'observer' is spatially distinct from the real body of that observer. Such a representation would fit patient descriptions of 'leaving their body' during a traumatic episode and viewing the scene as if from afar. Additionally one could investigate the role of mental recoding and restructuring during memory 'recovery' and psychotherapy" (pp. 19-20).

Ganaway, George K. (1994, October). The thin line: Reality and fantasy in hypnotically facilitated memory retrieval during psychotherapy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Historical review: Every hundred years there has been a peak in interest in altered states--a fin de siècle zeitgeist. It is the Brigadoon effect, i.e. something materializing for one day every 100 years. The theories developed then suffer from "paradigm grandiosity." In hypnosis, we can refer back to:

1694 Salem witch trials

1790s Gausser's exorcism (see Ellenberger); in a 1775 showdown between him and Mesmer, there occurred the turning point between exorcism and psychotherapy.

1880s Charcot at Salpêtrier 'demonstrated' that hypnosis was an organic, pathological condition. Ultimately this contributed information about the plasticity of hypnotized people. (In the 1880s Bernheim thought it wasn't pathological and thought that suggestion was the important element in hypnosis.)

Recent historical contributions have influenced our views of MPD. Spiegel and Kardiner published book about hypnosis and war neuroses. Cheek & LeCron developed ideomotor questioning, which ignores the contribution of unconscious fantasy. Jacob Arlow's metaphor for MPD is two movie projectors aiming at a screen from two different sides. The subjectively known experiential world thereby combines external reality and the person's internal, motivated perceptions. The author presented a case study of female therapist, who had been previously diagnosed as MPD, who presented with dissociative symptoms that she thought were due to abuse by her grandmother. She fabricated the memories in order to get the holding and physical nurturing from her therapist for being courageous and remembering the abuse.

Maintenance of professional boundaries is very important in treatment.

Krippner, Stanley (1994, August). Improvement of academic skills for children and adolescents with hypnosis. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

Literature and research in this area are sparse, though there is clinical evidence that hypnosis is useful. My definition of hypnosis is a procedure facilitating a variety of structured goals or procedures in which a suggestion or motivation is enhanced by a mechanical device, another person, or oneself.

There are 3 areas of application in academics:

study habits

test taking

strengthening academic motivation

The hypnotist should know the specifics of academic achievement, because specific suggestions (e.g. "Imagine you are at desk focusing well for 20 minutes,") are better. Emphasis on the positive is better than negative. Use the words "imagination," "concentration," or "imagining pictures," rather than "hypnosis." I try to determine what they expect, based in part on what words they use.

In elementary school I focus on attitude and self esteem. I have them imagine reading a story, then how well they feel; that when they notice mistakes they won't be bothered because everyone makes mistakes.

For high school, I help them develop good habits for time motivation (e.g. suggestions to "make an outline to follow while you study"). At college level, I introduce self hypnosis. I make frequent use of mental imagery, at all levels--especially imagery rehearsal, in which the person is engaged in a particular activity. In the NSF report on accelerated learning techniques (a project sponsored by the Army), Lozonov's "suggestopedia" techniques were studied. This review indicated it might enhance training effectiveness and reduce training time.

I have observed the suggestopedia classes in Bulgaria and Hungary. Classes had a relaxed comfortable learning environment. Rather than individual learning, it was group learning. It included preliminary exercises, new material, and a review of what was learned. The first stage used 2/3 of the time. Then suggestions were given by the teacher to promote learning. The presentation phase took one third of the time. The method encourages students to make mental images of the material. In foreign language classes, people take on new roles.

1993

Bennett, Henry L. (1993, October). Hypnosis and suggestion in anesthesiology and surgery. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

He began by saying that he is opposed to using hypnosis for surgery, though he favors a theory of how hypnosis effects physiological change, and cites T. X. Barber's classic "Changing Unchanging Bodily Processes."

Relaxation puts patient in a "psychological strait jacket" because surgery is so highly stressful. He gives information "about how to go through the surgery more comfortably," gets across the idea about coping style, tells them surgery is exertional and that they are tired afterward, that he can help them "using things you already know how to do," and specifies exactly what they can do--using model of himself as a trainer.

In some recent research he used pairs of pictures, some of which lead to pupillary constriction (blood pressure goes down) or dilation (blood pressure goes up). Instructing them to look, patients looked twice as long at the pictures than they did during free gaze. When not instructed to look, heart rate went down; when told to look, heart rate went up. So the researchers went back to free gaze. He uses this as a metaphor for many of the pre- surgery preparation activities that encourage relaxation "inappropriately."

He cites Cohen & Lazarus re vigilant copers, Price et al (1957), and some other studies on epinephrine effects. He uses examples of work patients may have done (e.g. planting a garden) when talking with patients prior to surgery, that gives them a sense of accomplishment later.

You have to give specific instructions or suggestion, not general relaxation suggestions.

Question from the audience: Can preoperative instructions (not hypnosis) diminish blood loss.

In Bennett's answer he seems to be reporting the earlier study: they found 150- 4000 cc blood loss, high variability. Extent of blood loss was determined by extent of surgery, by instructions to patients vs no instructions.

This study was replicated by Enqvist, Bystedt, & von Konow in the Anesthesia conference at Emory University in 1992.

May 1993 Western Journal of Medicine article, Disbrow, Bennett, & Owinos, with 40 lower abdominal surgery patients who got specific instructions or not. The SHCS was used to measure hypnotizability: highs resolved quicker than low hypnotizable patients. They also found that instructed patients did better than those who did not get specific instructions.

There are now 3 replications of McClintock's study: people use less medications after surgery, when tapes about rapid recovery are played \*during\* surgery.

Bennett is now using tapes with suggestions for recovery during surgery.

1992

Barrett, Deidre (1992). Fantasizers and dissociaters: Data on two distinct subgroups of deep trance subjects. Psychological Reports, 71, 1011-1014.

The study delineated two subgroups of highly hypnotizable subjects. The first subgroup (fantasizers) entered trance rapidly, scored high on absorption (mean of 34 on the 37-item Absorption Scale), and described hypnosis as much like their rich, vivid, and very realistic waking fantasy life. None of the fantasizers experienced unsuggested amnesia, and 5/19 failed to produce suggested amnesia. Only 2/19 fantasizers described hypnosis as very different from their other experiences. The earliest memories of fantasizers were all identified as occurring before age 3, and before age 2 for 11 of 19. The second subgroup (dissociaters) took time to achieve a deep trance (unlike Wilson and Barber's fantasy-prone subjects, but they did achieve as deep a trance as fantasizers), experienced hypnosis as different from any prior experiences, and were more likely to exhibit amnesia for both hypnotic experience and waking fantasies. None of the dissociaters described their waking imagery as entirely realistic, and the earliest memories in this group were all over the age of 3 (mean age - 5). Of the 15 dissociaters, 7 scored below the norm on the Absorption Scale (Mean - 26).

Blankfield, Robert; Scheurman, Kathleen; Bittel, Sue; Alemagno, Sonia; Flocke, Sue; Zyzanski, Stephen (1992, October). Taped therapeutic suggestions and taped music as adjuncts in the care of coronary artery bypass graft patients. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

18 studies have explored the issue with an experimental design; half used tapes, half didn't; majority of studies found benefits; 2 were of heart surgery patients.

This study used taped suggestions with coronary bypass patients. Used tape recorder rather than person delivering suggestions because it was more convenient; used tape intra-surgery and post-operatively for more impact.

We hypothesized: shorter length of stay, less narcotic analgesia, less anxiety, faster recovery, more positive mental outlook, resume activities sooner, have less symptoms postoperatively, etc.

Used a prospective, randomized, single-blind trial in 2 community hospitals in Cleveland with coronary artery bypass graft surgery patients. Study was done between Dec 1989 - Feb 1992.

3 groups were involved: (1) Suggestion, (2) music, and (3) tape. Control subjects had a blank tape. Tapes were played continuously and repeatedly with headphones. Postoperatively, a different tape was played.

**Excluded:** Patients with emergent surgery, hearing impairment, poor comprehension of English, patients who died in hospital, patients whose hospital stay lasted longer than 14 days (3 of them). 5% of sample were eliminated for last 2 reasons.

**Music:** Herb Ernst, Dreamflight II. **Suggestions:** Music background, permissive, based on Evans & Richardson's study.

**Outcome Measures:** Nurse assessment of anxiety and progress post operatively, Symptom scale, Depression scale.

Mean age 62, 3/4 men, 92% white, 75% married. The groups were same on a variety of preoperative variables (status of heart and arteries). Length of stay was 6.5 in all 3 groups. No difference in narcotics use, in nurse assessment of anxiety or of progress; of depression scale, or activities of daily living.

Recategorized data into patients who said the tapes were helpful (both music and suggestion) N = 33 vs the other patients N = 62. No difference in the variables evaluated.

1992

Christianson, S-A (1992). Emotional stress and eyewitness memory: A critical review. Psychological Bulletin, 112, 284-309.

Although not addressing hypnosis specifically, this is a comprehensive review of literature on memory for negative emotional events relevant to issues of hypnosis and memory. The final conclusion is that emotional events are indeed remembered differently than neutral or ordinary events and are well retained with respect to the event itself and concerning central, critical detail (not peripheral detail). Such memories seem less susceptible to forgetting. There is evidence for dissociation between memory for emotional information and memory for specific event information. There is also evidence of amnesia or memory impairment effects after high-arousal events, with memory increasing as more time passes after the event. The functional amnesia effects are probably due to an interaction between altered encoding operations and the specific retrieval circumstances aiding consciously and unconsciously controlled reconstructive processes. There is little evidence to support Loftus' contentions that emotional stress is bad for memory.

Claridge, Karen (1992). Reconstructing memories of abuse: A theory-based approach. Psychotherapy, 29, 243-252.

The recovery of traumatic memories is an important part of therapy with survivors of abuse. This article describes a conceptual framework for memory reconstruction based on Horowitz' (1986) theory of stress response syndromes. The client's history of intrusive symptoms provides a way to anticipate the nature of the trauma, even when no memory of it exists. Ongoing intrusive symptoms are used to retrieve memory fragments, and their emotional impact is used to build the client's

emotional tolerance. Emphasis is placed on preparing for memories by identifying what the client will need when the memories return, building coping skills, and beginning to restructure cognitions at the "what if" stage of remembering. Case material is used to illustrate.

Darken, Rachel (1992). Hypnosis in the treatment of survivors of sexual abuse. Australian Journal of Clinical and Experimental Hypnosis, 20, 105-110.

This paper outlines the problems of child sexual abuse and its long-term sequelae, often reaching down generations. In psychotherapy with survivors of childhood sexual abuse, hypnosis offers a flexible treatment modality and the paper focuses particularly on the use of hypnosis and self-hypnosis for the "reparenting" element of psychotherapy.

Erdelyi, Matthew, Hugh (1992). Psychodynamics and the unconscious. American Psychologist, 47, 784-787.

The original New Look integrated the constructivist-psychodynamic traditions of Bartlett and Freud. The unconscious (Greenwald's "New Look 3") is a logically different idea, although in practice it is often intertwined with constructivist - psychodynamic approaches. The unconscious is a pretheoretic term with a variety of problems: It has multiple and unsettled meanings; null reports need not signify null awareness; the conscious-unconscious dichotomy implied by the limen may not exist; even "absolute subliminality" (chance-level accessibility) is relative to the time interval of testing, as accessibility can increase to above-chance levels over time (hypermnnesia). Yet, the phenomena that the unconscious sloppily subsumes are not simple or dumb. The capacity of subliminal perception should not be confused with the capacity of subliminal (unconscious) memory and cognition.

Faller, Kathleen Couborn (1992, Summer). Can therapy induce false allegations of sexual abuse?. The Advisor (Published by American Professional Society on the Abuse of Children), 5 (3), 3-6.

"Concern about the impact of therapy on children's accounts of sexual abuse should be understood in the context of two phenomena: (1) the adult need to deny that children are sexually abused, and (2) adult identification with the alleged abuser. These phenomena operate at both individual and societal levels" (p. 3).

"Research related to impact of stressful situations on children's ability to recall provides mixed results, some studies finding children are less accurate if the event is traumatic (Peters, 1991) and others finding they are not (Goodman, Reed, & Hepps, 1985).

"Research reveals that it is rare for children to falsely allege that they have been touched in their private parts. In one study, a substantial proportion of children who experienced genital and anal touch during a physical examination by a doctor did not volunteer this information when asked general questions about the examination. The majority of children in the study revealed genital and anal touch

only when they were asked specific questions like, "Did the doctor touch you there?" (Saywitz, Goodman, Nicholas, & Moan, 1991)" (pp. 3-4).

"Clarke-Stewart and her colleagues (1989) have demonstrated that children's interpretation of ambiguous events can be manipulated and altered by an authority figure who insists upon a particular interpretation (see also Lindberg, 1991)" (p.4).

"In sum, the research suggests that older children are likely to provide more complete unassisted disclosure than younger children. Younger children may need more memory cues in the form of specific questions than older children. Therapists are much more likely to find false negatives than false positives. Finally, therapists should be aware of the possibility the child may identify the wrong person. ... Generally, however, the research indicates that concern about the contaminating effects of therapy on children's recollections of sexual abuse is exaggerated" (pp. 4-5).

"Research indicates that the proportion of fabricated reports may be higher in the divorce scenario than in other contexts (Faller, 1990; Jones & Seig, 1988). Studies suggest most false reports are made by adults, not children (Jones & McGraw, 1987; Jones & Seig, 1988)" (p. 5).

"Clinical research (Sorenson & Snow, 1991) and experience (Faller, 1988) indicate that for most children, revealing sexual abuse is a process which occurs over time. A typical pattern is one in which children begin with the least overwhelming experience and gradually disclose more and more as their accounts are accepted and believed" (p. 5).

"[In conclusion]... therapists should be aware of the findings from research on children's memory and suggestibility. This research indicates that there are vulnerabilities which should be taken into account during therapy" (p. 6).

Gravitz, Melvin A. (1992, October). Historical and legal issues. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

The 1976 Chowchilla kidnaping case in California stimulated interest in using hypnosis for forensic investigation; in the same year, it was used in a case of airline hijacking in the Mediterranean to Uganda. Hypnosis is used for obtaining "leads" and doesn't claim to develop "the truth."

Other uses include: lifting amnesia of witnesses and victims of trauma--including but not limited to crime; obtaining additional information in nonamnesic Ss; evaluation of a subject's mental condition (e.g. multiple personality disorder vs malingering, as in the Bianchi case). In each use, hypnosis is not infallible, is not complete. But no procedure is. Motivation, resistance, transference are all critical.

Historic questions: 1. whether coercion is entailed 2. impact of hypnosis on memory 3. possible harm to subject, physically and mentally

The coercion issue dates to Mesmer, whose procedures led to accusations of immoral suggestions. In the 1880s Charcot said no one could be forced to do anything while the Nancy school (Liebeault) said they could. Since then we have seen laboratory studies using student volunteers, fake "poison," rubber daggers, etc., as well as recent "real life" studies where Ss were induced to violate their morals (see Watkins). Review articles include those by Jacob Conn of Baltimore and the 1985 JAMA article written by a panel headed by Martin Orne.

For impact of hypnosis on memory, see the Orne report which did not fully support using hypnosis for memory enhancement.

Regarding possible harm to a hypnotic subject in the 19th century, a young man's death was attributed to nervousness and exhaustion and diabetes due to repeated hypnosis. Other studies of death (of chickens, of a frog) due to repeated hypnotization were published. Now the consensus is that hypnosis is not dangerous (but incompetence using hypnosis may be dangerous).

#### LEGAL PRECEDENTS.

In 1897 a California court refused to accept testimony of a Subject who had been hypnotized. *People vs Eubanks*.

The 1950's Cornell case established that a person can be hypnotized for their own defense.

In 1963 the California supreme court ruled that a lower court made a mistake in not admitting testimony from someone who had been hypnotized.

In Harding (a Maryland case), the trauma victim, amnesic, was hypnotized one month later. The testimony was accepted. A 1983 Maryland appeals court overturned it, influenced by the California Shirley case.

In 1983 Hurd case, a victim, hypnotized, identified her husband as attacker. Lower court didn't permit the testimony; then a higher court reversed it. The court issued what are known as the Hurd rules, governing testimony that is acceptable: 1. hypnotist is licensed psychologist or psychiatrist with training in hypnosis 2. hypnotist must be independent of both the prosecution and defense 3. all information given to the hypnotist about the case must be written 4. hypnotist must obtain a nonhypnotic account of the memory before hypnosis is used. 5. must have taped record of the hypnosis sessions (preferably videotaped) 6. only hypnotist and subject should be present in the room

Soon after, California had the Shirley case. The California court ruled hypnosis per se is unreliable because it produces confabulation. This decision had a chilling effect throughout the country for several years.

In 1987 we had Rock vs Arkansas, the first and only case involving hypnosis to come before the U. S. Supreme Court. Vicky Rock shot her husband. Under hypnosis, she remembered she did not have her finger on the trigger, and her husband grabbed her and shook her. Lower court wouldn't admit the testimony of the gun expert, who testified the trigger was sensitive to jarring. Supreme Court ruled defendants (not necessarily others) could use hypnosis in their own defense.

**Greenwald, Anthony G. (1992). *New Look 3: Unconscious cognition reclaimed. American Psychologist, 47, 766-779.***

Recent research has established several empirical results that are widely agreed to merit description in terms of unconscious cognition. These findings come from experiments that use indirect tests for immediate or long-term residues of barely perceptible, perceptible-but-unattended, or attended-but-forgotten events. Importantly, these well-established phenomena--insofar as they occur without initially involving focal attention--are limited to relatively minor cognitive feats. Unconscious cognition is now solidly established in empirical research, but it appears to be intellectually much simpler than the sophisticated agency portrayed in psychoanalytic theory. The strengthened position of unconscious cognitive phenomena can be related to their fit with the developing neural network (connectionist) theoretical framework in psychology.

**Jacoby, Larry L.; Lindsay, D. Stephen; Toth, Jeffrey P. (1992). *Unconscious influences revealed: Attention, awareness, and control. American Psychologist, 47, 802-809.***

Recent findings of dissociations between direct and indirect tests of memory and perception have renewed enthusiasm for the study of unconscious processing. The authors argue that such findings are heir to the same problems of interpretation as

are earlier evidence of unconscious influences--namely, one cannot eliminate the possibility that conscious processes contaminated the measure of unconscious processes. To solve this problem, the authors define unconscious influences in terms of lack of conscious control and then describe a process dissociation procedure that yields separate quantitative estimates of the concurrent contributions of unconscious and consciously controlled processing to task performance. This technique allows one to go beyond demonstrating the existence of unconscious processes to examine factors that determine their magnitude.

Kihlstrom, John F.; Barnhardt, Terrence M.; Tatarzyn, Douglas J. (1992). The psychological unconscious. American Psychologist, 47, 788-791.

In response to Greenwald's article on contemporary research on unconscious mental processes, the authors address three issues: (a) the independence of much recent research and theory from psychodynamic formulations; (b) the broad sweep of the psychological unconscious, including implicit perception, memory, thought, learning, and emotion; and (c) the possibility that the analytic power of unconscious processing may depend both on the manner in which mental contents are rendered unconscious and the manner in which they are to be processed.

Lewicki, Pawel; Hill, Thomas; Czyzewska, Maria (1992). Nonconscious acquisition of information. American Psychologist, 47, 796-801.

The authors review and summarize evidence for the process of acquisition of information outside of conscious awareness (covariations, nonconscious indirect and interactive inferences, self-perpetuation of procedural knowledge). Data indicate that as compared with consciously controlled cognition, the nonconscious information - acquisition processes are not only much faster but are also structurally more sophisticated, in that they are capable of efficient mechanisms of non-conscious acquisition of information provide a major channel for the development of procedural knowledge that is indispensable for such important aspects of cognitive functioning as encoding and interpretation of stimuli and the triggering of emotional reactions.

processing of multidimensional and interactive relations between variables. Those mechanisms of non-conscious acquisition of information provide a major channel for the development of procedural knowledge that is indispensable for such important aspects of cognitive functioning as encoding and interpretation of stimuli and the triggering of emotional reactions

1991

Block, Robert I.; Ghoneim, M. M.; Sum Ping, S. T.; Ali, M. A. (1991). Efficacy of therapeutic suggestions for improved postoperative recovery during general anesthesia. Anesthesiology, 75, 746-755.

There have been claims that the postoperative course of patients may be improved by presentation during general anesthesia of therapeutic suggestions which predict a rapid and comfortable postoperative recovery. This study evaluated the effectiveness of such therapeutic suggestions under double-blind and randomized conditions. A tape recording predicting a smooth recovery during a short postoperative stay without pain, nausea, or vomiting was played during anesthesia to about half the patients (N = 109), while the remaining, control patients were played a blank tape instead (N = 100). The patients were primarily undergoing operations on the fallopian tubes, total abdominal hysterectomy, vertical banding gastroplasty, cholecystectomy, and ovarian cystectomy or myomectomy. The anesthesia methods consisted of either isoflurane with 70% nitrous oxide in oxygen to produce end-tidal concentrations of 1.0, 1.3, or 1.5 MAC; or 70% nitrous oxide in oxygen combined with high or low doses of opioids. Assessments of the efficacy of the therapeutic suggestions in the recovery room and throughout the postoperative hospital stay included: the frequency of administration of analgesic and antiemetic drugs; opioid doses; the incidence of fever; nausea, retching, and vomiting; other gastrointestinal and urinary symptoms; ratings of pain; ratings of anxiety; global ratings of the patients' physical and psychological recoveries by the patients and their nurses; and length of postoperative hospital stay. There were no meaningful, significant differences in postoperative recovery of patients receiving therapeutic suggestions and controls. These negative results were not likely to be due to insensitivity of the assessments of recovery, as they showed meaningful interrelations among themselves and numerous differences in recovery following different types of surgery. Widespread utilization of therapeutic suggestions as a routine operating room procedure seems premature in the absence of adequate replication of previously published positive studies. (Key words: Anesthesia, depth: Awareness, Memory, Recall, Learning.)

Patients ages 19-55 were accepted into the study and they were paid for participation. (Older patients were excluded to guard against memory or hearing problems.) Other criteria for exclusion were: ASA physical status 4 or 5 indicating significant systemic disease, visual or hearing problems, middle ear disease (because it increases probability of nausea and vomiting), if their condition might require heavy sedation, if they were currently taking medication that interferes with memory (e.g. benzodiazepines, if there were intolerance to opioids, or if there were a likelihood of using postoperative pain treatment other than opioids).

The Spielberger State-Trait Anxiety Inventory was administered before surgery. Either suggestions (lasting 6 minutes) or a blank tape were played through headphones, starting 5 minutes after the surgical incision. The tape was played once for the first 59 patients, continuously for the remaining 150 patients. The first 139 patients received additional verbal materials on the tape, for memory tests to test possibility of learning under anesthesia. Operating room sounds were recorded by a tape recorder near the patient's head, throughout period of unconsciousness (except when tape was being played).

After the first 25% of cases, the team decided that lack of effect on therapeutic suggestions attributable to type of anesthesia did not warrant restriction to a single

anesthetic method; also, multiple presentations of the suggestions on tape did not show an effect different from a single presentation.

After the patient regained consciousness and was reoriented, pain, nausea, retching, and vomiting were assessed every 30 minutes. Pain was rated orally on a scale from 1 to 10 in the recovery room, then on visual analogue scales every 2 hours on the day of surgery and the second day, and every 4 hours on subsequent hospital days during waking hours. Variables that were rated by staff every 24 hours included: opioids, other analgesics, antiemetics, nausea, vomiting, retching, presence or absence of nasogastric tube, passage of flatus, bowel movement, fluid intake, solids intake, urination. Temperature was recorded every 4 hours for the first 2 days after surgery, and after that less often. The anxiety measures were repeated on Day 3 postsurgery, as well as self ratings and nurse ratings on physical and psychological recovery. Staff recorded length of postoperative hospital stay and reasons for any delay of discharge. Separate analyses were performed for patients receiving opioids via patient-controlled analgesia (52%) vs traditional administration (48%), but no differences were found for effects of therapeutic suggestions except on postoperative Day 8.

"The inability to detect beneficial effects of therapeutic suggestions probably was not due to insensitivity of the measures of recovery. These measures were sensitive enough to show numerous significant differences in recovery after different types of surgery" (p. 751). The authors supported their contention that the measures were sufficiently sensitive by demonstrating meaningful correlations among the measures themselves; and by demonstrating adequate statistical power for detecting the effects of theoretical interest--at least 1 day in postoperative hospital stay or one half day in fever.

**Discussion:** The authors note that a recent investigation that found positive results in a double-blind, randomized design with 39 hysterectomy patients (Evans & Richardson, 1988. Improved recovery and reduced postoperative stay after therapeutic suggestions during general anaesthesia. *Lancet*, 2:491-493) may not have controlled for variables such as presence of malignancy, physical status of patients before surgery, or ethnicity. Authors note that Evans and Richardson observed shorter periods of pyrexia despite there being no relevant suggestions, but no differences in pain intensity, nausea, vomiting, or urinary difficulties despite there being suggestions relating to those symptoms. There also were no differences in mood and anxiety test scores postoperatively for the experimental and control groups.

The authors note that McLintock, Aitken, Downie, & Kenny (Postoperative analgesic requirements in patients exposed to positive intraoperative suggestions. *Br M J* 301:788-790. 1990) reported a 23% reduction in opioids by patients receiving suggestions, but no reduction in pain, nausea, or vomiting. They contrast the present study with these earlier studies that had obtained positive results.

"We studied patients who had more than one type of surgery to obtain a large sample size and to assess the possibility that beneficial effects of therapeutic suggestions would be restricted to certain types of operations. Had this been the case, interactions of therapeutic suggestions with type of surgery would have been significant in the overall analyses, and follow-up analyses would have indicated that

they were attributable to beneficial effects of therapeutic suggestions for certain surgeries. This did not occur. The two types of surgeries involving the largest numbers of patients seemed particularly promising for demonstrating beneficial effects. It has been reported that therapeutic suggestions presented during anesthesia are likely to be less successful with major and extensive surgery. Certainly, surgery on the fallopian tubes and gastric stapling did not involve a great deal of tissue trauma and blood loss. Patients were motivated to have the surgery and to recover quickly; particularly motivated were those having operations on the fallopian tubes, who were very eager to become pregnant, and those having vertical banding gastroplasties, who wanted desperately to lose weight" (pp. 753-754).

"In practice, we observed no beneficial effects of therapeutic suggestions, and there was no hint that anesthesia methods influenced the efficacy of the therapeutic suggestions. Interestingly, anesthetic methods also did not influence learning under anesthesia in the implicit memory tests we have used previously. Patients anesthetized with nitrous oxide and opioids did not differ from those anesthetized only with inhalational agents. In general, implicit or unconscious memory occurs in patients regardless of anesthesia methods or dosages of drugs" (p. 754).

"The few significant effects of therapeutic suggestions in our study did not point toward a beneficial influence of these suggestions. We found, in fact, an increased frequency of retching (but not nausea or vomiting) in the experimental group. The multiple variables examined in this study increased the likelihood of significant differences arising by chance, such that the null hypothesis was rejected when it should have been accepted. This is the way we interpret the effect on retching---i.e., as a type I error. We used in our therapeutic suggestions one negative or exclusionary sentence, 'You won't feel nauseous or have to vomit', among several positive or affirmative statements, e.g., 'You will enjoy eating, drinking...You will swallow to clear your throat and everything will go one way, straight down. . . The food will taste good....Your stomach will feel fine.' We do not think that the negative sentence led to paradoxical results. Evans and Richardson (personal communication) used in their therapeutic suggestions a negative sentence ('You will not feel sick'), which they repeated, yet the reported incidence of nausea and vomiting did not differ between the experimental and control groups" (p. 754).

when tape was being played). Bodden, Jack L. (1991). Accessing state-bound memories in the treatment of phobias: Two case studies. American Journal of Clinical Hypnosis, 34, 24-28.

Two cases of simple phobia demonstrate the inadequacies of both behavioral and psychodynamic theories. These cases and their treatment outcomes provide support for the state-dependent memory and learning theory. Hypnosis and ideomotor signaling proved to be not only effective treatments but also useful means of illuminating the role and nature of symptom function. Issues of symptom removal and substitution are also discussed in relation to these cases

The authors state that Rossi and Cheek (1988) summarize a number of experimental studies on animal memory that demonstrate that different information substances are involved in different learning situations. For example, ACTH and cortisol are involved in avoidance learning while angiotensin is involved in operant conditioning. In hypnosis, state dependent memory seems to be implicated. "Hilgard (1977) interpreted the state-dependent memory studies by Overton and others as entirely consistent with and supportive of his theory of hypnosis. Milton Erickson (1948) has also strongly suggested that it is the altered levels of arousal and affect that are responsible for the encoding and recall of stress-related problems with hypnosis" (p. 26).

"Affective experiences are apparently stored independently from their intellectual counterparts, or the emotional unit form one set may attach itself to a constellation of cues that make up a totally different cognitive set. Hypnosis may facilitate recall by providing relevant cues during an altered state of consciousness" (p. 27).

"In commenting upon [one of Erickson's cases], Rossi (1986) states that Erickson was effective because he helped the patient access state-bound memories by reviewing the context and sensory-perceptual cues that surrounded their original acquisition" (p. 27).

"When traditional behavior therapy fails it may be because the original fear stimulus is state bound or unconscious. What is conscious to the patient are those stimuli that are similar in some important respect to the original phobic stimulus and are acquired by stimulus generalization. Desensitization may reduce the patient's reactivity to the associated or acquired stimuli but cannot desensitize the original stimulus until it can be accessed consciously" (p. 27).

"The two main psychological explanations of phobic behavior are psychodynamic and behavioral. The psychodynamic approach is built upon the early writings of Freud (1956) on the traumatic basis of neurosis. Freud speculated that the intense anxiety (psychic pain) associated with the emotional trauma lead to dissociation, repression, and amnesia. Symptoms represented a dissociated or symbolic vestige of the repressed ('forgotten') trauma.

**"Behavioral explanations (e.g., Rimm & Masters, 1974) are built upon classical and operant conditioning models of learning. Classical conditioning explains how a neutral stimulus (e.g., a bridge) can acquire reactivity and elicit a fear response. Avoidant behavior, which preserves the phobia, is acquired and maintained by operant conditioning. Treatment apparently involves gradual extinction of the fear response.**

**"These two divergent explanations have spawned quite different therapeutic approaches, with the behavioral approach (systematic desensitization) demonstrating greater empirical support for its effectiveness (Kaplan & Sadock, 1986). The problem is made complex theoretically by the fact that desensitization doesn't always work, even when applied in a competent fashion" (p. 25).**

**"Freud's early work on the traumatic basis of neurosis pointed to but offered an incorrect explanation of phobias whose origins were unconscious or state bound (i.e., not available to recall during the normal conscious state)" (p. 25).**

Bowers, Kenneth S. (1991). Dissociation in hypnosis and multiple personality disorder. International Journal of Clinical and Experimental Hypnosis, 39, 155-176.

The first part of this paper examines the concept of dissociation in the context of hypnosis. In particular, the neodissociative and social psychological models of hypnosis are compared. It is argued that the social psychological model, in describing hypnotic enactments as purposeful, does not adequately distinguish between behavior that is enacted "on purpose" and behavior that serves or achieves a purpose. 2 recent dissertations (Hughes, 1988; Miller, 1986) from the University of Waterloo are summarized, each of which supports the neodissociative view that hypnotic behavior can be purposeful (in the sense that the suggested state of affairs is achieved) and nonvolitional (in the sense that the suggested state of affairs is not achieved by high level executive initiative and ongoing effort). The second part of the paper employs a neodissociative view of hypnosis to help understand the current epidemic of multiple personality disorder (MPD). In particular, it is argued that many symptoms of MPD are implicitly suggested effects--particularly prone to occur in persons who have a lifelong tendency to use dissociative type defenses. The present author believes that this account is easier to sustain conceptually and empirically than the current view, which states that a secondary (tertiary, etc.) personality accounts for the striking phenomenological discontinuities experienced by MPD patients.

As an example of the fact that behavior that serves a purpose is not always performed on purpose, the author cites not falling out of bed while sleeping, and waking up in response to signals from the bladder to go to the bathroom. Lower levels of control can be dissociated from executive initiative and/or monitoring. "Since the experience of volition is closely tied to executive initiative and effort, suggested behaviors that bypass such initiative and effort are typically experienced as nonvolitional" (p. 157). Dissociated control occurs under waking conditions also, as when one dials a very familiar phone number rather than the one that they intended to dial. In this case, the behavior that is enacted is not what one consciously intended.

Miller's dissertation, also published as Miller & Bowers, 1986, is described on p. 158 ff. Without hypnosis, cold pressor pain (cold water immersion) reduced accuracy of performance on a multiple choice vocabulary test 35%. Both hypnotic analgesia and cognitive pain management strategies were equally effective in reducing pain of cold pressor test (and both interventions were more effective for high than for low hypnotizable Ss). However, the cognitive strategy group showed an additional drop of 30% in vocabulary performance from pre- to posttreatment cold water immersion (despite successfully reducing their pain). In the hypnosis condition, lows showed only a slight additional decrease (8%) while highs showed a slight (10%) increase in their vocabulary performance from pre- to posttreatment immersion.

Thus, the effect of hypnosis in pain control "does not depend on S's utilization of high-level cognitive strategies. Rather, hypnotic analgesia seems to involve the dissociated control of pain--that is, control which is relatively free of the need for high-level, executive initiative and effort. ... Because hypnotic analgesia minimizes the degree of executive initiative and ongoing effort required to reduce pain, however, it seems inappropriate to view such reductions as something achieved on purpose" (p. 161).

Hughes' dissertation is described on p. 162 and ff. Instead of performance decrement on a cognitive task like vocabulary testing, she used increased heart rate as an index of cognitive effort. If heart rate increases when Ss successfully use hypnotic imagery, that would confirm the social psychological view that "suggested effects are achieved by this kind of ongoing allocation of high-level cognitive force or work" (p. 162).

Highs and lows were hypnotized and administered three trials of neutral and three trials of fearful imagery in counterbalanced order. Each imagery trial lasted 1 minute, after which Ss rated vividness of imagery, effort required, and amount of fear experienced.

Average imagery vividness was higher in highs than lows, for both neutral and fear imagery. For lows the correlation between heart rate increases and ratings of cognitive effort were .54 (neutral imagery) and .49 (fear imagery). For highs, the correlations were -.05 (neutral) and -.52 (fear). Thus, "for low but not high hypnotizable Ss, we find the predicted positive relationship between a cardiac indicator of cognitive effort and the ratings of cognitive effort involved in producing neutral imagery" (p. 163).

"First, for low hypnotizables engaged in fear imagery, ratings of effort are correlated .66 with ratings of fear. In other words, the more low hypnotizable Ss work to produce a fearful image, the more frightening the image is. Second, for high hypnotizables engaged in fear imagery, the correlation between ratings of fear and effort is minus .68-- indicating that the less effort highs report in producing fear imagery, the more frightened they become. Finally, for high hypnotizables, the correlation between ratings of fear and heart rate increase is .59, indicating that the more fear high hypnotizable Ss experience when engaged in fear imagery, the more their heart rate increases (the comparable figure for low hypnotizables is .16)" (p. 164).

The authors discuss why the pattern of correlations is different for people high and low in measured hypnotizability, and summarize the implications of both Miller's and Hughes' research. Both investigations indicate that, at least for high hypnotizable people, less initiative and effort are required to effect a response to hypnotic suggestion than one would expect. They show how behavior can be both purposeful and nonvolitional (in the sense of not exhibiting conscious intention and strategic efforts). By noting that the sense of nonvolition that accompanies a response to suggestion is an actual alteration in executive control, they provide a model for dissociative psychopathology such as MPD. For although executive control is dissociated, these experiments do not suggest that there is a second executive system or 'personality' that is responsible for the behavior.

Patients diagnosed with MPD have very high measured hypnotizability (Bliss, 1984). In fact, they seem to engage in self hypnosis, withdrawing into a trance or a dissociated state (Bliss, 1984). The authors quote Wilson & Barber (1983) as indicating that highly hypnotized, fantasy-prone normal individuals may become so absorbed in a character being imagined that they lose awareness of their own identity.

The authors offer a neodissociative account of MPD: "People prone to MPD are very high in hypnotic ability and are, therefore, vulnerable to the suggestive impact of ideas, imaginings, and fantasies; what is more, they are high in hypnotic ability because they have learned to use dissociative defenses as a way of dealing with inescapable threat-- such as physical and sexual abuse (Kluft, 1987). ... Fantasied alternatives to reality (including a fantasied alter ego ... ) can become increasingly complex and differentiated. Gradually, these fantasied alternatives begin to activate subsystems of control more or less directly--that is, with minimal involvement of executive level initiative and control. Such 'dissociated control' of behavior does not necessarily eliminate consciousness of it, though one's actions are apt to be experienced as increasingly ego-alien. If and when the activating fantasies and resulting behaviors become sufficiently threatening, however, they can also be repressed into an unconscious (i.e., amnesic) status, thus further separating high-level executive and monitoring functions from the dissociated, ego-alien aspects of oneself. The fully realized result of this process is an individual who is subject to profound discontinuities in his or her sense of self. ... The experience of behaving in an outwardly uncharacteristic manner requires only that subsystems of control are more or less directly activated by ideas and fantasies in a manner that effectively bypasses executive initiative and control" (pp. 168-169).

923, Bowers, 1992 NOTES: Tart allegedly taught ESP skills based on reinforcement, using a machine that projected display and gave feedback immediately, so the subjects could learn to anticipate the picture better. But the picture presented next was time-linked to the S's response (so S could learn it).

1987 Behavioral and Brain Sciences review, with 2 target articles, makes one doubt strength of findings. ESP research doesn't distinguish between description of an observation and it's proposed cause.

MPD shares with ESP a tendency to predispose toward a certain explanation. Feeling like one has a separate personality leads to finding evidence for one. But an MPD account is wrong-headed because the diagnosis misconstrues a notion of personality, which is a developmental concept (a pattern of thought, feeling, and behavior). Mischel's (1968) account of human functioning competed with trait theory, so "personality" concept became extraneous.

Defining personality in terms of one's experiences or beliefs about oneself has led to further problems, encouraged by the descriptive approach of DSM III (which depends on patient reports). Drew Weston distinguished between the self and self representation. One can't argue that a computer programmed to describe itself is the same as it's descriptions.

Personality can't be reduced to person's beliefs about themselves. A secondary personality cannot be reduced to bizarre experiences a person believes are due to a second personality. Clinicians do not accept as valid the beliefs of a paranoid

schizophrenic; or of an anxious neurotic. With multiple personality disorder (MPD) the patient becomes the expert and the clinician the student.

William Smith's 1986 SCEH paper: case study of patient who was convinced her problems were due to unresolved problems from a previous life. He didn't challenge her system but still worked with her successfully, communicating respect without validating her belief.

Advocates of MPDs think the observation that it is associated with high hypnotizability indicates great dissociation; critics think the association indicates great suggestibility. There is a historical parallel: Mesmer probably didn't suggest seizure-like episodes, but implicit suggestions for seizures were probably partially responsible. Mistaken attribution permitted Mesmer to see this as validation of his theory of animal magnetism.

Clinicians are not the only ones to "suggest" MPD syndrome. High profile cases are in the media. We should also remember Orne's 1959 research showing that students who received false information a week earlier in lecture on hypnosis showed the behavior when they were hypnotized.

Janet's disaggregation (dissociation) theory said hysterics and hypnotized people responded to ideas dissociated from the main stream of consciousness. So his contemporaries thought that spontaneous amnesia was a defining feature of hypnosis; yet it is not thought to be so in our era. The idea may have circulated in Janet's time, by popular culture.

MPDs are always highly suggestible so can respond to circulating accounts in the media, and every account that reaches the media can influence these people.

We could abandon the diagnosis of MPD in favor of Spiegel's "disorder of self integration." It is less provocative, does not imply any clinical benefit in the benefits of seeking out more personalities. This might reduce the incidence of this disorder, or likelihood that a suggestible person would develop the disorder iatrogenically.

Davidson, T. M.; Bowers, K. S. (1991). Selective hypnotic amnesia: Is it a successful attempt to forget or an unsuccessful attempt to remember. Journal of Abnormal Psychology, 100, 133-143.

Subjects in two experiments learned a 16-item, 4-category word list and were then administered hypnotic suggestions to be amnesic for all the words in one of the categories. Even when selective amnesia was completely successful, subjects in both experiments revealed a high level of recall for words not targeted for amnesia; moreover, these words were recalled in a highly organized, category-by-category fashion. Evidently, attention to relevant retrieval (i.e., organizational) cues does not oblige recall of words targeted for amnesia. Forgetting in the presence of such powerful mnemonic cues seems to characterize hypnotic amnesia and some spontaneous forms of forgetting as well.

Grabowski, Karen L.; Roese, Neal J.; Thomas, Michael R. (1991). The role of expectancy in hypnotic hypermnesia: A brief communication. International Journal of Clinical and Experimental Hypnosis, 39, 193-197.

Previous research has yielded equivocal evidence of hypnotic memory enhancement. This study assessed effects of expectancy and hypnotizability on recall for videotaped material under waking and hypnotic conditions. Ss (n = 138) were informed of hypnotic induction either before (expectancy condition) or after (no expectancy condition) watching a videotaped enactment of a crime and completing an initial waking recall test (R1). Both groups then underwent hypnotic induction, and completed the test again (R2). Ss' raw recall scores were significantly greater under hypnotic than waking conditions, but this hypermnesia was not evident when scores were corrected for mere increase in rate of responding. Ss expecting later hypnosis scored significantly higher than Ss with no such expectations, but again, this difference was not evident in corrected scores. Hypnotizability of Ss was, however, related to corrected recall, with high hypnotizability Ss displaying the greatest increase in rate of responding from R1 to R2. No evidence for the hypothesized "suppression effect" underlying hypnotic hypermnesia was found.

Thus Ss tended to answer more questions on R2 but most of this increase was error. Moreover, high hypnotizability Ss displayed this pattern to a far greater extent than other Ss, indicating that they were more likely than others to increase the no. of responses made between tests.

The finding of an interaction effect between hypnotizability and corrected recall suggests that hypnosis does play some role in the hypnotic hypermnesia described in

the literature, possibly refuting the findings of several recent studies (e.g., Nogrady, McConkey, & Perry, 1986; Register & Kihlstrom, 1987). High hypnotizability Ss increased the number of responses made from R1 to R2 to a greater extent than other Ss. The lack of an interaction between hypnotizability and expectancy, however, fails to support the suggestion by Salzberg and DePiano (1980) that people of differing hypnotizabilities differ also in their susceptibility to demand biases. As both Klazky and Erdelyi (1985) and Whitehouse et al. (1988) have noted, however, the use of hypnosis with witnesses of crimes may be useful if it can stimulate individuals to share uncertain recollections, perhaps providing otherwise unconsidered clues. The present data suggest that such guessing may also be increased by mere expectation of hypnosis. The value of forensic hypnosis may, therefore, be in part one similar to placebo: the simple notion of hypnosis placed in witnesses' minds may be sufficient to inspire useful leads.

Hasher, L.; Stoltzfus, E. R.; Zacks, R. T.; Rypma, B. (1991). Age and inhibition. Journal of Experimental Psychology: Learning, Memory, and Cognition, 17 (1), 163-169.

Two experiments assess adult age differences in the extent of inhibition or negative priming generated in a selective-attention task. Younger adults consistently demonstrated negative priming effects; they were slower to name a letter on a current trial that had served as a distractor on the previous trial relative to one that had not occurred on the previous trial. Whether or not inhibition dissipated when the response to stimulus interval was lengthened from 500 ms in Experiment 1 to 1,200 ms in Experiment 2 depended upon whether young subjects were aware of the patterns across trial types. Older adults did not show inhibition at either interval. The age effects are interpreted within the Hasher-Zacks (1988) framework, which proposes inhibition as a central mechanism determining the contents of working memory and consequently influencing a wide array of cognitive functions.

Jansen, C. K.; Bonke, B.; Klein, J.; van Dasselaar, N.; Hop, W. C. J. (1991). Failure to demonstrate unconscious perception during balanced anaesthesia by postoperative motor response. Acta Anaesthesiologica Scandinavica, 35, 407-410.

Eighty patients undergoing a standardized balanced anaesthesia were randomly assigned to either a suggestion group (N = 38) or a control group (N = 42), in a double-blind design. Anaesthesia was maintained with nitrous oxide, enflurane and fentanyl. Patients in the suggestion group were played seaside sounds, interrupted by statements of the importance of touching the ear during a postoperative visit, by means of a prerecorded audiotape and headphones. Tapes containing these suggestions were played from 30 min after the first incision, for a duration of 15 min. Patients in the control group were only played seaside sounds. There were no significant differences between the groups in either the number of patients touching their ears postoperatively or the number and duration of ear touches.

This research follows upon other studies in which patients carried out postoperative motor responses while still being amnesia for the source of the suggestions for the action (e.g. Bennett, Davis, & Giannini, 1985; Goldmann, Shah, & Hebden, 1987). The earlier studies used widely varied anesthesia techniques, small sample sizes, and did not measure baselines for those responses or clearly delimit the amount of time for recording the responses postoperatively. This investigation was an attempt to improve on the research design of earlier investigations that had obtained positive results.

Patient assignment to groups was stratified over three levels of estimated intensity of pain stimulation during surgery (based on the type of surgery).

The outcome measure, number of ear touches and their duration, was made by the anesthetist and an observer during the first 10 minutes of the pre- and postoperative interviews. (The observer was blind for the patient group assignment.) 75 of the patients were interviewed on the first postoperative day, and the remainder on the second postoperative day. The interview included questions regarding recall of the intravenous administration of drugs and of events during surgery. The outcome data may be seen in the Table below.

Distribution of ear touches during the first 10 min of the preoperative interview and, after the intraoperative suggestion, during the first 10 min of the postoperative interview. -----

No. of patients with ear touches for all responders		Total no. of ear touches for all responders		Duration of ear touches for all responders		Grp		N		Pre					
Post	Pre	Post	Pre	Post	Pre	Post	Pre	Post	Pre	Post	Pre

S = suggestion group C = control group

In discussing their results, the authors offer several reasons why they might not have obtained the same results as those of previous investigators. "First, our anaesthetic techniques were different from those used in the studies of Bennett et al., 1985, and Goldmann et al., 1987" (p. 408).

"A second reason for the discrepancy between our results and those of the other two studies could be that our suggestion was perhaps less meaningful to the patients undergoing surgery than the one used by our fellow researchers. It has been argued that recollection of perioperative events is influenced by the salience of the stimuli [Dubovsky & Trustman, 1976, Anesth Analg; Goldmann & Levey, 1986 (letter) Anaesthesia]. This salience depends largely on the content of the message. It may be that the requested response, i.e., to touch the ear, is one that in our culture, or environment, has insufficient emotional impact and is thus ignored. It is interesting to note in this context that the percentage of patients touching the ear postoperatively was significantly lower (Fisher's exact test: P<0.01) in our study than in the study by Bennett et al., both for the suggestion group and the control group. On the other hand, recent findings showed robust effects with emotionally neutral stimuli [Jelicic, Bonke, & Appelboom, 1990, Lancet; Roorda- Hrdlickova, Wolters, Bonke, & Phaf, 1990, in Bonke, Fitch, Millar, Eds. Memory and awareness

in anesthesia. Amsterdam: Swets & Zeitlinger]. Salience also depends on the timbre and strength of the requesting person's voice, the manner in which the response is requested and, possibly, many other subtle factors. We tried to increase the emotional impact of the message by adding reassuring phrases, as had been done in the previous studies. Furthermore, we had the message recorded by the anaesthetist who also conducted the pre- and post-operative interviews, assuming this would make the voice more familiar to the patient. During all interviews, as well as on the tape, the anaesthetist clearly introduced himself to the patient, mentioning his name a number of times. This was done to increase the possibility that the voice was 'recognized'" (p. 409).

408).

"A second reason for the discrepancy between our results and those of the other two studies could be that our suggestion was perhaps less meaningful to the patients undergoing surgery than the one used by our fellow researchers. It has been argued that recollection of perioperative events is influenced by the salience of the stimuli [Dubovsky & Trustman, 1976, *Anesth Analg*; Goldmann & Levey, 1986 (letter) *Anaesthesia*]. This salience depends largely on the content of the message. It may be that the requested response, i.e., to touch the ear, is one that in our culture, or environment, has insufficient emotional impact and is thus ignored. It is interesting to note in this context that the percentage of patients touching the ear postoperatively was significantly lower (Fisher's exact test:  $P < 0.01$ ) in our study than in the study by Bennett et al., both for the suggestion group and the control group. On the other hand, recent findings showed robust effects with emotionally neutral stimuli [Jelicic, Bonke, & Appelboom, 1990, *Lancet*; Roorda- Hrdlickova, Wolters, Bonke, & Phaf, 1990, in Bonke, Fitch, Millar, Eds. *Memory and awareness in anesthesia*. Bonnano, George A. (1990). Remembering and psychotherapy. *Psychotherapy*, 27, 175-186.

Reviews some of the empirical literature demonstrating the reconstructive nature of memory. The notion that the memory trace can consist of different forms of information is integrated with J. S. Bruner's (see PA, Vol 38:6801) tripartite model of representation, using the concepts of narrative and memory schemata. A case illustration demonstrates the pervasive organizing quality of the nuclear script and how, through such a structure, childhood events can hold a lasting impact on adult

behavior. It is concluded that conceptual understanding can be translated into schematic terminology provided it is adequately modified to account for the reconstructive nature of memory.

Evans, Frederick J. (1990). Behavioral responses during sleep. In Bootzin, Richard R.; Kihlstrom, John F.; Schacter, Daniel L. (Ed.), Sleep and Cognition (pp. 77-87). Washington, DC: American Psychological Association.

Subjects were 19 male student nurses who met a criterion of having EEG alpha density of at least 40% during an eyes closed, waking condition. They slept in the laboratory for two nights in succession, while being monitored by an EEG, and were told only that sleep cycles were being studied. Suggestions were presented while they were sleeping, e.g. "Whenever I say the word itch, your nose will feel itchy until you scratch it" "Whenever I say the word pillow, your pillow will feel uncomfortable until you move it." Then they were tested by Experimenter saying the cue word ("itch" or "pillow") during the word pillow, your pillow will feel uncomfortable until you move it." Then they were tested by Experimenter saying the cue word ("itch" or "pillow") during subsequent REM periods later that night and again on the next night. (The suggestions were not repeated on the second night; but two new suggestions were given on the second night when possible.)

After the Subjects awakened in the morning, they were interviewed to test their memory for the events that had occurred, and also cue words were presented in the context of a word association test to assess memory indirectly by observing behavioral and physiological responses. A more detailed inquiry was made after the second night.

The results were as follows. Ss responded to a mean of 21% of cue words administered. Ss continued to demonstrate REM sleep for at least 30 seconds for 71% of all cues administered, indicating that they were not aroused by the cue. When a suggestion was successfully completed (i.e., without eliciting alpha activity) it was not repeated. However, the cue words were tested in several subsequent REM periods. Cue word testing occurred immediately (during the same REM period as the suggestion) on the same night, as well as in a later REM period, and during REM on Night 2 (after the suggestion had been given during Night 1).

Correct responses were given for 20% of immediate, 23% of delayed, and 23% of carry-over conditions. Ss did not remember the suggestion, verbal cues, or their responses when they awoke. Since Ss often responded to the cue the next night without repetition of the suggestion itself, the authors inferred amnesia rather than forgetting had occurred. Responses were not elicited by repeating the cue word in the waking state, but appeared to be specific to the sleep condition.

Six Ss returned five months later for a third night of testing. Four had shown carryover response on Night 2 to a Night 1 suggestion. When verbal cues were presented (without re-administering the suggestion) those 4 Ss responded, even though there was no intervening waking memory about the procedure or the suggestions. Some Ss responded even more frequently than during the original two nights; hypnotic depth did not seem to account for the increased responsivity.

Experimenters attempted to reverse the amnesia observed during the waking condition by using hypnosis, age regression, and other hypnotic techniques, with some positive effect. The author speculates that perhaps the techniques originally used to probe morning recall were not sufficiently sensitive. He also raises the question of whether this waking state amnesia is related to the amnesia for night dreams when people awaken in the morning.

The relationship between hypnotizability and sleep suggestibility was analyzed. Hypnotizability was measured with the Harvard Group Scale, several weeks later, by Experimenters who were blind to the Ss' rate of responding to suggestions given during sleep. More hypnotizable Ss slept through the verbal stimuli more than low hypnotizable Ss; so they slept longer and more cues could be tested. Ss who responded most frequently to sleep-induced suggestions were more responsive to hypnosis. Analysis of response rate percentage (which controls for higher number of cues administered when Ss slept longer) showed that correlations between sleep suggestibility and hypnotizability were higher for percentage of delayed responses than for percentage of immediate responses.

Analysis by type of item on the hypnotizability scales suggested that the correlation with sleep suggestibility was due to the hallucinatory-reverie and the posthypnotic-dissociative clusters of hypnotic behavior, which are more difficult kinds of items. Correlations were significant for carry-over responses but not for immediate responses. These items represent phenomena experienced by Subjects who can be deeply hypnotized. The author reports that this relationship observed between hypnotizability and response to sleep-induced suggestions was not significant in a later study by Perry et al. (1978).

This author raises a question about why high hypnotizable subjects sleep better than low hypnotizables. The 6 Ss who were least susceptible accounted for 48% of all awakenings that occurred during the 2 experimental nights; the 6 Ss who were most hypnotizable accounted for only 26% of the awakenings ( $p < .01$ ).

in a later study by Perry et al. (1978).

This author raises a question about why high hypnotizable subjects sleep better than low hypnotizables. The 6 Ss who were least susceptible accounted for 48% of all awakenings that occurred during the 2 experimental nights; the 6 Ss who were most hypnotizable accounted for only 26% of the awakenings ( $p < .01$ ).

Because sleep learning ("hypnopedia") has been extensively practiced in Russia and Eastern Europe, especially for language learning, the author investigated language learning with nine subjects. (Hoskovec, 1966, and Rubin, 1968, have reviewed the hypnopedia literature, which suggests that only "suggestible" subjects respond; it is not clear whether "suggestible" refers to hypnotizable, or whether expectation of success is cultivated by information given in the waking state.) The nine Ss had responded to the suggestions at least twice while remaining asleep, had no waking recall of the suggestions, but were given pre-sleep instructions (increasing expectancy) that they would learn during sleep.

The verbal association material ("A is for apple; P is for palace;" etc.) was given during EEG sleep stages 2, 4, and REM. (Eight letter-word stimuli pairs were given, two per sleep stage whenever possible.) When they awakened, Ss were asked to

check "any familiar word" on a list of 10 words beginning with the letter A, with the letter P, etc. So the probability was .10 for each of the eight lists that they might check one correct word by guessing. They also responded to two dummy lists containing letter-word pairs not used during sleep.

None of the dummy list words were checked, whereas 28% of the administered words were correctly checked; also, Ss selected the correct letter (without identifying the word and with instructions not to "guess") in an additional 17% of all lists. Words were rarely recalled from Stages 2 and 4, but Ss often recognized letters from those stages. False positives (incorrectly recalled words or letters) was almost never observed. Furthermore, no control Subjects (people who had not received a presleep set that they would recall) recalled any words correctly.

It was observed that whenever words presented during REM were later recalled, a transient slower frequency alpha (10.25 Hz vs. 9.64 Hz,  $p < .01$ ) had been evoked within 30 sec after the presentation of the stimuli during sleep.

Total recall of words correlated with the Harvard Group Scale of Hypnotic Susceptibility .69 and the Stanford individually administered scale .42, for the 7 Ss administered hypnotizability tests.

The author concludes that under optimal conditions, sleep learning of relatively easy material can occur with subsequent waking recall.

Fischer, Donald G.; Elnitsky, Sherry (1990). A factor analytic study of two scales measuring dissociation. *American Journal of Clinical Hypnosis*, 32, 201-207.

The present study was designed to investigate the construct validity of dissociation. We administered the PAS and the DES to 507 male (48%) and female (52%) undergraduate students. Factor analysis on each scale separately showed that neither the PAS nor the DES adequately measures the three dimensions hypothesized to underlie dissociative experience. For both scales, a single factor emerged as replicable and reliable. Use of the scales, in their present form, therefore, should be limited to a single dimension representing disturbances in affect-control in the case of the PAS and disturbances in cognition-control if the DES is used at least with normal populations. Analysis of the combined items showed that the scales are measuring conceptually different but statistically correlated dimensions of dissociation. Further development of both scales is desirable, and further research should investigate the effect of different response formats on the internal structure of the scales.

scales is desirable, and further research should investigate the effect of different response formats on the internal structure of the scales.

The stated purpose of this study was to investigate the internal structure of the Perceptual Alterations Scale (PAS) and the Dissociative Experiences Scale (DES) using a large sample from a normal population.

"Sanders (1986) conceived of dissociation as a personality trait that is characterized by modification of connections between affect, cognition, and perception of voluntary control over behavior, as well as modifications in the subjective experience of affect, voluntary control, and perception. She chose items from the

MMPI to represent this trait. Bernstein and Putnam (1986), utilizing the DSM-III definition of dissociation, constructed items from information derived from interviews with patients and clinicians to represent a number of different types of dissociative experiences" (0. 202).

"The PAS (Sanders, 1986) is a 27-item scale; subjects respond by checking one of the following categories using a 4-point Likert format: never, sometimes, frequently, almost always. The items related to modifications of regulatory control, changes in self- monitoring, concealment from self and others, and modifications of sensory, perceptual, and affective experiences.

"The DES (Bernstein & Putnam, 1986) contains 28 items. Subjects indicate the percentage of time they experience the feelings or behavior described by the items on a 10- point scale. The items related to the experience of disturbances in identity, memory, awareness and cognition, and feelings of derealization or depersonalization" (pp. 202- 203).

Results were as follows. The one-factor solution for the PAS accounted for 18.5% of the total variance.; 11 of the 28 items did not load significantly on the factor. The one-factor solution for the DES accounted for 26.3% of the total variance; 7 of the 28 items did not load significantly on the factor.

"The 3-factor solution obtained by Sanders (1986) for the PAS was not replicated. An obvious reason for the different is that principal factor extraction was used in the present study, whereas principal components extraction was utilized by Sanders. ... Even when principal components analysis is performed on the present data, however, there are difficulties with the 3-factor solution" (pp. 204-205).

"All of the criteria suggest that a single factor best represents the latent structure of dissociative experience as measured by the PAS and DES. Although the total amount of variance accounted for is low, the one-factor solutions for both scales are interpretable, replicable, and have high internal consistency. The items for the PAS appear to represent primarily the affect and control dimensions, whereas those for the DES represent the cognitive dimension" (pp. 205-206).

"Overall, both scales contain similar items, although the DES has more items relating to disturbances in memory and altered perception of time (i.e., cognition), whereas the PAS has more items reflecting specific disturbances in identity and control. It appears, therefore, that the scales are measuring conceptually separate but statistically correlated dimensions of dissociation" (p. 206).

Friedman, Howard; Taub, Harvey A.; Sturr, Joseph F.; Monty, Richard A. (1990). Hypnosis and hypnotizability in cognitive task performance. British Journal of Experimental and Clinical Hypnosis, 7 (2), 103-107.

Gwynn, Maxwell I.; Quigley, Celia; Perlini, Arthur; Glatt, Richard; Spanos, Nicholas P. (1990, August). Eyewitness testimony: Effects of hypnotic interrogation and witness preparation. [Paper] Presented at the annual meeting of the American Psychological Association, Boston.

There is notable absence of empirical research on the effects of witness preparation on subsequent testimony. The present study investigates the separate and combined effects of hypnotic recall procedures and witness preparation on subjects' confidence in, and maintenance during cross-examination, of mug-shot identifications.

Session 1: Subjects viewed a 65 second videotape of a mock crime involving a shooting. The offender in this video was a male approximately 40-50 years old, whose face was partially obscured by the brim of a baseball cap.

Subjects were then taken individually to another room, where a second experimenter presented them with a series of five photographic mug shots. Half of the series contained the mug shot; the other did not. Subjects indicate if any portrayed the offender and then to rate their confidence in their identification.

Subjects for Session 2 were randomly assigned to one of two conditions:

Hypnotic condition ... followed by "reliving" instructions modeled after Reiser's procedures used in training police detectives.

Nonhypnotic condition ... Each subject was then presented with the mug shot lineup and rated their confidence as in Session 1 with the same second experimenter.

Subjects who in Session 2 identified any mug shot as portraying the offender returned about one week after for a mock courtroom appearance. Subjects were randomly assigned to either a "prepared" condition, or a "nonprepared" condition, with the restriction of equal numbers of offender-present vs. offender-absent lineups and hypnotic vs. nonhypnotic subjects in each condition ... The subject-witness was questioned by the third same experimenter under direct examination and then cross-examined by a fourth experimenter in the role of defense attorney.

Subjects in the prepared condition were given pointers concerning their courtroom appearance. These pointers included counseling to answer all of the questions fully, to speak in complete sentences, and to present themselves confidently.

The videotapes of the subjects' testimonies were then shown to independent blind raters who rated the degree of confidence displayed by the subject-witness at two points, first after direct examination, and again after cross-examination.

To summarize the results: 1) As in a number of previous studies, eyewitness confidence was unrelated to mug shot identification accuracy. 2) The use of hypnotic techniques as practiced by many police investigators did not lead to an increase in the frequency or accuracy with which subjects identified a mug shot as portraying a previously viewed offender. 3) Again consistent with previous research, the use of hypnosis did lead to an increase in eyewitness confidence, without a corresponding increase in accuracy, and this confidence increase was correlated with pretested levels of hypnotic susceptibility. 4) Contrary to the speculation of researchers such as Orne, Laurence & Perry, hypnotic procedures did not lead to the creation of unshakable witnesses who were impervious to cross-examination. And, 5) The usual practice of pre-trial preparation of witnesses did lead to a resistance of witnesses to be broken down under cross-examination.

In conclusion, the key factor found to affect eyewitness confidence and mug shot identification was not the use of hypnotic memory enhancement techniques, but rather the usual practice of pre-trial witness preparation.

Hajek, P.; Jakoubek, B.; Radil, T. (1990). Gradual increase in cutaneous threshold induced by repeated hypnosis of healthy individuals and patients with atopic eczema. Perceptual and Motor Skills, 70, 549-550.

Gradual increase in cutaneous pain threshold was found in healthy subjects and patients with atopic eczema during repeated hypnotic sessions with specific suggestions. This increase was less in the former than in the latter group. Repeated threshold measurements did not influence the threshold. The analgesic effect outlasted the hypnotic sessions by several months. It could be, however, suddenly reduced by appropriate hypnotic suggestion.

Cutaneous pain threshold was measured in "time in seconds from onset of heat source of defined size, distance from skin, and temperature, to subjective threshold percept of pain" (p. 549). Used two symmetrical locations on both forearms, at healthy areas of the skin. Ten hypnotic sessions were induced in each S three times weekly, each lasting one hour.

Suggestions were the following type: "The "conduction of switch to the brain is interrupted." Your "immunologic system will digest the damaged skin cells like a shark."

Subjects were 14 healthy subjects and 13 patients with atopic eczema treated for years with the usual medications, unsuccessfully or with complications.

There was gradual increase in cutaneous pain threshold across the 10 sessions, especially for the patient group. Control experiments with repeated threshold measurements in repeated sessions without hypnosis showed no changes.

"Time of increases in cutaneous pain threshold was associated with improvement of atopic eczema. Both effects correlated significantly ( $r = 0.8$ ) with hypnotizability as measured by the Stanford scale" (pp. 549-550).

"In 9 patients without further hypnotic sessions a slow spontaneous decay of the cutaneous pain threshold was observed during a 17-mo. period. Special experiments performed with six repeatedly hypnotized healthy subjects showing increased thresholds did prove, however, that the cumulative analgesic effect could be reduced to control values immediately by using the hypnotic suggestion that the 'skin sensitivity returns to normal values.'

"These results suggest a close association between hypnosis and activation and/or deactivation of endogenous analgesic systems (irrespectively whether they are of opioid or nonopioid nature)" (p.550)

Kihlstrom, John F.; Schacter, Daniel L.; Cork, Randall C.; Hurt, Catherine A.; Behr, Steven E. (1990). Implicit and explicit memory following surgical anesthesia. Psychological Science, 1, 303-306.

Paired associates were presented to 25 surgical patients following the induction of anesthesia by thiopental, vecuronium, and isoflurane. Postoperative testing (immediately or after two weeks) showed no free recall for the list; nor was there significant cued recall or recognition, compared to a matched control list. However, a free-association task showed a significant priming effect on both immediate and

delayed trials. At least under some conditions, adequate surgical anesthesia appears to abolish explicit, but not implicit, memory for intraoperative events. anesthesia appears to abolish explicit, but not implicit, memory for intraoperative events.

Labelle, L.; Laurence, J. R.; Nadon, R.; Perry, C. (1990). Hypnotizability, preference for an imagic cognitive style, and memory creation in hypnosis. Journal of Abnormal Psychology, 99, 222-228.

1989

The author notes a current trend toward viewing multiple personality disorder (MPD) and its variants as a form of chronic post-traumatic stress disorder based solely on exogenous childhood trauma, and cautions against prematurely reductionistic hypotheses. He focuses on Kluff's Third Etiological Factor, which includes the various developmental, biological, interpersonal, sociocultural, and psychodynamic shaping influences and substrates that determine the form taken by the dissociative defense. He hypothesizes a credibility continuum of childhood and contemporary memories arising primarily from exogenous trauma at one end, and endogenous trauma (stemming from intrapsychic adaptational needs) at the other. The author offers alternative multidetermined explanations for certain unverified trauma memories that currently are being accepted and validated as factual experiences by many therapists. He describes some potentially deleterious effects of validating unverified trauma memories during psychotherapy, and recommends that the MPD patients' need for unconditional credibility be responded to in the same manner as other transference-generated productions.

Lindsay, D. S.; Johnson, M. K. (1989). The eyewitness suggestibility effect and memory for source. Memory and Cognition, 17, 349-358.

Examined the possibility that eyewitness suggestibility reflects failures of the processes by which people normally discriminate between memories derived from different sources. Misled and control subjects were tested either with a yes/no recognition test or with a "source-monitoring" test designed to orient Ss to attend to information about the sources of their memories. The results demonstrate that suggestibility effects obtained with a recognition test can be eliminated by orienting Ss toward thinking about the sources of their memories while taking the test. Findings indicate that although misled Ss are capable of identifying the source of their memories of misleading suggestions, they nonetheless sometimes misidentify them as memories derived from the original event. The extent to which such errors reflect genuine memory confusions (produced, for example by lay judgment criteria) or conscious misattributions (perhaps due to demand characteristics) remains to be specified.

1988

Boeke, S.; Bonke, B.; Bouwhuis-Hoogerwerf, M. L.; Bovill, J. G.; Zwaveling, A. (1988). Effects of sounds presented during general anaesthesia on postoperative course. British Journal of Anaesthesia, 60, 697-702.

In a double-blind, randomized study, patients undergoing cholecystectomy were administered one of four different sounds during general anaesthesia: positive suggestions, nonsense suggestions, seaside sounds or sounds from the operating theatre. The effect of these sounds on the postoperative course was examined to assess intraoperative auditory registration. No differences were found between the four groups in postoperative variables.

Postoperative course was evaluated by 5 variables: pain, nausea and vomiting, evaluation by nursing staff, subjective well-being, and duration of postoperative hospital stay. From the chart they used amount of postoperative analgesia, volume of nasogastric suction or drainage and fluid lost through vomiting over 6 days post-operatively; duration of postoperative hospital stay was registered after discharge. See p. 699 for details, including wording of questions. They cite their own earlier study that got positive results, and explain the difference as possibly due to use of only male voices on tapes, lack of difference in the sounds on tapes in this study, insensitivity of outcome measures (patients stayed longer in first study than in this one), and sample too small in this study (106).

Boeke et al. (1988) report that this double-blind, randomized study of positive suggestions, noise or sounds from the operating theatre presented to 3 groups of patients undergoing cholecystectomy during general anaesthesia had positive results for older patients. patients > 55 years who received positive suggestions had a significantly shorter postoperative hospital stay than the other patients in this age category.

Council, James R.; Loge, D. (1988). Suggestibility and confidence in false perceptions: A pilot study. British Journal of Experimental and Clinical Hypnosis, 5, 95-98.

Subjects received audiotaped instructions implying that they would perceive increases in odor or heaviness while comparing stimuli in a sensory-judgment task. Stimuli were actually indiscriminable. Subjects pretested as higher or indiscriminable. Subjects pretested as higher or lower in hypnotizability performed the task in either hypnotic or non-hypnotic conditions. In both treatments, greater hypnotizability was associated with more perceived changes in the stimuli and greater confidence in the reality of those perceptions. Results support a general factor underlying suggestibility in hypnotic and nonhypnotic situations. The findings are discussed in relationship to false confidence effects reported in hypermnesia research.

Dywan, Jane (1988). The imagery factor in hypnotic hypermnesia. International Journal of Clinical and Experimental Hypnosis, 36, 312-326.

Week-long repeated recall attempts were used as baseline against which to assess the effects of hypnosis on the recall of pictures. Hypnosis increased errors for all Ss but especially for high hypnotizables. In Experiment 1, dividing Ss on the basis of imagery ability had the same effect on recall as dividing them on the basis of hypnotic ability. In Experiment 2, imagery ability was found to interact with hypnosis in mediating the level of error during waking trials. Results do not support the claim that hypnosis enhances recall, but they do suggest that further study is needed to clarify the role that imagery ability plays in recall patterns over time

Author reviews research indicating that introduction of confident errors is a reliable finding in hypnosis-memory research, and notes that the role of imagery ability has not as yet been examined even though imagery is viewed as important to memory functioning. She also reviews the imagery- hypnotizability correlation literature.

**EXPERIMENT 1** involved 54 Ss screened by Harvard Scale and SHSS:C, divided into highs (7-12) and lows (1-6) by SHSS:C. Stimuli were 60 black and white line drawings. There were 3 baseline trials in the lab; Ss were then given 6 envelopes, each containing a 60 blank item recall sheet, and asked to complete one each day and return it via campus mail. (When unable to recall more items, they were asked to draw a line under the last item recalled and then use "educated guesses." ) After a week of repeated recalls, Ss in the hypnosis condition were told they would be able to 'see' the slides appear before them; in the task motivating condition Ss were informed about such things as context dependent recall, the importance of focused attention, and the importance of good recall for forensic investigations.

Results were analyzed for increase in recall over the cumulative number of correct items recalled. Neither hypnotizability nor visual imagery ability influenced the cumulative baseline measures. High hypnotizable Ss produced a small but significantly greater increase in new, correct information during hypnosis than other Ss, but also made 3 times as many errors.

Dividing Ss by imagery score produced similar results. That is, people with very good imaging ability reacted in the same manner as the highly hypnotizable Ss: in hypnosis they increased the number of items they were willing to call a memory but also increased the number of errors.

**EXPERIMENT 2** differed from Experiment 1 in that Ss were selected for hypnotic ability and imagery ability so that both would be adequately represented. (The high hypnotizable - low visual imagery group is a group that hasn't been represented much in earlier research, and the author notes that those Ss are rather difficult to locate. ) The task motivation condition was not used, based on results of Experiment 1. Ss who were low on hypnotizability and imagery ability served as the controls.

Ss were told that they could be either in a hypnosis condition or a control condition but actually all Ss received a hypnotic induction. (This is like the London- Fuhrer, 1961, research design, which goes on the assumption that low hypnotizables do not enter into hypnosis even though they are exposed to an induction. Thus, hypnotic effects are not assumed for lows in the hypnotic condition and they become "controls.")

Results of correct and error recall over the baseline week were analyzed. There was no difference in correct recall as a function of hypnotic ability or visual imagery ability. However, there was a main effect for visual imagery ability and for hypnotizability, and a significant interaction between trials, for cumulative errors over the baseline week.

Effects of hypnosis were weaker than in Experiment 1 but followed same pattern. Those Ss most likely to have been hypnotized (highs) produced slightly more correct information than lows, and showed a greater increase in errors than lows. However high and low visualizers did not differ in response to hypnosis for correct information or for errors.

Since there was an interaction between hypnotic ability and visual imagery ability for error rate during waking trials, the author tested for the interaction during hypnosis. Using a 2 x 2 ANOVA with new errors as the dependent measure; no interaction was found. Hypnotic ability was therefore responsible for determining Ss' responses in the hypnosis condition. Author attributes the effect to being hypnotized rather than to individual differences in hypnotizability or to context effects.

all Ss received a hypnotic induction. (This is like the London- Fuhrer, 1961, research design, which goes on the assumption that low hypnotizables do not enter into hypnosis even though they are exposed to an induction. Thus, hypnotic effects are not assumed for lows in the hypnotic condition and they become "controls.")

Results of correct and error recall over the baseline week were analyzed. There was no difference in correct recall as a function of hypnotic ability or visual imagery ability. However, there was a main effect for visual imagery ability and for hypnotizability, and a significant interaction between trials, for cumulative errors over the baseline week.

Effects of hypnosis were weaker than in Experiment 1 but followed same pattern. Those Ss most likely to have been hypnotized (highs) produced slightly more correct information than lows, and showed a greater increase in errors than lows. However high and low visualizers did not differ in response to hypnosis for correct information or for errors.

Since there was an interaction between hypnotic ability and visual imagery ability for error rate during waking trials, the author tested for the interaction during hypnosis. Using a 2 x 2 ANOVA with new errors as the dependent measure; no interaction was found. Hypnotic ability was therefore responsible for determining Ss' responses in the hypnosis condition. Author attributes the effect to being hypnotized rather than to individual differences in hypnotizability or to context effects.

DISCUSSION includes the author's delineation of differences between the two experiments that might explain differences in results. The increase in errors that was observed may be due to increased fluency in producing items under hypnosis (Sheehan & Tilden, 1984, 1986) or to a shift in reporting criterion (e.g., M. T. Orne, Soskis, Dinges, & E. C. Orne, 1984).

"Both high and low hypnotizable Ss produced more memories in the task-motivating condition, and low hypnotizables are not totally immune from the effect

in the hypnotic context. What the report-criterion hypothesis does not explain is the reason why the memory reports of high hypnotizable Ss are differentially affected by task demands (e.g., task-motivating instructions versus hypnosis in Experiment 1) nor why hypnotized Ss so often seem surprised by the ease with which information seems to be 'recalled' during hypnosis. An alternative hypothesis is that being hypnotized results in a shift to a more imagistic style of information processing. The enhanced vividness of items generated during the retrieval process may convince Ss that these items must have been part of the original stimulus presentation (Dywan, 1985).

"Whatever the mechanisms might be, it is clear that the hypnotic effect is the result of an interaction between contextual factors and pre-existing characteristics of the individual. Moreover, these same mechanisms would likely be at work when hypnosis is actually used in the forensic situation, where the pressure to retrieve information could be more acute than what can be mustered in the experimental context. This should cause some concern because the differential increase in errors did not occur only for the relatively small proportion of Ss who were very high in hypnotic ability. The 'high' hypnotizable group in these experiments consisted of Ss of moderate to high levels of hypnotic ability and so the results can be generalized to at least one-half the population" (p. 323).

"In summary, it would seem that any pressure for Ss to increase their recall--whether it be repeated trials, task-motivating instructions, or hypnotic suggestion--results in higher levels of output and lower levels of accuracy. Repeated recall attempts lead to increases in recall and in errors. Some Ss (viz., those with high levels of hypnotic ability and low levels of imagery ability) are particularly prone to producing false-positive responses over the course of repeated recall attempts. When Ss are pressed to recall more information, they all try to do so by increasing their output and this increased output is usually accompanied by an increase in error. When hypnosis is introduced, however, those Ss who are hypnotizable show a differential increase in output. The amount of new correct information retrieved by hypnotized Ss is small and not a highly reliable phenomenon. The increase in errors that occurs in the recall of hypnotized individuals, however, is a substantial and highly reliable effect. Irrespective of how many errors were made as a function of repeated recall attempts, hypnosis can be counted on to increase errors over and above the increases in errors that occur when Ss are not hypnotized. Further work is needed to identify the mechanisms involved in the hypnotic distortion of recall. The role that imagery ability might have in the context of waking and hypnotic recall has not been resolved and this also presents an interesting problem for future study" (pp. 323-324).

Gudjonsson, Gisli H. (1988). The relationship of intelligence and memory to interrogative suggestibility: The importance of range effects. British Journal of Clinical Psychology, 27 (2), 185-187.

60 normal adults and 100 adult psychiatric patients completed a suggestibility scale and the Wechsler Adult Intelligence Scale (WAIS). Clear range effects of IQ and memory were evident in their relationship with suggestibility

**Kingsbury, Steven J. (1988). Hypnosis in the treatment of posttraumatic stress disorder: An isomorphic intervention. American Journal of Clinical Hypnosis, 31, 81-90.**

**Reviews literature on hypnosis treatment for PTSD and presents a rationale, based on the type of symptoms presented (blunting vs intrusions). Case presentations are provided.**

**"Several types of physiological processes may underlie dissociation. State-dependent learning, in which that learned during drug-induced alterations in consciousness may only be recalled during later similar alterations, is believed to be dependent upon hippocampal mechanisms (Gerrien & Chechile, 1977).The relationship of state-dependent learning to hypnosis has remained at the level of theory (Hilgard, 1977; Rossi, 1986). A second possible explanatory construct suggests everyday experience is primarily (but not exclusively) mediated by verbal, dominant hemisphere functioning. The images and sets mediating hypnosis, PTSD, and other forms of dissociation may be mediated by analogic processing and the nondominant hemisphere (Carter, Elkins, & Kraft, 1982; Galin, 1974; Hilgard, 1977; Watzlawick, 1978)" (p.83).**

**Kumar, V. K.; Pekala, Ronald J. (1988). Hypnotizability, absorption, and individual differences in phenomenological experience. International Journal of Clinical and Experimental Hypnosis, 36, 80-88.**

**The phenomenological effects associated with a baseline condition of eyes- closed and a hypnotic induction condition were compared across individuals of differing absorption capacity and hypnotizability. The results indicated that individuals of differing absorption capacity and hypnotizability reported different intensities of phenomenological experience**

**during the baseline eyes-closed condition. The induction further augmented intensity differences for low, medium, and high absorption and hypnotizable Ss, but more so for high (and medium) than low hypnotizable Ss. The results support both a trait and state interpretation of hypnotizability, and highlight the importance of the interaction between these factors on the resulting hypnotic experience of S.**

**Based on a review of relevant literature, the authors predicted that (1) during hypnosis and a baseline condition (eyes-closed), high absorption and high hypnotizable Ss will report the phenomenological effects at greater intensity relative to low absorption and low hypnotizable Ss, respectively; (2) hypnotic induction will be associated with increased absorption; greater alterations in awareness and experience; and decreased volitional control, rationality, and memory; (3) phenomenological intensity differences (hypnosis compared to eyes-closed) will be significantly greater for high than for low hypnotizable Ss.**

**They used the Phenomenology of Consciousness Inventory (PCI) developed by Pekala (1982), which is a 53 item self-report instrument that is completed retrospectively in reference to a preceding stimulus condition. The PCI measures**

the following dimensions and subdimensions: internal dialogue; self-awareness; state of awareness; imagery (amount, vividness); positive affect (joy, sexual excitement, love); negative affect (anger, fear, sadness); altered experience (time sense, body image, perception, unusual meanings); attention (absorption, direction); memory; rationality; volitional control; and arousal.

The 217 Ss were administered the Tellegen Absorption Scale, then sat quietly with eyes closed for four minutes, then completed the PCI, Form 1, relative to that 4-minute period. They were administered a slightly shortened version of the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A); before the posthypnotic suggestion and amnesia suggestion they experienced another 4-minute silent period during which they were told to 'continue to experience the state you are in right now.' After the HGSHS:A they completed PCI, Form 2, in reference to the silent period during the HGSHS:A, before they completed the 11-point questionnaire on the HGSHS:A.

Subjects who did not have reliable PCI response forms were removed from the sample, leaving 173 Ss who were divided into high, medium, and low Absorption groups, and high, medium, and low hypnotizability groups. The statistical analysis employed MANOVA on intensity scores for first the major PCI dimensions and then the 14 subdimensions using Conditions (eyes closed, hypnosis) and Groups. There were significant main and interaction effects. Subsequent ANOVAs for each (sub)dimension, Conditions by Hypnotizability Groups (2 x 3) were then performed. Hypnosis "was associated with significantly less positive affect (joy, sexual excitement, love); negative affect (anger, sadness); visual imagery (amount, vividness); self-awareness, internal dialogue, rationality, volitional control, and memory; and significantly more altered experience (time sense, perception) and altered state of awareness.

"Significant main effects for Hypnotizability Groups were found for positive affect (joy, love); altered experience (body image, time sense, perception, meaning); attention (direction, absorption); self-awareness; altered state of awareness; rationality; volitional control; and memory

"Post-hoc comparisons for the eyes-closed condition revealed that high relative to low, hypnotizables reported significantly greater alterations in body image, time sense, meaning, and altered state of awareness. Medium hypnotizable Ss, compared to low hypnotizables, reported significantly increased alterations in body image and state of awareness.

"Post-hoc comparisons for the eyes-closed condition revealed that high relative to low, hypnotizables reported significantly greater alterations in body image, time sense, meaning, and altered state of awareness. Medium hypnotizable Ss, compared to low hypnotizables, reported significantly increased alterations in body image and state of awareness.

Geiselman, R. Edward; Machlovitz, Helen (1987). Hypnosis memory recall: Implications for forensic use. American Journal of Forensic Psychology, 1, 37-47.

Examines 38 major published experiments (1930-1985) on hypnosis memory recall. Concludes that differences in experimental methodology significantly predict the success versus failure of hypnosis aided recall and remarks that, "Even if forensic hypnosis aids in the solution of only a small percentage of cases, it is still a valuable tool from the perspective of law enforcement." As Tarasoff has balanced the right of the victim to enjoy protection from violence with the patient-litigant's right to confidentiality, so too does the increased acceptance of hypnotically induced testimony go toward redressing in part the uneven balance between the slender compensations afforded the innocent victim of violent crime and the multiple constitutional protections and indemnities enjoyed by criminal perpetrators in our judicial system.

Goldmann, Les (1987, October). Ways of maximizing patient memory for events during anesthesia. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Los Angeles.

Reported a series of experiments: 1. Under atropine, we did not get an orienting response to things having to do with the operation, but did get an orienting response to jokes, dogs barking, and the name of a polite anesthetist. 2. Replicated the research by Bennett and didn't get ear pulling response. 3. Studied cardiac patients. Gave subjects a pre-anesthesia speech of importance [of hearing under anesthesia? Notes here are not clear.] and a chin touch suggestion that was successful. 7 of 30 subjects gave reports of recall - usually recalled something of particular interest to them. These 7 subjects appeared more anxious postoperatively than previously. 4. Recognition study: Pre-op "IQ" test. Gave subjects answers to the questions while they were under anesthesia, and postoperatively they had better performance than previously. 5. Recall study, double blind. Interviewer learned something about the patient, and told them something about what was learned about the patient during anesthesia e.g., You have a lovely garden. After surgery they were hypnotized by someone who did not know what information was given, and then recall for information "heard" under anesthesia was tested. 6. 10 female patients who were good hypnotic subjects, all received the same statement under anesthesia, that they would believe for a moment that they had green hair. During the interview, one said she was fascinated by green things, one wanted to go home and wash her hair.

Kihlstrom, John F. (1987). The cognitive unconscious. Science, 237, 1445-1452.

Contemporary research in cognitive psychology reveals the impact of nonconscious mental structures and processes on the individual's conscious experience, thought, and action. Research on perceptual-cognitive and motoric skills indicates that they are automatized through experience, and thus rendered unconscious. In addition, research on subliminal perception, implicit memory, and hypnosis indicates that events can affect mental functions even though they cannot be consciously perceived or remembered. These findings suggest a tripartite division of the cognitive unconscious into truly unconscious mental processes operating on knowledge structures that may themselves be preconscious or subconscious.

The use of hypnosis with witnesses and victims may have serious consequences for the legal process when testimony is based on material that is elicited from a witness who has been hypnotized for the purposes of refreshing recollection.

Davidson, Thomas McCabe (1986, January). Recall organization and volitional/non-volitional experiencing in posthypnotic and intrahypnotic amnesia: Inattention versus dissociation hypotheses (Dissertation, University of Waterloo). Dissertation Abstracts International, 47 (7), 3103-B.

"Two studies are reported which seek to evaluate the relative merits of two differing hypotheses concerning the cognitive processes underlying suggested hypnotic amnesia. The inattention hypothesis maintains that amnesia effects are produced when subjects volitionally divert attention from relevant retrieval cues so that recall is inefficient. The dissociation position is that amnesic subjects are prevented from utilizing normally relevant retrieval cues by a dissociative barrier that blocks access to target memories -- a forgetting over which subjects experience no volitional control. The two hypotheses were evaluated by means of a selective amnesia suggestion in the recall organization paradigm. "In the first experiment, high, medium, and low hypnotic susceptible subjects were administered either hypnotic induction or task-motivating instructions. Results indicated that there was no disorganization of amnesia trial recall or forgetting of words not targeted for amnesia, contrary to predictions from the inattention hypothesis. "In the second experiment, high hypnotizable subjects received the selective amnesia suggestion in both posthypnotic and intrahypnotic conditions. Intrahypnotic subjects were also separated into one group that received a ten second interval between the administration of the amnesia suggestion and the amnesia trial, and another group that had a delay between the suggestion and the amnesia trial equivalent to the posthypnotic group. Eight subjects who had testified that they were volitionally amnesic on a pre- screening amnesia test were also included in the posthypnotic condition. Again, the results indicated no recall disorganization or

reduction in recall of words not targeted for amnesia. Subjects also uniformly provided evidence that their amnesia was experienced as non-volitional. There was, however, evidence that some amnesiacs were aware during the amnesia trial of the specific category targeted for amnesia. "The most important finding of both experiments is that subjects may attend to normally relevant retrieval cues and yet continue to evidence amnesia. The evidence is therefore consistent with the dissociation hypothesis, but disconfirms the inattention account of hypnotic amnesia. It appears that the selective amnesia context effectively prevents the successful use of volitional forgetting strategies. (Abstract shortened with permission of author)" (p. 3103).

**Laurence, Jean-Roch; Nadon, Robert; Nogrady, Heather; Perry, Campbell (1986). Duality, dissociation, and memory creation in highly hypnotizability subjects. International Journal of Clinical and Experimental Hypnosis, 34, 295-310.**

The present paper reports an initial attempt to create a pseudomemory in a group of highly hypnotizable individuals. It was found that for approximately 50% of Ss tested, recall of a specific event was modified when Ss integrated hypnotically suggested material which then posthypnotically was believed to be veridical. This modification in a previously reported memory was linked to a particular cognitive style found in high hypnotizable Ss, namely dual cognitive functioning. Ss reporting duality in hypnotic age regression, and, to a lesser extent, the hidden observer effect, were found to be the most prone to accept a suggested memory as real. These findings suggest the need to emphasize the importance of a cognitive-phenomenological approach to hypnosis and hypnotizability.

**1985**

**Acosta, Enrique; Crawford, Helen J. (1985). Iconic memory and hypnotizability: Processing speed, skill or strategy differences?. International Journal of Clinical and Experimental Hypnosis, 33, 236-245.**

The purported relationship between hypnotizability and speed of information transfer from iconic to short-term memory was studied in a comparison of 12 low and 12 high hypnotizable Ss. As in Ingram, Saccuzzo, McNeill, and Ss. As in Ingram, Saccuzzo, McNeill, and McDonald (1979), high hypnotizable Ss showed less interference from a visual mask in the report of a briefly presented item than did low hypnotizable Ss when the mask delays were predictable. When the delay of the mask could not be anticipated, however, differences between high and low hypnotizable Ss disappeared. It is suggested that differences in information processing related to hypnotizability may be due to differences in strategy, skills, or other factors, rather than underlying information processing speed.

Hypnosis may require concentrative or selective attention, which usually is measured by self-report (e.g. Absorption) or by experimental measures. Several investigations indicate that high hypnotizable people are better than low hypnotizables at focusing on a task and ignoring extraneous information (Brown,

Crawford, Smith, Leu, & Brock, 1983; Graham & Evans, 1977; Karlin, 1979; Miller, 1975; Wallace, 1979; Wallace, Garrett, & Anstadt, 1974; Wallace, Knight, & Garrett, 1976). One way to study attentional processes is through the effect of presenting a mask (e.g. \$\$\$\$) shortly after presenting a stimulus (e.g. ABCDE). Ingram (1979) found that highs had faster information processing, but that might be due to anticipation bias associated with the method of limits employed. This study uses both an ascending method of limits, like Ingram, and a condition in which the mask delays were presented randomly within another block of trials.

## RESULTS

"While the present study replicated Ingram et al.'s (1979) findings when an ascending method of limits was used (the same used by Ingram et al.) differences were not found in processing when ISIs were presented randomly. Thus, these results suggest that high and low hypnotizable Ss do not differ in their information transmission rates, but rather they may differ in other aspects which mediate performance in this task" (pp. 241- 242).

"Several lines of evidence point towards strategy or skill differences between high and low hypnotizable Ss as a possible explanation for the present findings. First, it was found that when Ss could anticipate the mask delay (the ascending condition), high hypnotizable Ss outperformed the low hypnotizables. When this anticipation was controlled, as in the random condition, the two groups did not differ when the data were scored by serial position. When the data were scored by a free recall scheme, there was a nonsignificant trend for high hypnotizable Ss to score higher than did the low hypnotizables. This trend suggests that high hypnotizable Ss may be more willing to guess, and to guess more accurately than low hypnotizables, when they have partial information about a letter, and/or they may have greater skill in perceiving incomplete information. The latter suggestion finds indirect support from Crawford (1981) who reported that high hypnotizable Ss can process fragmented stimuli (Gestalt Closure tests, see Thurstone & Jeffrey, 1966), significantly better than can low hypnotizables. High imagers have been shown also to perform significantly better than low imagers in Gestalt Closure tasks (Ernest, 1980). At a speculative level, given that recent research has suggested that iconic memory may be a right hemisphere phenomenon (e.g. Cohen, 1976, but also see DiLollo, 1981), and high hypnotizable Ss outperform low hypnotizables on certain right hemisphere tasks (e.g. Crawford, 1981), it may be asked if the trends found with the free recall scoring scheme in the present study might be a reflection of differential right hemisphere processing. Such a hypothesis could be investigated in future research by comparing the performance of high and low hypnotizable Ss, as possibly moderated by visuo-spatial ability, for stimuli presented to the left versus the right visual hemifield (Ernest, 1983).

"A second set of evidence in favor of strategy differences was found in Saccuzzo et al. (1982) which was published after the data for the present experiment were collected. In the Saccuzzo et al. (1982) paper, which was an extension and replication of Ingram et al. (1979), the same mask delay was used throughout a 10-trial block. The order of the blocks (i.e., the mask delays) was random. Thus, while S did not know which mask delay was used in the first trial of a block, the

remaining 9 trials were the same and could be anticipated. During the first session, high hypnotizable Ss outperformed the low hypnotizables, but these differences disappeared on the second testing session. These results suggest that practice may have affected performance, rather than any underlying information processing speed differences" (pp. 242-243).

1985

Bennett, Henry L.; Davis, H. S.; Giannini, Jeffrey A. (1985). Non-verbal response to intraoperative conversation. British Journal of Anesthesiology, 57, 174-179.

In a double-blind study, 33 patients (herniorrhaphy, cholecystectomy and orthopedic) were randomly assigned to either suggestion or control groups. Under known clinical levels of nitrous oxide and enflurane or halothane anesthesia, suggestion patients were exposed to statements of the importance of touching their ear during a postoperative interview. Compared with controls, suggestion patients did touch their ear (tetrachoric correlation 0.61,  $P < 0.02$ ). test, U (Mann-Whitney frequently more so did they and

Coe, William C.; Yashinski, Edward (1985). Volitional experiences associated with breaching posthypnotic amnesia. Journal of Personality and Social Psychology, 48 (3), 716-722.

Highly responsive hypnotic subjects classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia were compared during posthypnotic recall. Subjects related their voluntariness after the experiment. Two contextual conditions were employed (2 x 2 design): a lie detector condition meant to create pressure to breach amnesia and a relax control condition. In contrast to earlier findings, the recall data showed that both voluntary and involuntary subjects breached under the lie detector condition compared with their counterparts in the relax condition; however, the degree of breaching was not great in any condition. The results are discussed as they relate to studies attempting to breach posthypnotic amnesia and characteristics of the voluntary-involuntary dimension.

Eich, Eric; Reeves, John L.; Katz, Ronald L. (1985). Anesthesia, amnesia, and the memory/awareness distinction. Anesthesia and Analgesia, 64, 1143-1148.

Several studies have shown that surgical patients cannot consciously recall or recognize events to which they had been exposed during general anesthesia. Might evidence of memory for intraoperative events be revealed through the performance of a postoperative test that does not require remembering to be deliberate or intentional? Results of the present study, involving the recognition and spelling of semantically biased homophones, suggest a negative answer to this question and imply that intraoperative events cannot be remembered postoperatively, either with or without awareness.

question and imply that intraoperative events cannot be remembered postoperatively, either with or without awareness.

"In this experiment, we attempted to apply the distinction between memory and awareness of memory to the question of whether adequately anesthetized and apparently unconscious patients can register and retain what is said in their presence during surgery. Prior research relating to this question has focused, for the most part, on the ability of postoperative patients to recall or recognize a specific item....The inference need not be drawn, however, that 'patients in so-called surgical planes of anesthesia cannot hear' (15, p. 89) or that anesthetized patients cannot encode and store in memory events that transpire during their surgery. The possibility remains that even though the effects of memory for intraoperative events may not--and probably cannot--be revealed in postoperative tests of retention that require remembering to be deliberate or intentional, such effects might be evident in the performance of tests that do not demand awareness of remembering.

"To explore the possible dissociation between memory and awareness of memory for intraoperative events, we modeled our experiment after a recent neuropsychological study by Jacoby and Witherspoon (5)" (p. 1143).

"...it appears that the prior presentation of a word has a substantial impact on its subsequent interpretation and spelling, regardless of whether or not the word is correctly classified as 'old' in a later test of recognition memory" (p. 1144).

"Approached from the standpoint of anesthesia theory and practice, the idea that recognition and spelling tap different memory processes or systems raises an interesting question for research. Specifically, suppose that during surgery, an anesthetized patient listens to a series of short, descriptive phrases, each consisting of a homophone and one or two words that bias the homophone's less common interpretation (e.g., war and PEACE, deep SEA). Suppose further that several days after surgery, the patient is read a list composed chiefly of old and new homophones (i.e., ones that either had or had not been presented intraoperatively) on two successive occasions. On one occasion, the patient is simply asked to spell each list item aloud; on the other occasion, the patient is asked to state aloud which list items he or she recognizes as having been presented during surgery. Given the situation sketched above, might the patient spell significantly more old than new homophones in line with their less common interpretations, and yet fail to reliably discriminate between the two types of items in the test of recognition memory" (p. 1144).

Geiselman, R. Edward; Fisher, Ronald P.; MacKinnon, David P.; Holland, Heidi L. (1985). Eyewitness memory enhancement in the police interview: Cognitive retrieval mnemonics versus hypnosis. Journal of Applied Psychology, 70, 401-412.

Compared effectiveness of three interview procedures for optimizing eyewitness memory performance: (a) the 'cognitive interview' based on memory-retrieval mnemonics from current memory theory, (b) the presently controversial hypnosis interview, and (c) the standard (control) police interview. Both the cognitive and hypnosis procedures elicited a significantly greater number of correct items of information from the Ss than did the standard interview. This result, which held

even for the most critical facts from the films, was most pronounced for crime scenarios in which the density of events was high. The number of incorrect items of information generated did not differ across the three interview conditions. The observed memory

Klatzky, Roberta L.; Erdelyi, Matthew H. (1985). The response criterion problem in tests of hypnosis and memory. International Journal of Clinical and Experimental Hypnosis, 33, 246-257.

Past experimental research on the effects of hypnosis on memory indicates both that hypnosis produces increases in correct recalls and that hypnosis produces increased vulnerability to misleading information and intrusions in recall. The present paper uses the framework of signal detection theory to account for this pattern of data. It suggests that the effects of hypnosis on memory cannot be ascertained from previous work, because of a general failure to discriminate between effects on the amount of information retrieved from memory and the criterion adopted by Ss for reporting what they remember.

Past experimental research indicates that hypnosis produces increases in correct recalls and as well as increased vulnerability to misleading information and intrusions in recall. This paper uses signal detection theory to account for the data. Signal detection theory describes performance as reflecting two underlying parameters--the information accessible to S at any point in time (designated as  $d'$ ) and the criterion adopted by S when making decisions about memory reports (report or decision criterion, response bias, or Beta). They review the recent literature on hypnosis and memory and conclude:

1. When the response output is not controlled, hypnotic instructions and/or hypnotizable have been found to produce increases in the number of correct recalls but this does not mean that the accessible information in memory has increased. What may be changing is the criterion for report.
2. When the response output is not controlled, hypnotic instructions and/or hypnotizable have been found to produce increases in incorrect recalls, i.e., intrusions, and compliance with leading questions, but this does not mean diminution or distortion of accessible memory ( $d'$ ). What may be changing is the criterion for report.
3. When response bias is controlled, hypnosis has been found to produce no enhancement of recognition but this does not imply that (a) Beta cannot change in recognition tests where it is allowed to vary, nor that (b) hypnosis has no effect on recall.
4. The proper experiment to determine whether hypnosis affects the accessibility of information in memory should place demands on the retrieval process and control the criterion for memory report.

The most decisive experimental outcome for the forensic situation would be a null or negative one: the demonstration that hypnosis does not enhance measures of memory accessibility. Then there would be no reason to use hypnosis to enhance memory.

1983

Crawford, Helen J.; Allen, Steven N. (1983). Enhanced visual memory during hypnosis as mediated by hypnotic responsiveness and cognitive strategies. Journal of Experimental Psychology: General, 112 (4), 662-685.

To investigate the hypothesis that hypnosis has an enhancing effect on imagery processing, as mediated by hypnotic responsiveness and cognitive strategies, four experiments compared performance of low and high, or low, medium, and high hypnotically responsive subjects in waking and hypnosis conditions on a successive visual memory discrimination task that required detecting differences between successively presented picture pairs in which one member of the pair was slightly altered. Consistently, hypnotically responsive individuals showed enhanced mean number of correct performance during hypnosis, whereas nonresponsive ones did not. Hypnotic responsiveness correlated .52 ( $p < .001$ ) with enhanced performance during hypnosis, but it was uncorrelated with waking performance (Experiment 3). Reaction time was not affected by hypnosis, although high hypnotizables were faster than lows in their responses (Experiments 1 and 2).

Subjects reported enhanced imagery vividness on the self-report Vividness of Visual Imagery Questionnaire during hypnosis. The differential effect between lows and highs was in the anticipated direction but not significant (Experiments 1 and 2).

Two cognitive strategies appeared to mediate visual memory performance: (a) detail strategy (memorization and rehearsal of individual details) and (b) holistic strategy (looking at and remembering the whole picture with accompanying imagery). Both lows and highs reported predominantly detail-oriented strategies during waking; however the highs shifted to a more holistic strategy during hypnosis. It appears that high hypnotizables have a greater capacity than lows for cognitive flexibility (Battig, 1979).

Results are discussed in terms of Paivio's (1971) dual coding theory and Craik and Tulving's (1975) depth of processing theory. The authors also discuss whether hypnosis involves a shift in cerebral dominance, as reflected by the cognitive strategy changes and enhanced imagery processing.

Dillon, F. Richard; Spanos, Nicholas P. (1983). Proactive interference and the functional ablation hypothesis: More disconfirmatory data. International Journal of Clinical and Experimental Hypnosis, 31, 47-56.

According to the functional ablation hypothesis, memories for which amnesia has been hypnotically suggested do not interact with other information in memory do not interact with other information in memory.

Geiselman, Ralph E.; Fishman, D. L.; Jaenicke, C.; Lerner, B. R.; MacKinnon, D. P.; et al. (1983). Mechanisms of hypnotic and nonhypnotic forgetting. Journal of Experimental Psychology: Learning, Memory, and Cognition, 9, 626-635.

40 undergraduates participated in 2 experimental sessions designed to study laboratory-induced amnesia, one using a standard hypnosis paradigm and one using a nonhypnotic directed forgetting paradigm. Two independent sources of variation were derived from the hypnotic amnesia data: retrieval inhibition and inhibition release. In the nonhypnotic directed-forgetting procedure, some items were cued to be either forgotten or remembered. At test, over 39% of the variance in the recall of the to-be-forgotten items could be accounted for by the inhibition and release constructs obtained with hypnosis. These relations between the 2 procedures were not mediated by verbal ability (WAIS) or cognitive style (Hidden Figures Test). It is concluded that the mechanisms of forgetting involved in laboratory demonstrations of hypnotic and nonhypnotic amnesia are related, and the implication is that some of them are the same, namely, retrieval inhibition and inhibition release. Possible demand characteristics that accompany the hypnosis procedure were not apparent with the nonhypnotic procedure. Results provide evidence that hypnotically induced amnesia is not entirely the result of Ss' reactions to demand characteristics.

Kihlstrom, John F.; Easton, Randolph D.; Shor, Ronald E. (1983). Spontaneous recovery of memory during posthypnotic amnesia. International Journal of Clinical and Experimental Hypnosis, 31, 309-323.

Repeated testing of posthypnotic amnesia indicates that some Ss, initially responsive to the suggestion, show appreciable recovery of memory before the pre-arranged signal is given to cancel the amnesia. Comparison of Ss who received 2 successive memory tests during amnesia with others who received only a single test preceded by a distracting activity indicated that the recovery effect was attributable to the passage of time rather than to prior testing. There were wide individual differences in the extent of recovery, with some Ss maintaining a fairly dense amnesia on the second test. Those Ss who maintained amnesia were more hypnotizable, and showed a denser initial amnesia, than those who breached it. An analysis of subjective reports lent credence to the notion of partial response among some hypnotizable Ss who fail to meet a standard criterion of complete amnesia, and pseudoamnesia among some insusceptible Ss who appear to pass it. Some Ss reported voluntarily engaging in cognitive activity designed to induce forgetting, but these reports were related to neither the occurrence of initial amnesia nor its persistence. A failure of memory which reflects momentary disorientation upon transition from one mental state to another should be conceptually distinguished from a reversible amnesia initiated by hypnotic suggestion.

by hypnotic suggestion

1981

Bower, Gordon H. (1981). Mood and memory. American Psychologist, 129-148.

This article describes experiments in which happy or sad moods were induced in subjects by hypnotic suggestion to investigate the influence of emotions on memory and thinking. One result was that subjects exhibited mood-state-dependent memory in recall of word lists, personal experiences recorded in a daily diary, and childhood

experiences; people recalled a greater percentage of those experiences that were affectively congruent with the mood they were in during recall. Second, emotion powerfully influenced such cognitive processes as free associations, imaginative fantasies, social perceptions, and snap judgments about others' personalities (e.g., angry subjects generated angry associates, told hostile stories, and were prone to find fault with others). Third, when the feeling-tone of a narrative agreed with the reader's emotion, the salience and memorability of events in that narrative were increased. Thus, sad readers attended more to sad material, identified with a sad character from a story, and recalled more about that character. An associative network theory is proposed to account for these several results. In this theory, an emotion serves as a memory unit that can enter into associations with coincident events. Activation of this emotion unit aids retrieval of events associated with it; it also primes emotional themata for use in free association, fantasies, and perceptual categorization.

1979 Cole, Randy D. (1979). Use of hypnosis in a course to increase academic and test-taking skills. International Journal of Clinical and Experimental Hypnosis, 27 (1), 21-28.

The present study was undertaken to provide additional information on the effects of hypnosis on academic and test-taking skills. Previous research indicated inconclusive results with inadequate experimental design and statistical methodology. The present study used an experimental research design with appropriate statistical analysis. Ss were 93 college students and treatment was administered by pre-recorded cassette tapes over a 4-week period during regular class time. Tapes consisted of hypnotic and waking suggestions related to course content and general academic skills. Results indicated hypnotic and waking suggestions did not facilitate academic skill learning significantly more than class curriculum alone. Pre-post comparisons did indicate significant improvement by all groups on reading, writing, study skills, and spelling variables.

Holroyd, Jean; Nuechterlein, Keith; Shapiro, David; Ward, Frederick (1979). Biofeedback and hypnotizability. In Burrows, Graham D.; Collison, David R. (Ed.), Hypnosis 1979: Proceedings of the 8th International Congress of Hypnosis and Psychosomatic Medicine, Melbourne, Australia (pp. 335-343). New York: Elsevier/North Holland Biomedical Press.

8 high and 8 low hypnotizable Ss used biofeedback and hypnosis to lower blood pressure in one session and forehead EMG activity in another session. Results were analyzed by repeated measures analyses of covariance using baseline physiological level on the dependent variable as the covariate. Electromyographic level was reduced more immediately by biofeedback than by hypnosis. When the task was to lower blood pressure, blood pressure and skin conductance were more effectively reduced by hypnosis than by biofeedback, considering only the first half of each session to eliminate within-session transfer effects.

Hypnotizability did not predict overall outcome. Factors which may have prevented demonstrating a clearer relationship between hypnotizability and success using biofeedback or hypnosis are discussed. State and trait anxiety, cognitive strategies used during the tasks, and self-reported hypnotic depth are examined for correlates of successful performance.

1977

Chertok, Leon; Michaux, D.; Droin, M. C. (1977). Dynamics of hypnotic analgesia: Some new data. Journal of Nervous and Mental Disease, 164, 88-96.

Following two surgical operations under hypnotic anesthesia, it was possible, during subsequent recall under hypnosis, to elicit a representation of the past operative experience. It would seem that under hypnosis there is a persistence of the perception of nociceptive information and of its recognition as such by the subject. From an analysis of these two experiments in recall, it is possible to formulate several hypotheses concerning the psychological processes involved in hypnotic analgesia. In consequence of an affective relationship, in which the hypnotist's word assumes a special importance for the subject, the latter has recourse to two kinds of mechanism: a) internal (assimilation to an analogous sensation, not, however, registered as dangerous-- rationalization); and b) external (total compliance with the interpretations proposed by the hypnotist), which lead to a qualitative transformation of nociceptive information, as also the inhibition of the behavioral manifestations normally associated with a painful stimulus.

Delprato, D. J. (1977). Pavlovian conditioning of Chevreul's movement. American Journal of Clinical Hypnosis, 20, 124-130.

This essay deals with both the intra-individual and inter-individual varieties of arousal state-bound experiences. The former are labelled as "flashbacks" while the latter embrace the great fantasies and repetitive schemes, the ever re-written plots and images of literature, art, and religion.

Flashbacks are both arousal-state and stage (i.e., set and setting) bound experiences. Flashback and hypnotic recall differ only in the ways by which they are induced. Induction methods should be distinguished from induced states on the hyperaroused perception-hallucination and hypoaroused perception-meditation continuum.

Flashbackers may be characterized by their (a) variability on perceptual-behavioral tasks; (b) tendency to minimize (or reduce) sensory input; (c) high resting heart rates; (d) hypnotizability; and, hence (e) preferential right-cerebral-hemispheric cognition; and (f) a display of EEG-alpha dominance in the resting, waking state.

Coe, William C.; Basden, B.; Basden, D.; Graham, C. (1976). Posthypnotic amnesia: Suggestions of an active process in dissociative phenomena. Journal of Abnormal Psychology, 85, 455-458.

A retroactive inhibition design was used to examine the process of posthypnotic amnesia. The results supported the notion that "forgotten" material is as available to amnesic subjects at some level as it is to nonamnesic subjects. Further, so-called forgetting appears to be the result of an active process, that is, something the subject does. Implications for understanding dissociative phenomena in general are discussed.

Coe, William C.; Baugher, R. J.; Krimm, W. R.; Smith, J. A. (1976). A further examination of selective recall following hypnosis. International Journal of Clinical and Experimental Hypnosis, 24, 13-21.

29 Ss were tested for posthypnotic amnesia on SHSS:C. They rated each item for emotional tone (pleasant-unpleasant) and judged whether or not they had passed or failed it. There was some support for the notion that failed items are judged more unpleasant than passed items, but the emotional tone of an item was not related to its being recalled posthypnotically. There were minimal findings to suggest that Ss recall items which stand out in their experience. Discrepancies with earlier findings and the possible role of processes associated with normal memory are discussed.

Erickson, Milton H.; Rossi, Ernest L. (1976). Two level communication and microdynamics of trance and suggestion. American Journal of Clinical Hypnosis, 18, 153-171.

The authors provide the transcript and commentaries of an hypnotic induction and an effort to achieve automatic writing. An unusual blend of Erickson's approaches to two level communication, dissociation, voice dynamics and indirect suggestion are made explicit in the commentaries. The junior author offers a 'context theory of two level communication' that conceptualizes Erickson's clinical approaches in terms consonant with Jenkins' (1974) recent contextual approach to verbal associations and memory. A summary of the microdynamics of Erickson's approach to trance induction and suggestion is outlined together with a utilization theory of hypnotic suggestion.

Jenkins, J. J. (1974). Remember that old theory of memory? Well, forget it! American Psychologist, 29, 785-795.  
Psychologist, 29, 785-795.

Illovsky, J.; Fredman, N. (1976). Group suggestion in learning disabilities of primary grade children. International Journal of Clinical and Experimental Hypnosis, 24, 87-97.

This study reports the effects of tape-recorded hypnotic suggestions given to 48 hyperactive children between the ages of 6 and 8 from 3 public schools. The children

had short attention spans, low frustration and tolerance [sic], and poor learning motivation. They were taught by the same method in class and received remedial instruction as in the previous year. In order to participate in this study, the children were brought from their regular classrooms every morning to listen in groups of 9, 10, or 19 -- according to the available accommodation in the school -- to suggestions of relaxation, to ideas of coping with emotional problems, and to suggestions of modifying attitudes towards learning. The corrective reading teachers conducted these 15-minute sessions. After the session was over, the children were returned to their respective classes. At the beginning and at the end of the school year, the classroom teachers evaluated the children's behavior in class and their attitudes toward learning. The addition of the modified hypnotic technique enabled 45 of 48 children to function better in school. The improvement ranged from decreased hyperactivity to better than average performance in class. Significant correlations were found between percent of relaxation with increased attention span ( $r = .40$ ) and number of sessions attended with increased self-confidence ( $r = .46$ ).

Johnson, R. F. Q. (1976). Hypnotic time distortion and the enhancement of learning: New data pertinent to the Krauss-Katzell-Drauss experiment. American Journal of Clinical Hypnosis, 19, 98-102.

Krauss, Katzell, and Krauss (1974) reported that free-recall learning can be markedly enhanced by suggestions given under hypnosis that three minutes of study time is equivalent to 10 minutes of study time. The present investigation, which incorporated features similar to the Krauss et al. study, did not yield similar results. Subjects learned a comparable number of words for a comparable amount of study time, regardless of whether they were exposed to hypnotic time distortion instructions, special motivating instructions, or control instructions. The results are discussed in terms of general problems in modern research on hypnotism.

1975

Cowings, Patricia S. (1975, September). Observed differences in learning ability of heart rate self-regulation as a function of hypnotic susceptibility. [Paper] Presented at the 3rd Congress of the International College of Psychosomatic Medicine, Rome.

Three groups of eight men and women were given personality tests and were taught to control their own heart rates. Experimental group I and the control group had low hypnotic susceptibility (Stanford Hypnotic Susceptibility Scale), and subjects in experimental group II had high hypnotic susceptibility. The experimental groups received autogenic therapy and biofeedback, while the control group was given biofeedback only. Subjects who received autogenic therapy and biofeedback performed better than the control group. Significant differences, however, were found in all psychological test scores between high and low hypnotic susceptibles.

Cedercrentz, C. (1972). The big mistakes: A note. International Journal of Clinical and Experimental Hypnosis, 20, 15-16.

In his book, *A System of Medical Hypnosis*, Ainslie Meares writes, "Most books on hypnosis, from Bernheim to the present time, devote a great deal of space to the description of successful and dramatic cures. These accounts may be of prestige value to the author, and may do something to inform the profession of the potential value of hypnosis in medicine, but these success stories are really of little help to those who would learn the technique of hypnotherapy because the emphasis is always on the success of the treatment rather than on analysis of the psychodynamic mechanisms which brought it about. As in everything else, we learn most from a study of our failures [p. 3]." These comments remain as true today as they were ten years ago. With the notable exception of Meares, few colleagues have been willing to share their errors, allowing us to profit from their experience. Thus, when Dr. Cedercrutz sent along a note describing his experience with one of his patients, I was struck by his generosity, and it seemed most appropriate for all of us to share his experience by way of the Journal. Hopefully, this may encourage other colleagues to share their failures as well as their successes so that all of us may learn to be more effective therapists and better scientists. M.T.O. [Martin Orne]

The case reported involves a patient who had migraine headache removed with hypnosis, but later developed gastrointestinal symptoms that were operated surgically with absence of positive (physical) pathology noted. Subsequent investigation of the psychological component of the problem with hypnosis revealed an early trauma (seeing a soldier killed with a bayonette) that led to migraine-like pain in the head and vomiting.

Goldstein, M. S.; Sippelle, Carl N. (1970). Hypnotically induced amnesia versus ablation of memory. *International Journal of Clinical and Experimental Hypnosis*, 19 (3), 211-216. (Abstracted in *Current Contents*, 2, 35, 21)

Divided 33 hypnotizable undergraduates, all capable of achieving the criterion of amnesia for a 7-digit number, into 3 groups: 2 hypnotized and 1 pretend. The distributions of errors for an amnesic performance of these groups were compared with the theoretical chance distribution of errors expected in an amnesic performance

errors expected in an amnesic performance. Both hypnotized groups differed significantly from the pretend group and from the theoretical distribution, while the performance of the pretend group did not differ significantly from the chance distribution. The performance of the pretend group conformed to the expectancy for amnesia significantly better than did the performance of either of the hypnosis groups. **Edmonston, William E., Jr.; Stanke, F. James (1966). The effects of hypnosis and meaningfulness of material on verbal learning. American Journal of Clinical Hypnosis, 8 (4), 257-260.**

**Results: "The number of trials to criterion for each subject was analyzed in a two-way analysis of variance. The analysis indicates that hypnosis does not significantly effect the learning process. A significant difference does appear between the acquisition of high and low meaning words, the former being learned more rapidly. Also there are no interaction effects between hypnosis and the meaningfulness level of the material to be learned. The apparent gain of the hypnosis-low meaning over the nonhypnosis-low-meaning group is not statistically significant ( $t = 1.53$ ;  $p = .20$ )" (p. 258).**

**Evans, Frederick J.; Thorn, Wendy A. (1966). Two types of posthypnotic amnesia: Recall amnesia and source amnesia. International Journal of Clinical and Experimental Hypnosis, 14 (2), 162-179.**

**Posthypnotic recall amnesia refers to S's inability to recall, when challenged posthypnotically, the events which occurred during hypnosis. Posthypnotic source amnesia, occurs when S subsequently remembers the experiences of hypnosis, but has no recollection of acquiring the experiences. Data from 3 samples are presented to support the distinction between the 2 types of amnesia. Of 243 Ss, 18 experienced recall amnesia, 26 displayed source amnesia, but only 4 developed both kinds. There were no differences in rated depth of hypnosis of these 3 subgroups. Recall amnesia and source amnesia correlated .37, .38, and .39, respectively ( $p < .001$ ) in the 3 samples. The evidence indicates the 2 types of amnesia are different phenomena. Similarities between source amnesia and certain (dissociative) normal and psychopathological memory processes are discussed. (Spanish & German summaries) (32 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)**

LeCron, Leslie M. (1963). Uncovering early memories by ideomotor responses to questioning. International Journal of Clinical and Experimental Hypnosis, 11, 137-142.

The author argues for the veridicality of birth and prenatal memories elicited by hypnosis, and in any event states they are therapeutically useful fantasies. He also advocates use of ideomotor signalling as a means of access to unconscious material. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Dorcus, Roy M. (1960). Recall under hypnosis of amnesic events. International Journal of Clinical and Experimental Hypnosis, 8 (1), 57-61.

The author reported on hypnosis work with eight cases, four dealing with attempts to recall misplaced or lost articles and four dealing with recall of information related to the commission of crimes. He concluded "that recall is not greatly improved under hypnosis. However, when strong emotional elements surround the events to be recalled some additional information may be secured" (p. 60).

1954

Hammer, Emanuel Frederick (1954). Post-hypnotic suggestion and test performance. Journal of Clinical and Experimental Hypnosis, 2, 178-185

College students were tested in Normal and Post-hypnotic suggestion conditions, in balanced order (N-P-P-N, or P-N-N-P) but were actually hypnotized before the Normal as well as the Post-hypnotic trials (i.e. without and with post-hypnotic suggestions, with suggestions for amnesia for the events in the hypnotic state).

"Summary. The purpose of this investigation was to determine whether or not post-hypnotic suggestion can improve some aspects of hypnotizable students' application and efficiency as applied to a number of selected performances connected directly or indirectly to schoolwork. Before the post-hypnotic testing periods, each subject was given post-hypnotic suggestions of ease, confidence, motivation, and increased ability. The study consisted of a comparison of normal and post-hypnotic performances of nine subjects in the areas of motor capacity, attention and perception, association, learning and memory, speed of reading comprehension, and application of abstract ability.

To the extent to which psychomotor speed and endurance, physical fatigue, span and duration of attention, clerical performance, speed of learning (as tested by Meaningful Syllable Lists and Digit Symbol Substitution), speed of association, mental alertness, concentration, mental efficiency, application of abstract number abilities, and speed of reading comprehension are related to schoolwork, the

hypothesis is supported that post-hypnotic suggestion can be of aid in hypnotizable college students' schoolwork" (p. 184).

Guze, Henry (1953). Posture, postural redintegration and hypnotherapy. Journal of Clinical and Experimental Hypnosis, 1, 76-82. (Abstracted in Psychological Abstracts 53: 6559)

The use of postural analysis, and directives regarding posture and their importance in hypnotherapy are discussed. Theoretically, it is indicated that a chronic postural condition may act to elicit an emotional state with which it was originally associated. Such an emotional condition may have caused the posture in the first place, and then established a feed-back relationship with it. The breaking of feed-back mechanisms of this kind depends largely upon postural change when a chronic situation is established in the absence of realistic cause for the emotion. Posture may also act redintegratively, when directly suggested, in rearousing traumatic memories. Several clinical cases are reported.

Kunzendorf, Robert G.; Beltz, Susan McLaughlin; Tymowicz, Gina (1991-92). Self-awareness in autistic subjects and deeply hypnotized subjects: Dissociation of self-concept versus self-consciousness. Imagination, Cognition and Personality, 11, 129-141.

By refining past tests of self-awareness in mirrors, current testing demonstrates that autistic subjects' percepts are dissociated from self-concept, whereas hypnotized subjects' sensations are dissociated from self-consciousness. In the current test of self-concept, subjects could not directly see a line inside the box on their lap, but subjects could see the line indirectly in a televised mirror image. When instructed to touch the line, autistic subjects reached towards the televised line, whereas nonautistic subjects reached towards the actual line occluded inside the box. This first result suggests that the autistic subject's visual percept of the televised line is dissociated from its spatial relationship to the subject's self-concept. In the current test of self-consciousness, subjects were told to use a televised mirror-image to move their hands together until touching, but were not told that they were actually seeing a pre-recorded tape of their hands struggling unsuccessfully to touch. When queried, hypnotized subjects denied that their tactually joined hands were touching, whereas nonhypnotized subjects confirmed that their hands were touching. This latter result suggests that the hypnotized subject's hand-touching sensations are dissociated from the immediate and incontrovertible self-consciousness that one is perceiving the hands touching (not imaging them touching).

1960

McCord, Hallack (1960). A note on a change in mental age accompanying hypnosis of a teen-age-girl. International Journal of Clinical and Experimental Hypnosis, 8 (4), 259-262.

An adolescent with questionable diagnosis (mental retardation due to organic brain damage or functional psychological disorder) was given the E-G-Y test for an estimate of verbal intelligence. After initial testing, in which attention span was limited and she was very negativistic, she was re-tested in light hypnosis. Her mental age "more than doubled -- went up by six years -- "in the intervening 24 hours. The author ascribes improvement to relaxation from light hypnosis and opined that the 10 year level achieved under hypnosis was close to her "true" level of functioning. Subsequent attempts to hypnotize her were not successful, possibly due to short attention span and negativistic tendencies.

1956

McCord, Hallack (1956). Hypnosis as an aid to the teaching of a severely mentally retarded teenage boy. Journal of Clinical and Experimental Hypnosis, 4 (1), 21-23. (Abstracted in Psychological Abstracts 57: 3729)

A 16 year old boy with I.Q. measured at 55 was hypnotized for 20 minutes daily for one month. During each session he was given material to learn (multiplication tables, spelling words, reading recognition, and general information -- only one presented during each hypnosis session). "At the end of 90 days, the subject was still retaining almost 100 percent of all material presented except for the multiplication tables which showed about 50 percent loss" (p. 22). "As a result of routinely introduced hypnotic suggestions for well-being, happiness, desire to learn, and assurance of acceptance, Ben's motivation to learn in the classroom situation took a sharp surge upward. (It was for this reason that giving him parallel material in the normal state to be used to measure comparative learning rates promptly became scientifically unsound as a control in this study.)" (p. 22). Although he was not given material to study in between sessions, "it was known that he mentally reviewed the material while working and playing in the school program" (p. 23). measure comparative learning rates promptly became scientifically unsound as a control in this study." (p. 22). Although he was not given material to study in

between sessions, "it was known that he mentally reviewed the material while working and playing in the school program" (p. 23).

**McCord, Hallack (1956). The hypnotizability of the mongoloid-type child. Journal of Clinical and Experimental Hypnosis, 4 (1), 19-20.**

Seven mentally retarded people ranging in age from 9 to 30 were involved in a pilot study. The induction involved eye fixation coupled with sleep suggestions and lasted not more than 30 minutes. Five were judged to go into light trances; one "seemed to enter a trance, but she failed all of the usual tests through [sic] successfully meeting all challenges" (p. 19) and one appeared not to become hypnotized.

**Erickson, Milton H. (1954). Special techniques of brief hypnotherapy. Journal of Clinical and Experimental Hypnosis, 2, 109-129. (Abstracted in Psychological Abstracts 55: 2508)**

Author describes techniques used with patients who aren't able, for internal or environmental reasons, to undertake comprehensive therapy, "Intentionally utilizing neurotic symptomatology to meet the unique needs of the patient" (p. 109). He provides 8 case reports.

Patient 1 was reassured, in hypnosis, that his arm paralysis was due to "inertia syndrome" which he would continue to have, but it wouldn't interfere with his work.

Patient 2, also with arm paralysis had another comparable, non-incapacitating, symptom substituted.

Patients 3 and 4, for whom restrictions on therapy were the limits of time and situational realities, had their symptoms transformed (e.g. by introducing in hypnosis the obsessional thought or worry that he would NOT have the symptom for which he sought help).

Patients 5 and 6 were helped, through hypnosis, to symptom amelioration. (Patient 5 had an IQ of 65.)

Patient 7 "Therapy was achieved ... by a deliberate correction of immediate emotional responses without rejecting them and the utilization of time to palliate and to force a correction of the problem by the intensity of the emotional reaction to its definition" (p. 121)

Patient 8 "the procedure was the deliberate development, at a near conscious level, of an immediately stronger emotion in a situation compelling an emotional response corrective, in turn, upon the actual problem" (p. 121).

**Elter-Nodvin, Edeltraud (2000). Computerized content analysis: A comparison of the verbal productions of high hypnotizable, low hypnotizable and simulating subjects (Dissertation). (<http://www.televid.com/elternodvin/dissertation/>)**

This research was designed to investigate the domain of hypnosis and to explore how the ""state"" of hypnosis, along with the susceptibility to hypnosis relate to lexical choice in verbal productions as well as to primary/secondary process mentation. ... College students were screened for level of hypnotic susceptibility ... [yielding] 32 high hypnotizable subjects and 57 low hypnotizable subjects [randomly assigned to two groups] ... 29 low hypnotizable subjects and 28 low hypnotizable simulating subjects.

Responses to six Thematic Apperception Test (TAT) cards and responses to five free speech story-openings were collected and tape-recorded during [counterbalanced waking and hypnosis conditions]... verbal productions were transcribed and [computer] analyzed by ... the Dartmouth Adaptation of The General Inquirer ... and COUNT with the Regressive Imagery Dictionary ... .

To summarize, findings suggest that the changes in SECONDARY PROCESS and THOUGHT, as well as the DAGI-III-variable EMOTION and the COUNT-RID-variable EMOTION, may be a result [sic] other than hypnotic ability or the hypnotic experience. The possibility has been raised, that subjects who had been instructed to simulate hypnosis were successful in discerning the experimental, implicit demands to respond with decreased SECONDARY PROCESS and THOUGHT as measured by the DAGI-III and COUNT-RID respectively and to present the appearance of a genuinely hypnotized subject. The same was true for the increase in EMOTION as measured by the DAGI-III as well as by the COUNT-RID. The interaction between the condition (baseline vs. hypnosis) and the group (level of hypnotic susceptibility) would have provided the strongest support for the assertion that hypnosis changes a dimension (e.g. enhances primary process responding or decreases secondary process mentation) in highly hypnotizable subjects.

The likelihood that the hypnotic main-effect can be attributed at least to some extent to demand characteristics has been supported by the current results. The hypnotic \_\_state\_\_, even though it can be measured through behavioral measures such as the HGSHS and the CAH, cannot be measured by content measures of verbal productions.

Findings are discussed in regard to previous literature suggesting a link between primary process and hypnosis and suggestions for future research are made. In addition, theoretical and practical implications are discussed. - From dissertation at web site <http://www.televi.com/alternodvin/dissertation/>

Benjamin Franklin's invention of the the armonica became the favorite instrument of Mesmer. In both Vienna and Paris, Mesmer used background armonica music to faciliate the effect of animal magetism. With the demise of mesmerism following the report of the French royal commissions, the armonica also faded into history2256

Ludwig, Arnold M. (1964). An historical survey of the early roots of mesmerism. International Journal of Clinical and Experimental Hypnosis, 12 (4), 205-217.

Many believe that Franz Anton Mesmer helped lay the foundations upon which modern hypnotic theory and practice evolved. However, as one views the history of healing through suggestion prior to Mesmer, it becomes apparent that neither his theories nor his practices showed much originality. In fact, there is good evidence that Mesmer plagiarized the work of others. With this in mind, it appears that Mesmer's contribution to later psychological healing and theory was related more to his personality than to his originality. (Journal Abstract)

1957

Conn, Jacob H. (1957). Historical aspects of scientific hypnosis. Journal of Clinical and Experimental Hypnosis, 5 (1), 17-24.

The author relates the history of hypnosis beginning with pre-historic therapeutic suggestion, the trances of Persian Magi and Indian Yogi, and incubation or temple sleep in Egypt and Greece. Touching on practices among Egyptians, Romans, Greeks and the Middle Ages in Europe, he writes in more detail about Mesmer, John Elliotson, James Braid, Ambroise Auguste Liebault, Hyppolyte Marie Bernheim, and Jean Martin Charcot.

Meta-Analysis

2002

Montgomery, Guy H.; David, Daniel; Winkel, Gary; Silverstein, Jeffrey H.; Bovbjerg, Dana H. (2002). The effectiveness of adjunctive hypnosis with surgical patients: A meta-analysis. Anesthesia and Analgesia, 94, 1639-1645.

Hypnosis is a nonpharmacologic means for managing adverse surgical side effects. Typically, reviews of the hypnosis literature have been narrative in nature, focused on specific outcome domains (e.g., patients' self-reported pain), and rarely address the impact of different modes of the hypnosis administration. Therefore, it is important to take a quantitative approach to assessing the beneficial impact of adjunctive hypnosis for surgical patients, as well as to examine whether the beneficial impact of hypnosis goes beyond patients' pain and method of the administration. We conducted meta-analyses of published controlled studies (n = 20) that used hypnosis with surgical patients to determine: 1) overall, whether hypnosis has a significant beneficial impact, 2) whether there are outcomes for which hypnosis is relatively more effective, and 3) whether the method of hypnotic induction (live versus audiotape) affects hypnosis efficacy. Our results revealed a significant effect size (D = 1.20), indicating that surgical patients in hypnosis treatment groups had better outcomes than 89% of patients in control groups. No significant differences were found between clinical outcome categories or between methods of the induction of hypnosis. These results support the position that hypnosis is an effective adjunctive procedure for a wide variety of surgical patients.

**IMPLICATIONS:** A meta-analytical review of studies using hypnosis with surgical patients was performed to determine the effectiveness of the procedure. The results indicated that patients in hypnosis treatment groups had better clinical outcomes than 89% of patients in control groups. These data strongly support the use of hypnosis with surgical patients. [National Library of Medicine Abstract]

**Kirsch, Irving (1996).** Hypnosis in psychotherapy: Efficacy and mechanisms. Contemporary Hypnosis, **13** (2), 109-114.

Meta-analyses have established that different psychotherapies have different outcomes. Cognitive-behavioural therapies are significantly more effective than psychodynamic therapies, and their superiority increases when long-term follow-up is assessed. Hypnosis enhances the efficacy of both psychodynamic and cognitive-behavioural psychotherapy, and this effect is especially strong in long-term outcome of treatment for obesity. The paucity of procedural differences between hypnotic and non-hypnotic treatments in many of the studies demonstrating a substantial advantage for hypnosis suggests that the effect depends on the use of the word 'hypnosis'. Hypnosis can be regarded as an empirically-validated, non-deceptive placebo, the effects of which are mediated by response expectancies.

**Kirsch, Irving (1996).** Hypnotic enhancement of cognitive-behavioral weight loss treatments--Another meta-reanalysis. Journal of Consulting and Clinical Psychology, **64** (3), 517-519.

In a 3rd meta-analysis of the effect of adding hypnosis to cognitive-behavioral treatments for weight reduction, additional data were obtained from authors of 2 studies, and computational inaccuracies in both previous meta-analyses were corrected. Averaged across posttreatment and follow-up assessment periods, the mean weight loss was 6.00 lbs. (2.72 kg) without hypnosis and 11.83 lbs. (5.37 kg) with hypnosis. The mean effect size of this difference was 0.66 SD. At the last assessment period, the mean weight loss was 6.03 lbs. (2.74 kg) without hypnosis and 14.88 lbs. (6.75 kg) with hypnosis. The effect size for this difference was 0.98 SD. Correlational analyses indicated that the benefits of hypnosis increased substantially over time ( $r=.74$ ).

Kirsch, Irving; Montgomery, Guy; Sapirstein, Guy (1995). Hypnosis as an adjunct to cognitive behavioral psychotherapy: A meta-analysis. Journal of Consulting and Clinical Psychology, 63 (2), 214-220.

A meta-analysis was performed on 18 studies in which a cognitive-behavioral therapy was compared with the same therapy supplemented by hypnosis. The results indicated that the addition of hypnosis substantially enhanced treatment outcome, so that the average client receiving cognitive-behavioral hypnotherapy showed greater improvement than at least 70% of clients receiving nonhypnotic treatment. Effects seemed particularly pronounced for treatments of obesity, especially at long-term follow-up, indicating that unlike those in nonhypnotic treatment, clients to whom hypnotic inductions had been administered continued to lose weight after treatment ended. These results were particularly striking because of the few procedural differences between the hypnotic and nonhypnotic treatments.

1993

Saperstein, Guy; Montgomery, Guy; Kirsch, Irving (1993, August). Cognitive-behavioral hypnotherapy: A meta-analysis. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.

Meta-analysis was used to compare the effectiveness of cognitive-behavior therapy (CBT) to that of cognitive-behavior therapy with hypnosis (CBHT). A review of the literature revealed 18 studies in which 20 hypnotic treatments were compared to similar non-hypnotic treatments and in which sufficient data were presented for the calculation of effect sizes. Effect sizes were weighted for sample size and then averaged. This resulted in a mean effect size of 1.37 standard deviation units, indicating that the average client receiving cognitive-behavioral hypnotherapy is better off than 90 percent of clients who receive the same treatment in a nonhypnotic context. Substantial variance in effect sizes was found, indicating the presence of a moderator variable. Further analyses indicated that this variance was limited to treatments in which obesity was the presenting problem. The mean effect size for the addition of hypnosis to treatments of obesity was larger ( $M = 1.98$ ) and more variable (variance = 4.10) than that for the addition of hypnosis to treatments for other presenting problems ( $M = .52$ ; variance = .06). Also, studies of clinical samples yielded larger effects ( $M = 1.72$ ) than analogue studies with college student samples ( $M = .07$ ). The effect of hypnosis was independent of whether relaxation training was included in the nonhypnotic treatment or whether the hypnotic treatment included suggestions that were not included in the nonhypnotic treatment. Consistent with response expectancy theory, these data indicate that the substantial positive effect obtained was due to labeling the treatment 'hypnosis,' rather than to any substantive change in clinical procedure. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall 1993, Vol. 2, No. 3.) to treatments for other presenting problems ( $M = .52$ ; variance = .06). Also, studies of clinical samples yielded larger effects ( $M = 1.72$ ) than analogue studies with college student samples ( $M = .07$ ). The effect of hypnosis was independent of whether relaxation training was included in the nonhypnotic treatment or whether the

Consistent with response expectancy theory, these data indicate that the substantial positive effect obtained was due to labeling the treatment 'hypnosis,' rather than to any substantive change in clinical procedure. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall 1993, Vol. 2, No. 3.)

1992

Kirsch, Irving (1992, August). Cognitive-behavioral hypnotherapy. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, DC.

The use of hypnosis to augment cognitive behavior therapy was described. Hypnotic inductions establish a context in which the effects of therapeutic interventions can be potentiated for clients with positive attitudes and expectancies toward it. Hypnosis can also provide a disinhibiting context for both clients and therapists, allowing them to behave in ways that are therapeutic, but that might seem awkward in other contexts. A meta-analysis of outcome studies in which the effects of a cognitive-behavioral treatment were compared to the effects of the same treatments supplemented by hypnosis resulted in a mean effect size of 0.87 standard deviations, indicating the average client receiving cognitive-behavioral hypnotherapy is better off at the end of it than more than 80 percent of clients who receive the same treatment in a nonhypnotic context. (ABSTRACT from the Bulletin of Division 30, Psychological Hypnosis, Fall, 1992, Vol. 1, No. 3.)

Lyons, Larry C. (1992, October). Absorption and hypnotizability: Meta-analysis of studies to determine if contextual effects are important. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

Correlations between hypnotizability and Absorption range from .20 to .40; Council et al. suggest the correlation between these variables is a context effect (expectancy). In our review there was no statistically significant difference between correlations that were found in and out of context (.26 and .23, weighted means) in more than 40 studies with more than one correlation per study.

When Absorption was measured before hypnosis experience the  $r = .25$ ; after the hypnosis experience,  $r = .32$  (significantly different), which also was different from what context hypothesis would predict. Any context difference may be a function of length of time between the Absorption and hypnosis sessions.

Data does not support the context hypothesis. Measuring Absorption after hypnosis resulted in higher mean correlations with susceptibility. However, the magnitude of this relationship was small. Variation due to test reliability and small sample size are likely explanations of the differences in the magnitude of the correlations across studies. We also must consider scale reliability and sample error (samples less than 1000 have departures from the population correlation that are fairly large).

**CONCLUSION.** We should construct confidence intervals around observed correlations and look at the overlap; don't look only at the significance of the difference between correlations.

Author is in the process of conducting a mail survey to obtain unpublished results on context effect.

**1991**

**Hinshaw, Karin E. (1991).** The effects of mental practice on motor skill performance: Critical evaluation and meta-analysis. Imagination, Cognition and Personality, 11, 3-35.

21 studies that met the criteria of having both an adequate control and a mental practice alone group were included. The 44 separate effect sizes resulted in an overall average effect size of .68 (SD = .11) indicating that there is a significant benefit to performance of using mental practice over no practice. A series of General Linear Models revealed that the use of "internal" imagery produced a larger average effect size than the use of "external" imagery, and that mental practice sessions of less than one minute or between ten and fifteen minutes in length produced a larger average effect size than sessions of three to five minutes in length. These findings suggest the complexity of the relationship between variables that influence mental practice.

**Marzi, C. A.; Bisiacchi, P.; Nicoletti, R. (1991).** Is interhemispheric transfer of visuomotor information asymmetric? Evidence from a meta-analysis. Neuropsychologia, 29, 1163-1177.

Using a meta-analytic procedure we have analysed 16 studies employing a simple unimanual reaction time (RT) paradigm and lateralized visual stimuli to provide an estimate of interhemispheric transfer time in normal right-handed subjects. We found a significant overall RT advantage of the left visual field over the right and of the right hand over the left. These asymmetries can be explained by a superiority of the right hemisphere for the detection of simple visual stimuli and by a corresponding superiority of the left hemisphere for the execution of the manual response, respectively. Alternatively, they may be interpreted as related to an asymmetry of interhemispheric transmission of visuomotor information, with transfer from the right hemisphere (side of stimulus entry) to the left (side of response generation) faster than in the reverse direction. Although a direct test of these hypotheses is still lacking, we think that the evidence available is more in keeping with the latter possibility.

**Weisz, G. (1991, December).** Meta-analysis of hypnosis and biofeedback pain control with children, adolescents and young adults (Dissertation, Pace University). Dissertation Abstracts International, 52 (6), 3321-B. (Order No. DA 9132945)

This study used meta-analysis to investigate the issues related to treatment efficacy with hypnosis and biofeedback in anxiety management and in child, adolescent, and

young adult pain. Analysis revealed that hypnosis and biofeedback were effective in pain and anxiety reduction and appeared equally effective. This contrasts with metaanalysis results by Malone & Strube (1988) showing almost triple superiority of hypnosis and autogenic training over biofeedback. The study notes methodologic variables that may distort or reduce the size of obtained effects.

**Bornstein, Robert F. (1990). Critical importance of stimulus unawareness for the production of subliminal psychodynamic activation effects: A meta-analytic review. Journal of Clinical Psychology, 46, 201-210.**

Performed meta-analysis that assessed the magnitude of behavior change produced by subliminal vs supraliminal drive-related stimuli (DRS) on 11 subliminal psychodynamic activation (SPA) studies (published 1966-1989) that employed both types of stimuli. The analysis revealed that subliminal presentation of DRS produced significantly stronger effects on behavior than supraliminal presentation of the same stimuli. Stimulus content, type of outcome measure, and S characteristics influenced the magnitude of subliminal/supraliminal response differences. Results support L. H. Silverman's (1983) hypothesis that DRS must be presented subliminally to produce SPA effects.

**1989**

**Epley, Kenneth R.; Abrams, Allan I.; Shear, Jonathan (1989). Differential effects of relaxation techniques on trait anxiety: A meta-analysis. Journal of Clinical Psychology, 45, 957-974.**

Conducted a meta-analysis of studies on the effects of relaxation techniques on trait anxiety. Effect sizes for the different treatments (e.g., progressive relaxation, biofeedback, meditation) were calculated. Most treatments produced similar effect sizes, although transcendental meditation (TM) produced a significantly larger effect size than other forms of meditation and relaxation. A comparison of the content of the treatments and their differential effects suggests that this may be due to the lesser amount of effort involved in TM. Meditation that involved concentration had a significantly smaller effect than progressive relaxation.

**Johnson, Blair; Eagly, Alice H. (1989). Effects of involvement on persuasion: A meta-analysis. Psychological Bulletin, 106 (2), 290-314.**

Defines involvement as a motivational state induced by an association between an activated attitude and the self-concept. Integration of the available research suggests that the effects of involvement on attitude change depended on the aspect of message recipients' self-concept that was activated to create involvement: (a) their enduring values (value-relevant involvement), (b) their ability to attain desirable outcomes (outcome-relevant involvement), or (c) the impression they make on others (impression-relevant involvement). Findings showed that (a) with value-relevant

involvement, high- involvement subjects were less persuaded than low-involvement subjects;

1988

Malone, M.; Strube, M. (1988). Meta-analysis of non-medical treatment for chronic pain. Pain, 34, 231-234.

Conducted a meta-analysis of 109 published studies which assessed the outcome of various nonmedical treatments for chronic pain, 48 of which had sufficient information to calculate effect sizes. The remainder were examined according to proportion of patients rated as improved. Mood and number of subjective symptoms consistently showed greater responses to treatment than did pain intensity, pain duration, or frequency of pain, indicating the importance of using a multidimensional framework for pain assessment. Effect sizes for treatments were 2.74 for autogenic training, 2.67 for hypnosis, 2.23 for pill placebo, 1.33 for package treatments that allowed patients to choose from diverse pain management strategies, .95 for biofeedback, .76 for cognitive therapy, .67 for relaxation, .55 for operant conditioning, and .46 for TENS units. However, the largest numbers of studies were in the area of biofeedback, a treatment package, and relaxation, and we must be cautious in interpreting the effect sizes due to the small number of studies in the sample.

1985

Olness, Karen N.; Conroy, Mary Margaret (1985). A pilot study of voluntary control of transcutaneous PO<sub>2</sub> by children: A brief communication. International Journal of Clinical and Experimental Hypnosis, 33, 1-5.

This pilot study took place to determine whether or not children could voluntarily change tissue oxygen as measured by a transcutaneous oxygen monitor. It tested 2 hypotheses: (a) children can voluntarily change tissue oxygen as reflected by a transcutaneous oxygen monitor and (b) children, experienced in use of self-hypnosis exercises, will be able to change tissue oxygen to a greater degree than children unfamiliar with such exercises. 11 children between the ages of 7 and 17 year were studied. 8 children were previously experienced in the use of self-hypnosis; 3 were not. A Novametrix transcutaneous O<sub>2</sub>/CO<sub>2</sub> monitoring system provided a constant read-out of PO<sub>1</sub>, PCO<sub>1</sub> and local perfusion. After stabilization, children were asked to attempt increases of oxygen. 9 children increased tissue oxygen significantly. Of those, 8 children had previous self-hypnosis training. 1 had not. Only 2 children with no previous self- hypnosis training were unable to change oxygen values. This pilot study upholds both hypotheses; however, it does not conclude that self-hypnosis mediated the changes noted or that self-hypnosis would be essential to success in voluntary control of tissue oxygen.

1984

Holmes, David S. (1984). Meditation and somatic arousal evidence. American Psychologist, 39 (1), 1-10.

The conceptual and methodological issues associated with research on the effects of meditation are reviewed. A summary of the research in which the somatic arousal of meditating subjects was compared to the somatic arousal of resting subjects did not reveal any consistent differences between meditating and resting subjects on measures of heart rate, electrodermal activity, respiration rate, systolic blood pressure, diastolic blood pressure, skin temperature, oxygen consumption, EMG activity, blood flow, or various biochemical factors. Similarly, a review of the research on the effects of meditation in controlling arousal in threatening situations did not reveal any consistent differences between meditating and nonmeditating (no-treatment, antimediation, or relaxation) subjects. The implications of these findings for research and practice are discussed.

1982

Throll, D. A. (1982). Transcendental meditation and progressive relaxation: Their physiological effects. Journal of Clinical Psychology, 38 (3), 522-530.

Measured oxygen consumption, tidal volume, respiration rate, heart rate, systolic and diastolic blood pressure before the Ss learned Transcendental Relaxation Meditation (Transcendental meditation: N = 21) or Jacobson's Progressive Relaxation (PR: N = 18). Ss were tested immediately after learning either technique and again 5, 10, and 15 weeks later. While there were no significant differences between groups for any of the physiological variables at pretest, the Transcendental meditation group displayed more significant decreases during meditation and during activity than did the Psychological Review group. Both groups displayed significantly lowered metabolic rates during Transcendental meditation or PR. The generally more significant and comprehensive results for meditators were explained primarily in terms of the greater amount of time the Transcendental meditation group spent on their technique, plus the differences in the two techniques themselves. Several avenues for future research are discussed.

1980

Crosson, B. (1980). Control of skin temperature through biofeedback and suggestion with hypnotized college women. International Journal of Clinical and Experimental Hypnosis, 28 (1), 75-87.

4 groups of 9 college women attempted to raise finger temperature relative to forehead temperature during hypnosis. After a hypnotic induction, each group of Ss received 1 of the following treatments for temperature control: (a) biofeedback, (b) suggestion and imagery, (c) biofeedback plus suggestion and imagery, and (d) a relaxation, false-feedback control. Groups were initially balanced for hypnotic susceptibility. Between-subject differences in baseline temperatures were statistically controlled. After 4 training sessions, only Ss in the groups receiving biofeedback and biofeedback plus suggestion and imagery demonstrated evidence of

learned temperature control, and only Ss in the biofeedback group demonstrated a significantly greater ability to control skin temperature than Ss in the control group. Changes in temperature during hypnotic induction did not appear to affect changes during the subsequent treatment. There was no significant correlation between hypnotic susceptibility and temperature control for Ss in any group, contrary to popular assumption. Future research should attempt to ascertain if combined use of biofeedback and hypnosis offers any advantages to the use of biofeedback alone.

**Jackson, J. Arthur; Gass, Gregory C.; Camp, Elizabeth M. (1979). The relationship between posthypnotic suggestion and endurance in physically trained subjects. International Journal of Clinical and Experimental Hypnosis, 27, 278-293.**

55 male Ss were assigned to 5 groups: control, hypnosis alone, motivation alone, low susceptible hypnosis with motivation, or high susceptible hypnosis with motivation. Ss performed 2 runs on a treadmill to their maximum capacity, as measured by oxygen consumption, blood lactate concentration, and respiratory quotient. Groups involving hypnosis performed in the posthypnotic state. A significant increase in endurance performance was revealed in the motivation alone Ss and in high susceptible hypnosis Ss who were given motivational suggestions. Maximum ventilation was significantly increased in high susceptible hypnosis Ss when compared with control Ss and significant increases in blood lactate concentrations were revealed when the high susceptible hypnosis Ss were compared with low susceptible hypnosis and motivation alone Ss. The reasons for the changes in metabolic variables are discussed. Findings demonstrated that in achieving greater endurance performance, motivational suggestions alone are as effective as identical suggestions given to high susceptible Ss.

**2000 Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)**

**This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.**

**1999 Harper, Gary W. (1999). A developmentally sensitive approach to clinical hypnosis for chronically and terminally ill adolescents. American Journal of Clinical Hypnosis, 42 (1), 50-60.**

Adolescents who suffer from terminal and/or chronic medical illnesses must face difficult developmental issues coupled with increased burdens of physical discomfort and uncertainty about survival. Clinical hypnosis is one technique that can be used to help these individuals gain a sense of comfort and control over their lives. I describe the use of a developmentally sensitive hypnotherapeutic intervention for chronically and terminally ill adolescents. I have used the technique for the reduction of various types of physical and psychological discomfort secondary to a range of medical problems such as cancer, end-stage renal disease, organ transplant, and HIV disease. The treatment focuses on the use of personalized procedures that attempt to increase perceptions of control through interactive formats. Movement through a personally intriguing journey is used as a metaphor for controlling and moving away from discomfort. I also present three case examples as well as general treatment recommendations for clinical use.

Eisen, Marlene R. (1989). Return of the repressed: Hypnoanalysis of a case of total amnesia. International Journal of Clinical and Experimental Hypnosis, 37 (2), 107-119.

A case study is presented of a woman suffering from global amnesia so profound that she had lost all sense of personal identity. Hypnotherapy was used to establish, through imagery, a solid inner core on which to rebuild a sense of self. From the image of a strong column on which rested a book with a golden lock (her history), to reading about other lives, books and stories were utilized to establish a safe external environment in which the reawakening of repressed memories was not longer perceived as dangerous. A discussion of relevant literature on the subjects of global amnesia, loss of personal identity, and post-traumatic stress is offered as a basis for discussing the present case.

**1988**

Kirmayer, Laurence J. (1988). Word magic and the rhetoric of common sense: Erickson's metaphors for mind. International Journal of Clinical and Experimental Hypnosis, 36 (3), 157-172.

Milton Erickson did not produce a systematic theory of psychotherapy. His talent was as a storyteller, inventing metaphors and more extended healing fictions for his patients. A great many of Erickson's cases did not involve hypnosis in any conventional sense of the term. He used a wide range of persuasive rhetorical forms to encourage behavioral change in his patients. Nevertheless, taken together his work represents a significant shift in paradigm from prevailing schools of psychotherapy. Erickson captured the power of word magic in the language of common sense. This coupling of magical power with folk psychology accounts for much of his current popularity. Attempts to experimentally test his techniques are likely to be unsuccessful because these techniques were unique inventions tailored to the individual idiosyncrasies of patient and context. Although regularities in his work can be found, Erickson's most important contributions are not techniques but changes in the values or ethos under which psychotherapy is conducted.

This paper focuses Erickson's implicit models of mind and the values they carry. "It is here that Erickson made his most significant contribution to the general practice of psychotherapy . Erickson avoided systematization. His writing is unusually anecdotal, even for psychotherapy (Erickson, 1980; Vol IV, passim). Erickson's writing format consists of 'thin' case descriptions, freely recycled in parable or homiletic form to serve his immediate rhetorical purpose. ... For Erickson, flexibility and eclecticism were not signs of a lack of coherence but a spirited rejection of rigid dogma that needlessly limited therapeutic possibilities" (pp. 158-59).

Erickson used language of the common man rather than a technical vocabulary, even when speaking of 'hypnosis' or 'trance' or 'the unconscious.' He called his approach 'naturalistic' and viewed hypnotic phenomena as an extension of normal experience and behavior. His common sense descriptions of events and techniques are easily understood in general terms. "Erickson took magic and dressed it in the familiar clothes of common sense. Some of his less critical followers, however, seem intent on taking common sense and dressing it in the cloak of magic" (p. 163).

Erickson used metaphors as a way of actively involving the patient in conceptual, affective, and sensory qualities of experiences, i.e. as a "tool for thought" (p. 164).

In attempting to understand Erickson's psychotherapy, one must note his "elastic use of the word 'hypnosis.' Sometimes Erickson uses the term narrowly with a focus on the elicitation of trance or dissociative phenomena, but more often he uses it broadly to mean any state of absorption" (p. 165). For him, this was "\_a state of special awareness characterized by a receptiveness to ideas\_" [Erickson, 1985, p. 223, emphasis in original]. By this he does not mean exclusively the classic suggestion effect where motor acts are experienced as involuntary (Evans, 1967). ... The hypnotic subject exhibits a "\_special willingness to examine ideas for their inherent values\_" [p. 224, emphasis in original]. ... For Erickson, any move in the direction of increased absorption is an instance of hypnosis. Dissociation accounts for a great deal but not all of hypnotic behavior" (p. 165). That is why he used the word hypnosis to describe heightened attention that might occur when someone is surprised. But in fact, his published cases include many other kinds of interventions, such as reframing, symptom prescription, etc.--forms of influence and persuasion used by many therapists who do not consider themselves working with hypnosis.

Erickson also emphasized that hypnosis enables one to work with 'the unconscious.'

Gibson, Michael; McCue, Peter A. (1986). Discussion commentary On Crowley's and Mills 'The nature and construction of therapeutic metaphors for children'. [Comment/Discussion] .

The authors are critical of the methods and conclusions of Crowley & Mills. They also offer an example of Milton Erickson claiming that a subject was hypnotized when it appeared to other experts present that the subject was nonresponsive to inductions by both Erickson and by Weitzenhoffer

the place where things just 'happen to us.' Erickson reversed this attribution, emphasizing the unconscious as the agent of active control working for the benefit of the patient while consciousness adopts the attitude of 'wait and see.' This leads consciousness into reverie--the state where images and events move of their own accord, animated by emotion, before the 'passive audience' of consciousness" (p. 167). So Erickson viewed hypnosis as liberating the unconscious. There was healing potential in helping the ego to relinquish "rigid control over the creative and benevolent processes of the unconscious" (p. 168). From this theoretical position, the patient and therapist are seen as allies and psychotherapy is a collaboration; there is no need for the Freudian concepts of resistance and defense.

**"Erickson's metaphors for hypnotherapy link it with normal processes of learning and imagining. His image of the unconscious as a storehouse of creative potential supports a non-pathologized view of man amid all his troubles and craziness. In contrast to psychiatry's current preoccupation with nosology, and the emphasis of psychoanalysis on the dimensions of human frailty, Erickson adopted a non-pathologizing attitude. He did not deny his patient's difficulties but neither was he excessively fascinated by them. He recognized that healing depends not on cataloguing deficiency but on fully mobilizing the person's intelligence, imagination, and integrity. This message of therapeutic optimism was balanced by his own example of the benefits and limitations of hypnotherapeutic practice" (p. 170).**

**Eisen, Marlene R.; Fromm, Erika (1983). The clinical use of self-hypnosis in hypnotherapy: Tapping the functions of imagery and adaptive regression. International Journal of Clinical and Experimental Hypnosis, 31 (4), 243-255.**

**The authors present a new method of interweaving hetero-hypnotic psychotherapy and self-hypnosis. In the hetero-hypnotic sessions, the hypnotherapist acts as a dependable parent figure who is supporting and available when that is desirable, but who also encourages and fosters the patient's efforts to develop his/her inner resources and ability to function autonomously. Self-hypnosis is utilized for its rich idiosyncratic imagery. The hypnotherapist uses and elaborates on this rich, affect-loaded imagery. At other times the therapist takes a guiding role in producing therapeutic metaphors of positive valence. The patient uses and enlarges on these during self-hypnosis between the weekly therapeutic hours. In addition, the hypnotist may counteract any negative strong self-hypnotic images during hetero-hypnosis. Self-directed self-hypnosis allows patients to experience openness and receptivity to internal and unconscious processes against which they may defend themselves in the dyadic relationship with the therapist. For patients struggling with issues of control and for patients fighting their own regressive pull towards dependency, this mode of therapy appears to be particularly effective. The emphasis in this paper is on imagery and on the inter-twining of the two modalities, hetero-hypnosis and self-hypnosis.**

**Barabasz, Arreed F. (1984). Antarctic isolation and imaginative involvement - preliminary findings: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32 (3), 296-300.**

**Group 1 Ss (N = 9) were interviewed in Antarctica prior to and following 1 year of Antarctic isolation. Group 2 Ss (N = 7) were exposed to 3 weeks of Antarctic field-site isolation and were interviewed upon return to the United States. A control group of 10 Ss was also interviewed on 2 occasions, paralleling Group 1. Group 1 showed a significant increase in imaginative involvement from pre- to post-Antarctic isolation. Group 2 showed a significantly greater level of imaginative involvement than the control Ss. The possibility that Antarctic living may have revived the mental processes available to these Ss as children is considered within both regression and learning explanations.**

**1974**

**Bloom, Richard F. (1974). Validation of suggestion-induced stress.**

**Sixty college men, divided into three equal groups, each attended two induced stress sessions in which their physiological, psychological and performance reactions were measured. Their responses were compared to determine if valid stress reactions could be induced through suggestion in an altered state (in this case, hypnosis), and also to determine the validity of such reactions if the subject had never before experienced that stress situation. It was demonstrated that valid stress reactions can be induced in an individual with the aid of suggestions, especially if the real stress situation has been experienced before. If no previous experience with that real situation exists, the subject still exhibits stressful reactions; however, the closest resemblance to real stress is found in the subjective or psychological measures, less similarity is found in the physiological measures, and the least similarity is found in the performance measures.**

Distribution limited to U.S. Government agencies only; Other requests for this document must be referred to Commanding General, U.S. Army Electronics Command, ATTN: AMSEL-PP-CM-CR4, Fort Monmouth, NJ 07703.**

**This document reports on a U.S. Army research project using hypnosis to collect high fidelity samples of the voice under "combat stress" conditions in the laboratory. Using hypnotic regression, combat veterans "re-experienced" their own, actual high stress combat situations. Besides subjective reports of stress levels by subjects, physiological stress measures were obtained from polygraph recordings of**

heart, respiration and GSR activity. The voice samples were later analyzed by spectrographic techniques to determine which factors remain invariant to identify and authenticate the speaker in a military communications situation. Hypnotic techniques were shown to be useful in establishing controlled emotional states for laboratory research purposes. (Richard Bloom)

1992

Mittleman, K. D.; Doubt, T. J.; Gravitz, Melvin A. (1992). Influence of self-induced hypnosis on thermal responses during immersion in 25 degrees C water. Aviation, Space & Environmental Medicine, 63, 689-695.

The efficacy of self-induced posthypnotic suggestion to improve thermogenic responses to head-out immersion in 25 degrees C water was evaluated in 12 males. An online computerized system permitted the change in body heat storage to be used as the independent variable and immersion time as the dependent variable. Two one- hour hypnotic training sessions were used. There were no differences in rates of heat production, heat loss, mean skin temperature, or rectal temperature between control and hypnotic immersions. Individual hypnotic susceptibility scores did not correlation with changes in thermal status. Ratings of perceived exertion during exercise were similar for both immersions, but perceived sensation of cold was lower during the second rest period of the hypnotic immersion. Three subjects used images of warm environments during their hypnotic immersion and lost heat at a faster rate than during control immersions. These results indicate that brief hypnotic training did not enhance the thermogenic response to cool water immersion.

1990

Spiegel, David; Cardena, Etzel (1990, October). New uses of hypnosis in the treatment of posttraumatic stress disorder. Journal of Clinical Psychiatry (Supplement), 51, 39-43.

Vietnam veterans with PTSD and those abused as children have above average hypnotizability. Hypnosis provides controlled access to memories that may otherwise be kept out of consciousness. New uses of hypnosis with PTSD victims involve coupling access to the dissociated traumatic memories with positive restructuring of those memories. Hypnosis can be used to help patients face and bear a traumatic experience by embedding it in a new context, acknowledging helplessness during the event, and yet linking that experience with remoralizing memories, such as efforts at self-protection, shared affection with friends who were killed, or the ability to ttheenvironment at other times. In this way, hypnosis can be used to provide controlled access to memories that are then placed into a broader perspective. Patients can be taught self-hypnosis techniques that allow them to work through and thereby reduce spontaneous, unbidden, intrusive recollections.

1989

Cooper, Nancy A.; Clum, George A. (1989). Imaginal flooding as a supplementary treatment for PTSD in combat veterans: A controlled study. Behavior Therapy, 20 (3), 381-391.

14 Vietnam veterans suffering from posttraumatic stress disorder (PTSD) were assigned either to standard treatment (control group), or standard treatment plus imaginal flooding (experimental group). The 2 groups were closely matched on medications and combat roles and tours of duty were comparable. Experimental Ss received up to 14 sessions of flooding for a maximum of one and one-half hours per session. Self-report measures were administered at pre-treatment, post-treatment, and at 3-mo follow-up. These measures included the Behavioral Avoidance Test, the Beck Depression Inventory, and a Modified Vietnam Experiences Questionnaire. Results indicate that flooding increased the effectiveness of usual treatment, particularly in such areas as re-experiencing symptoms and sleep disturbances. However, flooding had no effect on level of depression, trait anxiety, and violence-proneness.

1958

Moss, C. Scott (1958). Therapeutic suggestion and autosuggestion. Journal of Clinical and Experimental Hypnosis, 6 (2), 109-115. (Abstracted in Psychological Abstracts, 62: 3 II 09M)

The author describes the hypnotherapeutic treatment of a 32 year old man with a chronic anxiety reaction dating to the torpedoing of his ship 15 years previous, when only two out of 101 men in his compartment survived. "A frequently expressed objection to the use of hypnosis in psychotherapy is that such treatment is purely symptomatic and temporary. The thesis proposed here is that symptomatic relief is a legitimate therapeutic goal and that hypnosis skillfully applied provides a method of greatly increasing suggestive potency, especially when heterosuggestion is reinforced through the continuous practice of autohypnosis" (p. 109).

1954

Schneck, Jerome M. (1954). The divided personality: A case study aided by hypnosis. International Journal of Clinical and Experimental Hypnosis, 2 (3), 220-232.

"Summary. Amnesia as a symptom assumes proportions more complex than would appear on the surface and the role of memory loss with specific reference to hypnotic recovery methods has been presented in several reports. Hypnotherapy would appear to be a preferred technique for resolving the symptom and at times for more extensive investigation of the underlying problems. The case reported now involved an extensive memory loss for past life, including personal identity. This was followed after nearly a year by recall and concurrent amnesia for the intervening time period. The latter amnesia was dispelled by recall at first under hypnosis and then by post-hypnotic extension and elaboration of the nuclear material. The patient's history was outlined and several facts of apparent

importance in relation to the memory loss were revealed. The purposive and motivational features were stressed. Therapy was conducted in a medico-disciplinary setting with limitations based on administrative requirements. Military-legal complications of the patient's personality disorder and functioning were outlined. The concept of the divided personality was introduced and related to multiple personality and to another type of behavior which is quite similar to the divided personality except that periods of amnesia are not involved. The divided personality involves major cleavages in the continuity of living with amnesia and the establishment of the individual in a setting where he undergoes extensive, significant operations relating to work, general activities, and even courtship and marriage. Unlike the generally accepted attributes of multiple personality involving considerable overt behavior, affect, and attitude alterations, the divided personality continues to function with his accustomed overt attitudes, interests, affect, and method of relating on an interpersonal level. Descriptively and overtly he is not too different if at all, but he seems to begin life anew in terms of setting and personal contacts. Cases of this type should be studied further with care, whenever possible, for further elicitation [sic] of psychodynamics. Hypnosis as a tool in treatment and investigation should prove helpful and is to be considered important.

1953

Conn, Jacob H. (1953). Hypnosynthesis III. Hypnotherapy of chronic war neuroses with a discussion of the value of abreaction, regression and revivication. Journal of Clinical and Experimental Hypnosis, 1, 29-43. (Abstracted in Psychological Abstracts, 53: 6687)

Author's Summary - Three examples of chronic war neuroses which were successfully treated by hypnotherapy are presented. The clinical material would seem to indicate that the patient in the trance state is greatly influenced by the attitude and goal of the therapist and tends to produce the type of material which is expected of him. The protocols reveal that the hypnotized patient responds to a permissive, calm, attitude with relatively little emotional display, and by talking about harrowing war experiences in a matter-of-fact manner.

It would appear that merely to recall the traumatic experience without a personalized, constructive, emotional relation to a supporting, understanding therapist is of little therapeutic value. The crux of the therapeutic problem in every approach, whether it be narcosynthesis, narco-analysis, hypno-synthesis, or the hypnotic intensification of an emotion is to bring about the integration of unbearable experiences which previously had been dissociated and obliterated from memory or which automatically reappear and disrupt smooth ego functioning.

It is postulated that the hypnotic trance state provides a unifying, integrating interpersonal experience which is of value in the treatment of chronic war neuroses.

1947

Kaufman, M. R.; Beaton, L. (1947). A psychiatric treatment in combat. Bulletin of the Menninger Clinic, 11, 1-14.

Describes use of hypnosis in treating "combat fatigue" in field conditions during the Pacific campaign of WWII. Hypnosis was utilized for sleep and rest in tent hospitals in or near combat to avoid chemical sedation as well as for reliving and mastering traumatic events. The milieu was one of expectant recovery with patients pitching tents, digging foxholes and serving as litter bearers. Psychiatric admissions were 12.8% of the total with return to duty rates varying with intensity of combat and duration of campaign with over half returned to combat duty. Four detailed cases are reported.

## Mind-body

1995

Olness, Karen N.; Lee, Lai (1995, November). Effects of self-induced mental imagery on autonomic reactivity in children. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

One study that shows an IgA increase with hypnotic suggestion has been replicated and is in press.

The present study emerges from work using hypnosis with biofeedback. Morgan's work with athletes has suggested the relationship between imagery and physiological activation. This has been observed clinically but not heretofore documented.

We are not using formal hypnosis. Each child was asked to think about being in a quiet place, doing exciting activities, baseline, etc. The children exhibited no neurological disorders, cognitive dysfunction, nor were they on medications at time of the study.

We confirmed our clinical experience: there was an increase in pulse rate when imagery changed to activity. Skin temperature continued to go up during the period (despite imagery of being active like being on roller coaster). Skin conduction went down during baseline. EDA [electrodermal activities] was higher during active imagery.

How do average daily thinking processes impact on autonomic changes over long periods of time? Do these changes affect cardiovascular status?

Clinically we observed that some children are more labile in different modalities, and under stress they react more in that system.

1993

Covino, Nicholas A.; Frankel, F. M. (1993). Hypnosis and relaxation in the medically ill. Psychotherapy and Psychosomatics, 60, 75-90.

Interest in the application of hypnotic techniques for patients with medical disorders seems to rise and fall over the years. Enthusiasm for this work comes both from patients and from clinicians. Often, however, these techniques are offered without regard to the psychological theories that should inform their operation and the limits that clinical and experimental research suggest. This article offers a brief description of the elements of hypnosis and a review of the history of the use of

hypnotic techniques with a variety of medical problems, including asthma, habits, pain, cardiology, surgical preparation, irritable bowel syndrome, persistent nausea and vomiting, trichotillomania, and infection and immunity. Special attention is placed on the psychological and physiological principles that help to establish the valid use of hypnotherapy.

Don, Norman S. (1993, October). Trance surgery in Brazil. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Showed a videotape of a Brazilian trance surgeon, who cuts without analgesia or asepsis. Patients later report no pain, infections, etc. The healer/surgeon is believed by everyone to be in a trance state, and the body is believed to be taken over by a spiritual doctor. The people involved deny that the patient is in trance.

Everett, John J.; Patterson, David R.; Burns, G. Leonard; Montgomery, Brenda; Heimbach, David (1993). Adjunctive interventions for burn pain control: Comparison of hypnosis and Ativan. Journal of Burn Care and Rehabilitation, 14, 676-683.

Thirty-two patients hospitalized for the care of major burns were randomly assigned to groups that received hypnosis, lorazepam, hypnosis with lorazepam, or placebo controls as adjuncts to opioids for the control of pain during dressing changes. Analysis of scores on the Visual Analogue Scale indicated that although pain during dressing changes decreased over consecutive days, assignment to the various treatment groups did not have a differential effect. This finding was in contrast to those of earlier studies and is likely attributable to the low baseline pain scores of subjects who participated. A larger number of subjects with low baseline pain ratings will likely be necessary to replicate earlier findings. The results are argued to support the analgesic advantages of early, aggressive opioid use via PCA or through careful staff monitoring and titration of pain drugs.

Hall, Howard R.; Papas, Angela; Tosi, Michael; Olness, Karen (1993, October). Bi-directional changes in neutrophil adherence following hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

At the last time that I presented a paper, I talked about the neutrophil. The neutrophil is a model of convenience because it responds quickly to psychological interventions, it is important in upper respiratory infections, and it can be measured reliably in vitro.

We had found that Ss with two weeks of relaxation/imagery training showed an increase in stickiness of neutrophils. We wanted to replicate and extend that study. We wanted one group to increase, another group to decrease, stickiness in neutrophils. There were a total of three groups, including a resting control group. The model of investigation involves two weeks of training in self hypnosis or simply resting.

**Session 1**

**1 week of practice**

**Session 2**

**Results.** The Control group increased adherence in neutrophils. The imagery-increase group and imagery-decrease group both decreased adherence. (In the first study the controls had no previous experience in relaxation. Also, the experimental group that was tested showed a decrease in first week and increased in the second week.)

Imagery is work, and that may result in less adherence. Pulse rate increased for the group trying to increase stickiness, in Session 1--implying less relaxation for them.

Hypnotizability (measured with the Pennsylvania State University Scale) was not correlated with increase in neutrophil adherence.

**Olness, Karen N. (1993, October). Intentional immunomodulation - does it exist?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.**

Robert Ader coined the term psychoneuroimmunology. The immune system is modulated by feedback mechanisms mediated via neural and endocrine processes, and by feedforward mechanisms, as well (see the second edition of Ader's book).

Ader, Grotta, and Cohen have shown that the immune system of animals also can influence behavior (e.g. genetic influences on preference for chocolate). She thinks this should be considered in designing controlled studies.

In her review of studies, some investigators request Ss to focus on changing an immune parameter; others to "relax." There is evidence for intentional influence on the immune response. Black in England and Good in the U.S. presented studies (Manteaux, histamine sensitivity, etc.) and all were laboratory studies.

Olness (1986) worked with children: they were given self hypnosis practice with instructions to "increase the immune stuff in your spit." This suggestion or request resulted in an increase in saliva IgA. [N.B. In giving suggestions to children, don't use the words "I want you to ..." because that phrasing may arouse resistance.]

The area of hypnosis and suggestion curing warts has a lot of research papers. We are doing a consortium study on treatment of warts with hypnosis and found that basic agreement on methods, such as "how you define a wart," don't exist.

**Patterson, David R. (1993, October). Managing burn pain through hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.**

Since 1955 there were 13 published reports on managing burn pain through hypnosis, with generally positive results; but almost all were anecdotal, with a lack of standardized measures. Time, location, and duration of the hypnotic interventions were not specified, cost-effectiveness was hard to detect, and medications used were not reported. Publications don't even report the type of hypnotic intervention used.

Hypnosis is indicated for procedural pain more than for during resting periods. Going through dressing changes is typically more painful than the burn itself. Opioid medications don't control all the pain. In our research we use J. Barber's Rapid Induction Analgesia, which entails suggestions for: 1. Slow breathing 2. Going down 20 steps 3. Confusion and amnesia 4. Anchoring post-hypnotic suggestions 5. Touching cue for reinstating the hypnosis 6. Relaxing scenario (Patterson added this to the Barber script) 7. Returning up the steps

This intervention is good because it's replicable, and it's easy to train students to use it. The hypnosis is done the morning before the dressing change.

Instructions for nurses are: 1. Read the card 2. Have patient lie down comfortably, etc. 3. Provide post hypnotic cue (usually a touch on the shoulder)

In the first study we used patients refractory to opioids, and also used a historical control group. This was published in the American Journal of Clinical Hypnosis. Our subsequent study was published in the Journal of Consulting and Clinical Psychology (1992). We stabilized administration of opioids; then patients had hypnosis or anxiolytics or were in the control condition. There was significant reduction in pain for hypnosis.

Patterson et al (current study). Compared Benzodiazapines to hypnosis using four groups: Hypnosis plus Lorazepam Hypnosis and placebo Lorazepam Hypnosis attention control and Lorazepam Placebo hypnosis and placebo pills

Analgesia stabilized on 2 days. There was not an effect, no significant drop in pain scores for either hypnosis or Lorazepam. Perhaps we didn't get a significant drop in pain ratings because in this study we were taking all patients who applied and their initial pain ratings were not as high as in the other study. We have found no relationship or pain reduction with hypnotizability either.

Why did we not get the positive results found previously for hypnosis? There are several possibilities. There is always a trend toward a drop in pain ratings over time. People generally bottom out with a rating of 3 or 4, and it looks like a floor effect. Also, the efficacy of hypnosis may be partly contingent on baseline pain level, and motivation to cooperate with the intervention.

Could there be the same relation to baseline for benzodiazepines?

We have noted that improved application of opioids early on means pain is lower. Marks & Sacher, Annals of Internal Medicine, 1973, indicate physicians under-prescribe opiates. Also Melzack in the Scientific American states this.

We feel that we should not push hypnotherapy so much that we feed in to opioidphobia. Hypnosis is a useful adjunct to opiates. We believe that you should stabilize the patient with opioids, and if they are not responding well, then use hypnosis.

In future research we want to find out which patients do best with hypnosis.

**Pekala, Ronald J.; Ersek, Barrett (1993). Firewalking versus hypnosis: A preliminary study concerning consciousness, attention, and fire immunity. Imagination, Cognition and Personality, 12, 207-229.**

**This study assessed the subjective effects associated with firewalking, and compared them with the subjective effects associated with hypnosis and a baseline condition (eyes closed sitting quietly). Twenty-seven subjects, who walked over hot coals during a firewalk ceremony, completed questionnaires about what they subjectively experienced during the firewalk. Their experiences were subsequently compared with those of subjects (n = 246) who experienced hypnosis and a baseline condition. The data suggested that firewalking, as assessed across all subjects, is characterized by high levels of volitional control and rationality, and a very absorbed attentional style wherein the mind is one-pointed, and consciousness is characterized by strong feelings of joy and high levels of internal dialogue. Firewalking was also found to be associated with significantly more joy, one-pointedness of thought, absorption, and internal dialogue than hypnosis or the baseline condition. In addition, a cluster analysis suggested two subgroups of firewalkers based on their subjective experiences of the firewalk. Interestingly, analyzing the attentional experiences among these firewalkers who got slightly burned, versus those who did not, revealed significant differences. A one-pointed and absorbed attentional focus may be the critical variable for the fire immunity observed in firewalking.**

**About 500 people walked across coals, in 3-4 steps. At end of weekend, 71 said they would complete a questionnaire and it was mailed to them. Of those, 27 responded (25 of 26 in an average of 23 days). Hence, 5% of the population who walked responded to the questionnaire, and it was some time later. Three of 24 reported minor blisters. Those who didn't get burned reported less detachment, less of a feeling of being out of their bodies, and more thoughts than the firewalkers who got slightly burned**

**Pekala has defined an altered state of consciousness as associated with the perception of being in an altered state of awareness (the *\_subjective sense\_ of \_altered state\_ --SSAS [30]*), and a change in the patterning or configuration of the subsystems or dimensions of consciousness. A discrete state of consciousness, as defined by Pekala, is associated with a significant pattern change but no perceived alteration in state of consciousness (no SSAS). An identity state of consciousness, on the other hand, is defined as having neither a significantly perceived alteration in state of awareness nor a perceived pattern change among dimensions of consciousness in reference to another state of consciousness. Since the PCI can measure both intensity and pattern effects, it can be used to assess for altered, discrete, and identity states of consciousness.**

**Using a cluster analysis they found that one group of 16 subjects reported the firewalk experience to be characterized by a significant alteration in awareness and experience (body image, time sense, etc.), and significant intensities of internal dialogue, positive and negative affect, and arousal, while a second group of six subjects reported little alteration in consciousness or experience, little losses in rationality or control, and less internal dialogue, positive and negative affect or arousal than the larger group.**

**Whereas hypnosis is usually associated with a loss in control (the classic suggestion effect), firewalking was found to be associated with increased control, a more**

aroused state, and more fear! Firewalking appears to be a more absorbed and one-pointed state than even hypnosis.

The nature of attentional experience is similar across firewalkers (DAQ results).

Both firewalking and hypnosis meet the criteria for altered states of consciousness (different pattern and different subjective experience), but they are not altered states in reference to each other; they are discrete states of consciousness in reference to each other, because there is a significantly different patterning of PCI dimensions between the two conditions, but no significant SSAS. This suggests that the firewalk state is qualitatively different from the hypnotic state (as induced by the induction procedure to the Harvard Scale) and probably represents a different type of state of consciousness than hypnosis. Firewalkers obtained a lower mean hypnoidal state score than hypnosis subjects, so it does not appear that the fire immunity is due to being in a "hypnotized" state.

The fact that there appears to be two groups of successful firewalkers, one of which did not report much alteration in consciousness, calls into question the theorizing concerning the importance of alteration in state of consciousness as being etiologically related to successful firewalking. Since about 25 percent of the firewalkers clustered into what appears to be a nonaltered state of awareness, this suggests a sizable percentage of subjects who did not report any significant alteration in consciousness and experience.

Hence, what may be important is not an alteration in consciousness, but rather an alteration in attention. The cluster analysis revealed a relatively unitary attentional state across all subjects suggesting that attention was deployed in a rather similar manner across all subjects, that is, with very high absorption and one-pointedness. It was also the DAQ dimensions, and not the PCI dimensions, that successfully discriminated a trend between the blistered and nonblistered firewalkers. Hence, high levels of one-pointedness and absorption, that is, how attention is deployed during firewalking may be more critical (than an alteration in consciousness in general) for the fire immunity observed during firewalking.

1992

Ewin, Dabney M. (1992). Hypnotherapy for warts (*verruca vulgaris*): 41 consecutive cases with 33 cures. American Journal of Clinical Hypnosis, 35, 1-10.

Published, controlled studies of the use of hypnosis to cure warts are confined to using direct suggestion in hypnosis (DSIH), with cure rates of 27% to 55%. Prepubertal children respond to DSIH almost without exception, but adults often do not.

Clinically, many adults who fail to respond to DSIH will heal with individual hypnoanalytic techniques that cannot be tested against controls. By using hypnoanalysis on those who failed to respond to DSIH, 33 of 41 (80%) consecutive patients were cured, two were lost to follow-up, and six did not respond to treatment. Self-hypnosis was not used. Several illustrative cases are presented.

"I do not consider self-hypnosis necessary, and I believe it may be contraindicated. Once the change in sensation has been acknowledged by an ideomotor signal, I suggest that the subconscious will take care of healing the warts and that the patient

should ignore them and get interested in other things. Self-hypnosis would require regularly giving attention to the warts, and a high rate of cure is obtained without it. In their controlled study using DSIH with adults, Johnson and Barber (1978) included daily self-hypnosis and got cures in only 3 of 11 (27%) of the hypnotic group. This is the poorest result in the published literature. Their control group of 11 patients was given waking suggestions to 'practice imagining that the specified wart(s) were tingling for a few minutes each day until they were gone' and got no change in 3 months. Hellier (1951) got remission in 27 of 74 (36%) patients just using sham x-ray, (waking suggestion without any self-hypnosis). Spanos et al. (1988) instructed their hypnotic group to 'count their warts every day, and after each counting to close their eyes and spend 3 to 4 minutes imagining the warts on their target hand disappearing.' Only 2 of 8 patients (25%) with a single wart cleared, while 9 of 14 (69%) with multiple warts lost one or more warts at 6- weeks' follow-up. My impression is that conscious daily attention to the lesion is contrary to normal body healing of injuries such as cuts, burns, sprains, in which healing progresses best when ignored while undue attention increases suffering" (pp. 3-4). All Ss were private patients referred for hypnotherapy; most were diagnosed clinically.

"...I found that there were sexual implications in 7 of the 16 miscellaneous warts in patients over 13, so I separated the cases into pre- and postpuberty to evaluate the results" (p. 4).

"An early success was with a medical student (Case 28) with whom I used suggestions of warmth, with the blood vessels dilating and bringing in antibodies, leukocytes, opsonins, etc. Changes were visible in 3 days. This biased me toward using 'warm,' but two of the children (Cases 6 and 9) got no result until I gave them a choice. Using ideomotor signals they chose cold. Only two healed with 'warm,' while five did with 'cold.' All of them had either had the warts cauterized or frozen previously and had a personal feeling about heat and cold. I've learned to give the patient a choice on the first visit" (p. 5).

"Three... were first treated using DSIH without result and later responded to hypnoanalysis. After obtaining an ideomotor signal that there was no more subconscious value to the warts, the suggestion was given that the body's healing processes would take over without any more conscious attention by the patient. No self-hypnosis was prescribed" (pp 7-8).

Gainer, Michael J. (1992). Hypnotherapy for reflex sympathetic dystrophy. American Journal of Clinical Hypnosis, 34, 227-232.

Reflex sympathetic dystrophy (RSD) is an unusual, debilitating, chronic pain syndrome thought to be the result of a continuous excessive discharge of regional sympathetic nerves. Supportive and stress-reduction psychotherapies are commonly recommended as adjunctive treatments. Biofeedback is a more direct symptomatic treatment. Although hypnotherapy is effective in altering sympathetic reflex and pain responses, there are no reports of its use for the treatment of RSD. This article reviews some promising results of hypnotherapy with three RSD sufferers. I discuss

the role of hypnotherapy as a supportive adjunct to medical treatment. I also explore the possible role of hypnotherapy as a complementary treatment. discuss the role of hypnotherapy as a supportive adjunct to medical treatment. I also explore the possible role of hypnotherapy as a complementary treatment.

"Hypothetically, RSD represents a continuous excessive discharge of the regional sympathetic nerves. Such discharge normally occurs in response to an injury. In RSD this reflex response is unremitting despite the cessation or absence of an external stimulus" (p. 227).

The psychosomatic aspects of RSD are highly disputed. Some studies suggest a relationship between RSD and various psychopathological conditions. Also proposed is a predisposing character type, sometimes termed 'Sudeck personality' ... patients who are generally anxious, inactive, and hypertensive. ... Others cite chronic pain as the cause, not the result, of certain 'typical' behavior patterns and emotional responses (Abram, 1990; Ecker, 1984)" (p. 228).

"Reports of four cases described RSD treatment with temperature biofeedback. These studies suggest that the patients learned to warm the affected limb through increasing cutaneous circulation. The temperature change was associated with decreased regional sympathetic activity and decreased pain. Complete remission of symptoms is reported in three of these cases; significant improvement is reported in the fourth" (p. 228).

"Abram (1990) reported that in two independent studies the incidence of RSD was 6.3% and 10.7% of patients admitted to pain clinics" (p. 228).

"I hypothesized that hypnotic interventions could facilitate a decrease in local sympathetic nervous discharge. This would result in vasodilation and warming of the affected limb, decreased spasticity, and decreased pain. The following is a report of the effective treatment of three RSD cases with hypnotherapy" (p. 228).

Case #1. "The eventual resolution of her RSD symptoms was due, in part, to resolution of psychodynamic conflicts. ... She had a grade-four profile on the Hypnotic Induction Profile (Spiegel & Spiegel, 1978). In later sessions she readily demonstrated superior hypnotic capacity, achieving such phenomena as spontaneous amnesia, negative hallucination, and somnambulism" (p. 229).

Case #2. ... "She had a grade-three profile on the Hypnotic Induction Profile (Spiegel & Spiegel, 1978) Because of the success with the first patient, I used visualization techniques initially. ... She responded more readily to kinesthetic and tactile suggestions. ... These interventions produced dramatic improvement in the RSD symptoms" (p. 230).

Case #3. ... "He had a grade-three profile on the Hypnotic Induction Profile (Spiegel & Spiegel, 1978). He was readily able to use visualization techniques. He was able to affect dramatic temperature changes (8-10 degrees F) by visualizing 'warm' vacation scenes and imagining the feeling of the 'warm sun' on the affected limb" (p. 231).

DISCUSSION mentioned, "The patients presented in this report were all highly motivated and demonstrated an above-average to superior hypnotic capacity. Despite the obvious limitations of such a selective sample, the actual treatment results support the initial hypothesis. The treatment results of these three cases

indicate that hypnotherapy can be an adjunctive treatment to alleviate pain. Moreover, these results indicate that hypnotherapy can be a complementary treatment in RSD.

Holroyd, Jean (1992). Hypnosis as a methodology in psychological research. In Contemporary hypnosis research (pp. 201-226). New York: Guilford Press.

This chapter deals with how the changes brought about by hypnosis (in cognition, behavior, motivation, etc.) may be used in research in other areas of psychology. "The distinction between experimental effects attributable to a personality trait (i.e. hypnotizability), hypnosis context (i.e. an induction), and interaction between the two is particularly important in using hypnosis as a research strategy.

The author discusses suggestibility, imagery enhancement, and changes in the mind-body relationship (immunology, pain, cognitive neuropsychology, attention, learning and memory, and awareness) as they might be employed in social psychology or psychophysiology research. She reviews problems inherent in using hypnosis as part of the research methodology, while noting that hypnosis nevertheless offers new information when introduced into traditional content areas. "For example, in cognitive psychology it has re-introduced the importance of studying experiential aspects of cognition, i.e. I think, I remember, or self reference (Kihlstrom, 1987)" (p. 223).

She concludes, "Hypnosis as a research method will continue to benefit from contributions of radically different theoretical views of hypnotic phenomena. Social-cognitive psychologists have contributed significantly toward unifying the fields of hypnosis research and general experimental psychology. At the same time, advances in neurophysiology and psychosomatic medicine employing hypnosis indicate that there is a role for hypnosis as a research strategy, solely because of its altered-state characteristics. If theoretical physics can reconcile both wave and particle theories of light, it is conceivable that psychology can accommodate both behavioral and state theories of hypnosis" (p. 224).

Morse, Donald R.; Martin, John; Moshonov, Joshua (1992). Stress induced sudden cardiac death: Can it be prevented?. Stress Medicine, 8, 35-46.

Previously, psychosomatically induced death relative to stress, hypnosis, mind control, and voodoo was discussed. In this article, emphasis is on one aspect of that - stress induced sudden cardiac death (SCD). A brief review is presented of the sympathetic aspects of the acute stress response and stress induced SCD. Findings from previous studies are presented to highlight sympathetic aspects of the acute stress response. This is followed by a presentation of various strategies to prevent or decrease the possibilities for stress induced SCD. These include long-term measures (e.g. diet control, smoking control, hypertension control, stress management strategies) and immediate measures (e.g. calm, controlled approach, elicitation of the relaxation response, selected use of drugs, and heart rate variability monitoring). Relative to prevention strategies, findings are presented both from previous studies and new investigations.

1991

Acosta-Austan, Frank (1991). Tolerance of chronic dyspnea using a hypnoeducational approach: A case report. American Journal of Clinical Hypnosis, 33, 272-277.

A 48-year-old woman with severe, chronic obstructive pulmonary disease was instructed in the use of peak-flow feedback and hypnotically induced relaxation to reduce the intensity of dyspnea during periods of anxiety. Peak-flow information provided physiologic feedback as well as a safety feature in the event that subjective improvement did not correspond with objective physiologic improvement. I used a progressive relaxation method for inducing hypnosis and gave her suggestions of well-being and muscle relaxation. Peak-flow feedback was useful in enhancing the patient's confidence that hypnotic relaxation was successful in improving respiratory function.

Blankfield, Robert P. (1991). Suggestion, relaxation, and hypnosis as adjuncts in the care of surgery patients: A review of the literature. American Journal of Clinical Hypnosis, 33, 172-186.

He notes that the authors provide little information re complications, and length of stay (LOS) is one of the most sensitive response measures used in these studies. The mean difference in LOS for 5 studies that have randomized assignment is 1.3 days. The N's are 80-100 for 3 of the studies, 39 and 60 for others. For two well controlled studies that did not achieve significance, the N's were 40 and 45. Many studies mixed the diagnosis and types of surgeries, making it difficult to interpret the results

Bodden, Jack L. (1991). Accessing state-bound memories in the treatment of phobias: Two case studies. American Journal of Clinical Hypnosis, 34, 24-28.

Two cases of simple phobia demonstrate the inadequacies of both behavioral and psychodynamic theories. These cases and their treatment outcomes provide support for the state-dependent memory and learning theory. Hypnosis and ideomotor signaling proved to be not only effective treatments but also useful means of illuminating the role and nature of symptom function. Issues of symptom removal and substitution are also discussed in relation to these cases

The authors state that Rossi and Cheek (1988) summarize a number of experimental studies on animal memory that demonstrate that different information substances are involved in different learning situations. For example, ACTH and cortisol are involved in avoidance learning while angiotensin is involved in operant conditioning. In hypnosis, state dependent memory seems to be implicated. "Hilgard (1977) interpreted the state-dependent memory studies by Overton and others as entirely consistent with and supportive of his theory of hypnosis. Milton Erickson (1948) has also strongly suggested that it is the altered levels of arousal and affect that are responsible for the encoding and recall of stress-related problems with hypnosis" (p. 26).

"Affective experiences are apparently stored independently from their intellectual counterparts, or the emotional unit from one set may attach itself to a constellation of cues that make up a totally different cognitive set. Hypnosis may facilitate recall by providing relevant cues during an altered state of consciousness" (p. 27).

"In commenting upon [one of Erickson's cases], Rossi (1986) states that Erickson was effective because he helped the patient access state-bound memories by reviewing the context and sensory-perceptual cues that surrounded their original acquisition" (p. 27).

When traditional behavior therapy fails it may be because the original fear stimulus is state bound or unconscious. What is conscious to the patient are those stimuli that are similar in some important respect to the original phobic stimulus and are acquired by stimulus generalization. Desensitization may reduce the patient's reactivity to the associated or acquired stimuli but cannot desensitize the original stimulus until it can be accessed consciously" (p. 27).

"The two main psychological explanations of phobic behavior are psychodynamic and behavioral. The psychodynamic approach is built upon the early writings of Freud (1956) on the traumatic basis of neurosis. Freud speculated that the intense anxiety (psychic pain) associated with the emotional trauma lead to dissociation, repression, and amnesia. Symptoms represented a dissociated or symbolic vestige of the repressed ('forgotten') trauma.

"Behavioral explanations (e.g., Rimm & Masters, 1974) are built upon classical and operant conditioning models of learning. Classical conditioning explains how a neutral stimulus (e.g., a bridge) can acquire reactivity and elicit a fear response. Avoidant behavior, which preserves the phobia, is acquired and maintained by operant conditioning. Treatment apparently involves gradual extinction of the fear response.

"These two divergent explanations have spawned quite different therapeutic approaches, with the behavioral approach (systematic desensitization) demonstrating greater empirical support for its effectiveness (Kaplan & Sadock, 1986). The problem is made complex theoretically by the fact that desensitization doesn't always work, even when applied in a competent fashion" (p. 25).

"Freud's early work on the traumatic basis of neurosis pointed to but offered an incorrect explanation of phobias whose origins were unconscious or state bound (i.e., not available to recall during the normal conscious state)" (p. 25).

Dennett, Daniel C. (1991). Consciousness explained. Boston: Little, Brown & Co..

Material in this book is relevant to discussions about 'nonvoluntary' behavior and (un)conscious experiencing. It combines information from cognitive neuroscience with the philosophy of mind. The author presents a view that consciousness (the 'mind') is the consequence of the brain's activities which give rise to illusions about their own properties. He presents the Multiple Drafts model of consciousness, which reformulates the concept of a 'stream of consciousness.' This provides a basis for

consideration of concepts central to cognitive neuroscience and phenomena associated with hypnosis, e.g. experiential states and the nature of the self.

The author gives various examples of phenomenology and notes that although these examples are familiar to us, they are totally inaccessible to materialistic science; e.g. the way the sunset looks to someone. He treats people's descriptions of what they experience as a record of speech acts. Thus, observing and interpreting speech acts, inferring from them the speaker's inner states, is like a reader who is interpreting a work of fiction. He gives as examples of how one can scientifically study what does not 'exist' (a) literary theorists who describe fictional entities, (b) anthropologists who study cultural artifacts like gods and witches, and (c) physicists who study a center of gravity.

In Dennett's theory, multitrack processes of interpretation of sensory inputs and elaboration of those inputs amounts to a kind of 'editorial revision' by the brain. For example in the phi phenomenon a red dot is displayed, followed by a green dot in a different location; the first spot seems to begin moving and then change color in the middle of its illusory passage toward the second location. He points out that awareness of the change in color must occur after seeing the green spot, but one consciously experiences a single spot first red, then red-turning-to-green, finally green. In an example that relates directly to the words used for his theory, he cites contemporary publishing practices, in which several different drafts of an article are in circulation even while the author is revising it. Deciding on some specific moment of brain processing as the moment of consciousness is arbitrary, according to his Multiple Drafts model.

"Visual stimuli evoke trains of events in the cortex that gradually yield discriminations of greater and greater specificity. At different times and different places, various 'decisions' or 'judgments' are made; more literally, parts of the brain are caused to go into states that discriminate different features, e.g., first mere onset of stimulus, then location, then shape, later color (in a different pathway), later still (apparent) motion, and eventually object recognition. These localized discriminative states transmit effects to other places, contributing to further discriminations, and so forth. The natural but naive question to ask is: 'Where does it all come together'? The answer is: Nowhere. Some of these distributed contentful states soon die out, leaving no further traces. Others do leave traces, on subsequent verbal reports of experience and memory, on 'semantic readiness' and other varieties of perceptual set, on emotional state, behavioral proclivities, and so forth. Some of these effects--for instance, influences on subsequent verbal reports--are at least symptomatic of consciousness. But there is no one place in the brain through which all these causal trains must pass in order to deposit their content 'in consciousness'" (pp. 134-135).

The author describes the evolution of the brain, along Darwinian lines, and introduces the idea of culture as a repository and

"Visual stimuli evoke trains of events in the cortex that gradually yield discriminations of greater and greater specificity. At different times and different places, various 'decisions' or 'judgments' are made; more literally, parts of the brain are caused to go into states that discriminate different features, e.g., first mere onset of stimulus, then location, then shape, later color (in a different pathway), later still (apparent) motion, and eventually object recognition. These localized discriminative

states transmit effects to other places, contributing to further discriminations, and so forth. The natural but naive question to ask is: 'Where does it all come together'? The answer is: Nowhere. Some of these distributed contentful states soon die out, leaving no further traces. Others do leave traces, on subsequent verbal reports of experience and memory, on 'semantic readiness' and other varieties of perceptual set, on emotional state, behavioral proclivities, and so forth. Some of these effects--for instance, influences on subsequent verbal reports--are at least symptomatic of consciousness. But there is no one place in the brain through which all these causal trains must pass in order to deposit their content 'in consciousness'" (pp. 134-135).

The author describes the evolution of the brain, along Darwinian lines, and introduces the idea of culture as a repository and transmission medium for innovations (including innovations of consciousness) as a medium of evolution. Through learning, we humans evolve an American or a Japanese brain. Once we have evolved the 'entrance and exit pathways' for language, they become 'parasitized' by memes (entities that have evolved to thrive in such a niche).

Richard Dawkins coined the term memes to describe the smallest idea elements that replicate themselves reliably (e.g. wheel, alphabet, wearing clothes, right triangle). "The transformation of a human brain by infestations of memes is a major alteration in the competence of that organ" (p. 209).

Dennett discusses the similarities and dissimilarities of brains and computers. He suggests that human minds are like serial virtual machines implemented on parallel processing hardware. The stream of consciousness results from our rehearsal of brief experiences, to commit them to memory; language then permits us to describe to ourselves the process of thinking which leads to judgement and action.

The author's discussion of how a verbal expression evolves and becomes manifest is related to how so-called intentional action occurs. [This relates to discussions of nonvoluntary actions in hypnosis.] We assume that because our actions make sense, they are the product of serial reasoning. However, there are multiple channels "in which specialist circuits try, in parallel pandemoniums, to do their various things ... (pp. 253- 254). Bernard Baars has suggested "that consciousness is accomplished by a 'distributed society of specialists that is equipped with a working memory, called a global workspace, whose contents can be broadcast to the system as a whole (p. 42)'" (p. 257). Dennett states that there is no line dividing the events that are definitely in consciousness from those that are outside consciousness. He urges scientists to forgo the concept of the 'inner observer' implied by Cartesian materialism.

Examples of perception that is unaccompanied by consciousness include blindsight (in which the subject does better than chance on visual tests but denies consciousness, and the denials are given credence by neurological evidence of brain damage) and hysterical blindness, which is given less credence because subjects often use the visually provided information in ways blindsight Ss do not. Other behaviors not controlled by conscious thought include blinking when things approach the eye, walking without falling over, regulating our body temperature, adjusting our metabolism, etc. "If I am trying to see a bird that I hear, and stare at the spot but do not distinguish the bird from its background, can I say that it is present in the background of my (visual) consciousness or not?" (p. 336).

The author maintains that if an event doesn't linger and the person is unable to identify and reidentify the effect, it cannot be reported. But such reportability can be improved, as with training the palate of wine tasters. Often, however, we continue disregarding stimuli that impinge on us. There are minor oversights, such as our 'blind spots' or proof reading errors, and major oversights such as a brain-damaged patient's hemi-neglect. In the Multiple Drafts theory, the Observer is replaced by 'coalitions of specialists' that are distributed around in the brain, distributed in both time and space.

Though discrimination or discernment happens, there is no one Discerner doing the work. However, Dennett takes the middle ground on the question of whether a self exists: it is simply a creation like the nest of the Bower bird, or the organized colony of termite ants. "So wonderful is the organization of a termite colony that it seemed to some observers that each termite colony had to have a soul (Marais, 1937). We now understand that its organization is simply the result of a million semi-independent little agents, each itself an automaton, doing its thing. So wonderful is the organization of a human self that to many observers it has seemed that each human being had a soul, too: a benevolent Dictator ruling from Headquarters" (p. 416). The sense of self is a creation, like a physicist's center of gravity.

Thus, multiple personality disorder is viewed as a self that has gaps; and our sense of self might include different aspects from one year to the other. Hence, "selves are not independently existing soul-pearls, but artifacts of the social processes that create us, and, like other such artifacts, subject to sudden shifts in status. The only 'momentum' that accrues to the trajectory of a self, or a club, is the stability imparted to it by the web of beliefs that constitute it, and when those beliefs lapse, it lapses, either permanently or temporarily" (p. 423).

Finally, the author has an extensive discussion of the concepts of 'qualia' and of 'epiphenomena' and seems to have little use for either term in trying to understand Mind.

of my (visual) consciousness or not?" (p. 336).

Grossarth-Maticek, R.; Eysenck, H. J. (1991). Creative novation behaviour therapy as a prophylactic treatment for cancer and coronary heart disease: Part II - Effects of treatment. Behaviour Research and Therapy, 29, 17-31.

Reports on what they call creative novation behavior therapy or "autonomy training" to prevent cancer and coronary heart disease in prone individuals. This individually tailored cognitive-behavioral program includes the use of hypnosis and of imagery. When administered individually (20-30 hours) in a group (6-15 sessions of up to several hours) or via bibliotherapy with 4-6 hours of individual therapy, the outcome was better than that of control subjects. After 13 years, 45 of 50 cancer-prone subjects in individual treatment were still alive (and none of the 5 deaths were from cancer), while among 50 control subjects, 31 died, 16 from cancer. This study along with Spiegel et al. (1989) article in Lancet have important implications for health care.

Hopkins, Mildred B.; Jordan, Jeanette M.; Lundy, Richard M. (1991). The effects of hypnosis and of imagery on bleeding time: A brief communication. International Journal of Clinical and Experimental Hypnosis, 39, 134-139.

2 studies are reported, one using hypnotized Ss selected on hypnotizability and one using Ss selected on imagery vividness, whose purpose is to examine whether non-patient Ss can control their bleeding in a laboratory setting. All Ss were cut on both arms with the "Surgicutt" device, an instrument that automatically makes a cut that will bleed from 2 to 10 minutes. Results suggest that Ss, who are instructed to reduce the bleeding time in one arm and to let the other arm bleed normally, are not able to control bleeding time.

Morse, Donald R.; Martin, John; Moshonov, Joshua (1991). Psychosomatically induced death: Relative to stress, hypnosis, mind control, and voodoo: Review and possible mechanisms. Stress Medicine, 7, 213-232.

A common denominator in psychosomatically induced death is stress. Death can occur slowly, as from the preponderance of chronic stressor, or it can come on suddenly, as from an acute stressor. Sudden death is more likely in an individual with preexistent serious medical conditions, which were outlined. Seven types of individuals more prone to sudden death were outlined. Most cases of sudden death are related to the presence of a severely stressful situation in which there appears to be no means of control or escape. With mind control, hypnosis, and voodoo curses, circumstances can be manipulated to achieve severe stress and uncontrollability.

Palan, Bhupendra M.; Lakhani, Jitendra D. (1991). Converting a 'threat' into a 'challenge': A case of stress-related hemoptysis managed with hypnosis. American Journal of Clinical Hypnosis, 33 (4), 241-247.

A 24-year-old patient was treated using hypnosis for chronic repeated episodes of hemoptysis. The symptom episodes were related to academic examinations (perceived as a threat by the patient). Clinical examinations and laboratory investigations failed to indicate an organic cause for hemoptysis. He did not respond to empirical treatment trials. These negative findings suggested the psychosomatic nature of the illness. We used hypnotherapeutic ego-strengthening and guided-imagery approaches. This reduced his acute anxiety but failed to check hemoptysis. Use of explorative hypnotic dreaming revealed an emotional trauma as the possible cause of origin of the symptoms. We restructured the trauma experience during hypnotic regression. We advised him to skip the upcoming examination and conducted a total of six therapeutic sessions. The patient continued using self-hypnosis throughout the follow-up period of 3 years during which he remained symptom free and achieved remarkable academic progress. He now perceives an examination as a challenge.

1990

Barber, Theodore Xenophon (1990, August). Some things I've learned about hypnosis after 37 years. [Audiotape] Presented at the annual meeting of the American Psychological Association, Boston.

"We are a unity of cells. Every cell is a citizen with it's own jobs, communicating all the time; cells send messages; the way we communicate with them is by suggestions. Each \_cell\_ is a mind-body.... When I do it now [hypnotic inductions], I say, 'We're going to go into hypnosis, we're \_both\_ going to go into hypnosis. I'm going to close my eyes (etc.)' - modeling hypnosis for them."

Hajek, P.; Jakoubek, B.; Radil, T. (1990). Gradual increase in cutaneous threshold induced by repeated hypnosis of healthy individuals and patients with atopic eczema. Perceptual and Motor Skills, 70, 549-550.

Gradual increase in cutaneous pain threshold was found in healthy subjects and patients with atopic eczema during repeated hypnotic sessions with specific

suggestions. This increase was less in the former than in the latter group. Repeated threshold measurements did not influence the threshold. The analgesic effect outlasted the hypnotic sessions by several months. It could be, however, suddenly reduced by appropriate hypnotic suggestion.

Cutaneous pain threshold was measured in "time in seconds from onset of heat source of defined size, distance from skin, and temperature, to subjective threshold percept of pain" (p. 549). Used two symmetrical locations on both forearms, at healthy areas of the skin. Ten hypnotic sessions were induced in each S three times weekly, each lasting one hour.

Suggestions were the following type: "The "conduction of switch to the brain is interrupted." Your "immunologic system will digest the damaged skin cells like a shark."

Subjects were 14 healthy subjects and 13 patients with atopic eczema treated for years with the usual medications, unsuccessfully or with complications.

There was gradual increase in cutaneous pain threshold across the 10 sessions, especially for the patient group. Control experiments with repeated threshold measurements in repeated sessions without hypnosis showed no changes.

"Time of increases in cutaneous pain threshold was associated with improvement of atopic eczema. Both effects correlated significantly ( $r = 0.8$ ) with hypnotizability as measured by the Stanford scale" (pp. 549-550).

"In 9 patients without further hypnotic sessions a slow spontaneous decay of the cutaneous pain threshold was observed during a 17-mo. period. Special experiments performed with six repeatedly hypnotized healthy subjects showing increased thresholds did prove, however, that the cumulative analgesic effect could be reduced to control values immediately by using the hypnotic suggestion that the 'skin sensitivity returns to normal values.'

"These results suggest a close association between hypnosis and activation and/or deactivation of endogenous analgesic systems (irrespectively whether they are of opioid or nonopioid nature)" (p.550)

Holroyd, Jean (1990). How hypnosis may potentiate psychotherapy. In Fass, Margot L.; Brown, Daniel (Ed.), Creative mastery in hypnosis and hypnoanalysis (pp. 125-130). Hillsdale, NJ: Lawrence Erlbaum Associates.

This chapter is a reprint of an article published in the American Journal of Clinical Hypnosis in 1987. It provides a conceptual framework for understanding psychotherapy processes in the context of a hypnotic state. Based on empirical and theoretical considerations, the author identified nine changes occurring with hypnosis: changes in attention and awareness, imagery, dissociation, reality orientation, suggestibility, mind-body interactions, initiative or volition, availability of affect, and relationship. "This chapter proposes that hypnotherapy exploits hypnotic phenomena-- takes advantage of them--in the service of standard therapy endeavors" (p. 125).

Lazarus, A. A.; Mayne, T. J. (1990). Relaxation: Some limitations, side effects, and proposed solutions. Psychotherapy, 27, 261-266.

Deep-muscle relaxation has been widely regarded as anxiety inhibiting, and the relaxation response an antidote to tension and stress. However, some relaxation techniques have been shown to have negative effects. These include relaxation-induced anxiety and panic, paradoxical increases in tension, and parasympathetic rebound. Specific indications and contraindications are discussed.

The following unpleasant side effects have been observed: "unpleasant sensations of heaviness, warmth, perspiration, tingling, numbness, dizziness, floating, coolness; paradoxical increases in tension; rapid heart rate; feelings of physical and psychological vulnerability; depression; fear of losing control; depersonalization; dissociation; myoclonic jerks; spasms; headache; akathisia; negative auditory, gustatory, and olfactory reactions; intrusive images and thoughts; anxiety; irritability; guilt; regressive urges; hallucinations; and panic" (p. 261).

People have been observed to have "negative or untoward reactions to meditation ([Lazarus, 1976]; French, Schmid & Ingalls, 1975; Kennedy, 1976), relaxation (Borkovec & Grayson, 1980; Carrington, 1977; Edinger & Jacobsen, 1982), and biofeedback (Miller & Dworkin, 1977). In his doctoral dissertation Heide (1981) found that more than half of his subjects under focused relaxation reported increased tension due to the relaxation session. Recently, the concept of RIA--relaxation-induced anxiety--has appeared in the literature (Heide & Borkovec, 1983; 1984). Clients suffering from generalized anxiety appear to be especially prone to RIA" (pp. 261-262).

Others have suggested that relaxation may be counterindicated for asthmatics, because the small airways dilate with sympathetic nervous system arousal. The specific instructions of autogenic training may be counterindicated for patients with gastrointestinal disease because focusing on a sense of warmth in the abdomen tends to produce more peristalsis, increased blood flow in the gastric mucosa, and acidity in the gastric juice (Luthe & Schultz, 1979). Even the standard relaxation therapy for tension headache (as well as other pain problems) is being replaced with cognitive behavioral therapy, which may have relaxation as only one component. "The point again is that relaxation is not a panacea, and that an informed selection and administration of treatments is mandated, even in disorders where relaxation has traditionally been held second only to medication" (p. 264).

Interviews suggest people with relaxation induced anxiety (RIA) fear losing control. "Some are afraid of heightened arousal; others refer to helplessness, depression, some unidentified internal or external danger, a fear of going crazy, a negative association with anesthetics, a fear of falling from heights, plus any number of catastrophic expectations (Chambless & Goldstein, 1980)" (p. 264). Lazarus recommends that if someone displays RIA, the therapist may try alternative techniques, which might include for example tensing-relaxing muscles, passive receptivity, positive or pleasant imagery, focus on breathing, subvocal monotonous chant or mantra, or the Vipassana meditation practice of achieving awareness of spontaneous sensations and thoughts. The relationship with the therapist,

differences in room illumination, amount of time per session, and sitting or reclining may be important.

"If a therapist deduces that a client is likely to derive benefit from relaxation training, three obvious questions arise: (1) Which of the many types of relaxation training programs is this particular client likely to respond to? (2) How frequently, and for what length of time, should the client practice the selected relaxation sequence? (3) Will treatment adherence be augmented or attenuated by the supplementary use of cassettes for home use?" (P. 262).

The authors describe their Structural Profile Inventory (SPI; Lazarus, 1989), a 35-item questionnaire, which may be used to predict the preferred sequences and forms of relaxation to employ with individual clients. "A predominantly imagery/sensory reactor, for example, may do well with visualization and autogenic training, whereas a highly active/cognitive client might be better advised first to engage in strenuous exercise followed by calming self-statements (Zilbergeld & Lazarus, 1988)" (p. 265). They suggest that for those patients who are perfectionistic and simply can't "just let go," they might simply fill a bathtub with warm water and sit in it for 10-20 minutes and rest with a magazine (rather than "relax") once or twice a day.

Mason, Albert A. (1990, January). A psychoanalyst looks at a hypnotist; or, where the elephant skinned boy took me. [Paper] Presented at the Psychoanalytic Center of California Scientific Meeting.

"The results of working with hypnotism experimentally in the production of anaesthesia for surgery, dentistry and obstetrics; in controlled series of treatments of asthmatics, skin disorders, and allergic manifestations; as well as its clinical use, have convinced me that it is a delusional state akin to mania which depends on the omnipotent denial of mental pain. The mania is stimulated by the hypnotized subject having phantasies of an omnipotent object that it fuses with and shares in the omnipotence. The hypnotist has similar unconscious phantasies about himself. Both subject and hypnotist projectively identify with each others' phantasies, and together produce phenomena like anaesthesia which can be likened to delusional states. In fact, true hallucinations can also be deliberately produced.

"I believe that similar psychotic mechanisms can also occur in life between parents and children and in other relationships, and produce delusional states. These form a continuum from intractable narcissism on the one side, through Christian Science and the denial of evolution in the center, to frank folie a deux and transexualism on the other side. The therapeutic course of these states seems quite dissimilar from that of psychosis arising without the encouragement of external objects."

Prior, A.; Colgan, S. M.; Whorwell, P. J. (1990). Changes in rectal sensitivity after hypnotherapy in patients with irritable bowel syndrome. Gut, 31, 896-898.

Fifteen patients with irritable bowel syndrome were studied to assess the effect of hypnotherapy on anorectal physiology. In comparison with a control group who received no hypnotherapy, significant changes in rectal sensitivity were found in patients with diarrhoea-predominant irritable bowel syndrome both after a course

of hypnotherapy and during a session of hypnosis ( $p < .05$ ). Although patient numbers were small, a trend towards normalization of rectal sensitivity was also observed in patients with constipation- predominant syndrome. No changes in rectal compliance or distension-induced motor activity occurred in either subgroup nor were any changes in somatic pain thresholds observed. The results suggest that symptomatic improvement in irritable bowel syndrome after hypnotherapy may in part be due to changes in visceral sensitivity  
Sensitivity.

This research involved 15 patients diagnosed with irritable bowel syndrome (IBS), which was defined as abdominal pain with abdominal distension and 'an altered bowel habit'--10 had diarrhea mostly and 5 had constipation mostly. Patients with this disease usually have an exaggerated colon sensitivity to many different stimuli, as well as lower threshold to a balloon inflated in the bowel for diagnostic purposes. The patients were treated with ten sessions of hypnosis, 30 minutes each, over a three month period. Dependent variables included self ratings of abdominal pain, abdominal distention, and 'bowel habit disturbance.' Each of the three variables received a score of 0-10; the total score therefore could range from 0-30.

Other ratings were obtained using the inflation of a rectal balloon as stimulus. "After a basal period of at least 15 minutes the rectal balloon was serially inflated with air at intervals of 1 min in 20 ml increments up to 100 ml and then in 50 ml increments up to the sensation of discomfort. The study was repeated after a rest period of 15 minutes. After hypnotherapy the S was restudied first in the waking state and then, after 15 min, following induction of hypnosis" During this procedure they measured balloon volume, rectal compliance (a function of volume and pressure), and presence or absence of repetitive rectal contractions.

In order to learn whether the analgesia being experienced in the rectal or bowel area transferred to other areas, patients experienced cold water immersion induced pain on one hand, for a measure of time until discomfort was felt (pain threshold, essentially).

The control group of 15 patients diagnosed with IBS received the same measures of balloon volume, rectal compliance, and presence or absence of repetitive rectal contractions.

The total symptom score (which might have ranged 0-30) dropped from 23.5 to 9.6, and 13 of the 15 patients rated their symptoms as much improved. The two Ss who did not experience improvement also did not return for the assessment using the balloon. Therefore, the physiological assessment included only 13 Subjects, the ones who rated themselves as 'improved.'

"In patients with diarrhoea-predominant irritable bowel syndrome a decreased rectal sensitivity occurred after hypnotherapy which was significant for the sensations of gas and urgency. This was most pronounced in patients who could initially tolerate only small rectal balloon volumes (Fig 1). During hypnosis the results for rectal sensitivity in the diarrhoea-predominant group were similar to those noted after the course of hypnotherapy but were of a greater magnitude, reaching significance for all sensations (Fig 2).

**"In the constipation-predominant Subjects there was a tendency for rectal sensitivity to move towards normal values both after the course of hypnotherapy and during hypnosis. Patient numbers in this subgroup were small, however, and the changes were not significant (Figs 1 and 2). Rectal compliance and distension induced motor activity were unaffected by hypnotherapy in both the diarrhoea and constipation- predominant patients" (p. 897).**

**It was noted that of patients who had manifested depression and/or anxiety (8 of 13), most showed psychological improvement--3 of them to a great degree--but there was no correlation between psychological improvement and the degree that visceral sensitivity was diminished. Also, the ten sessions of hypnotherapy did not affect length of time subjects could tolerate hand immersion in cold water.**

**"In the control group of 15 patients with the irritable bowel syndrome who did not receive hypnotherapy no changes in rectal sensory or motor parameters occurred when manometry was repeated on the same day or on a second study day nine to 12 weeks later (Table II)" (p. 897).**

**In their Discussion, the authors remark that "hypnotherapy seemed to produce a trend towards normalization of visceral sensitivity (Figs 1 and 2). This was most pronounced in the patients with diarrhoea-predominant irritable bowel syndrome who initially had particularly low sensation thresholds" (p. 898).**

**They continue, "The pathophysiological abnormalities which lead to the symptoms of the irritable bowel syndrome remain unclear. The increased visceral sensitivity found in the large [7-9] and small intestine [18, 19] in some patients with the irritable bowel syndrome may contribute to their perception of pain. In addition, an increase in rectal sensitivity might also contribute to the symptoms of urgency and frequency of defecation seen in many patients with diarrhoea-predominant irritable bowel syndrome. ... Hypnotherapy also induces an improvement in well being by increasing coping capacities, and may therefore decrease perceived stress" (p. 898).**

**"The present study suggests therefore that hypnotherapy might operate by a variety of mechanisms in patients with the irritable bowel syndrome. In those with visceral hypersensitivity it seems to alter the perception of rectal sensation, although the mechanism by which this is achieved is unknown. Modification at a cortical level or more locally along afferent pathways are possibilities. This does not, however, explain the symptomatic improvement in all subjects and hypnotherapy is probably also acting in a non-specific psychotherapeutic sense" (p. 898).**

Alvarado, C. S. (1989). Dissociation and state-specific psychophysiology during the nineteenth century. Dissociation, 2, 160-168.

Reviews examples of state-specific psychophysiology in nineteenth century reports of dissociative disorders. These cases occurred in the context of rapid developments both in neurology and in the understanding of phenomena suggesting the possible influence of the mind, emotions, or psychological states on general health and specific bodily functions (e.g., the study of hypnosis and hysteria). It is argued that interest in such cases was part of a general concern with mind/body interactions. The explanations offered to account for these cases reflected different orientations to the mind/body problem prevalent during this era.

Barabasz, Arreed F.; Barabasz, Marianne (1989). Effects of restricted environmental stimulation: Enhancement of hypnotizability for experimental and chronic pain control. International Journal of Clinical and Experimental Hypnosis, 37, 217-231.

Enhancement of hypnotizability and pain tolerance has been demonstrated using restricted environmental stimulation therapy (REST) with university students as Ss (A. F. Barabasz, 1982). The purpose of the present study was to determine whether or not similar results could be obtained with chronic pain patients. Ss consisted of outpatients in treatment for conditions in which pain is prominent who also demonstrated low hypnotizability after repeated hypnosis plateau sessions. 2 groups of Ss were exposed to REST. Situational demand characteristics (Orne, 1962) favored an increase in hypnotizability for REST Group 1 (high demand). REST Group 2 (low demand) was exposed to situational demand characteristics designed to disguise the experimental hypothesis. 2 groups of control Ss were exposed to the same alternative demand characteristic manipulations as the experimental groups, but environmental stimulation was maintained. The Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) of Weitzenhoffer and E. R. Hilgard (1962), including a posthypnotic suggestion for an anesthetic reaction, and an ischemic pain test were administered prior to treatment and again immediately following treatment. After 6 hours of REST, significant increases in SHSS:C scores were found for high-demand and low-demand experimental Ss, as well as for high-demand control Ss. No such increase was found for low-demand controls. Significant decreases in pain scores were found for both high- and low-demand experimental groups. No significant pain score decreases were found for either

control group, suggesting a relatively weak effect of demand characteristics. An independent postexperimental inquiry suggested all Ss believed they received active treatments. The inquiry, conducted 10-15 days after the experiment, also revealed a majority of experimental Ss were using hypnosis on a daily basis to reduce pain with a substantial decrease in pain medication. Only 2 control Ss (highest in hypnotizability) reported similar success. Anecdotal reports of pain reduction experiences using hypnosis after REST intervention were supportive of E. R. Hilgard's (1977) neodissociation theory.

Enhancement of hypnotizability and pain tolerance has been demonstrated using restricted environmental stimulation therapy (REST) with university students as Ss (A. F. Barabasz, 1982). The purpose of the present study was to determine whether or not similar results could be obtained with chronic pain patients. The Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) of Weitzenhoffer and E. R. Hilgard (1962), including a posthypnotic suggestion for an anesthetic reaction, and an ischemic pain test were administered prior to treatment and again immediately following treatment. After 6 hours of REST, significant increases in SHSS:C scores were found for high-demand and low-demand experimental Ss, as well as for high-demand control Ss. No such increase was found for low-demand controls. Significant decreases in pain scores were found for both high- and low-demand experimental groups. No significant pain score decreases were found for either control group, suggesting a relatively weak effect of demand characteristics. An independent postexperimental inquiry suggested all Ss believed they received active treatments. The inquiry, conducted 10-15 days after the experiment, also revealed a majority of experimental Ss were using hypnosis on a daily basis to reduce pain with a substantial decrease in pain medication. Only 2 control Ss (highest in hypnotizability) reported similar success. Anecdotal reports of pain reduction experiences using hypnosis after REST intervention were supportive of E. R. Hilgard's (1977) neodissociation theory.

The authors note that because they used the posthypnotic suggestion of anesthesia for all Subjects, "it is not possible to determine whether the lowered pain reports of REST Ss were due to the posthypnotic suggestion because of enhanced hypnotizability or whether the lowered pain sensitivity was a nonsuggested collateral consequence of REST" (p. 226).

The data support the conclusion that REST enhances hypnotizability and concomitantly decreases ischemic pain reports after a posthypnotic suggestion. This effect, of course, may or may not be mediated by a response to hypnotic suggestion. "It is important to recognize the quality of the anecdotal pain control reports as

remarkably consistent with E. R. Hilgard's (1977) neodissociation theory of hypnosis. Successful pain controllers did not anesthetize their clinical pains, as asked to do for the ischemic pain, but rather dissociated their pain to other parts of their bodies or outside their bodies" (p. 227).

Griffiths, M. D.; Gillett, C. A.; Davies, P. (1989). Hypnotic suppression of conditioned electrodermal responses. Perceptual and Motor Skills, 69, 186.

With 5 subjects who had previously been aversively conditioned to a stimulus, during hypnosis previously acquired electrodermal responses were found to be significantly lower than in 12 control Ss. Thus previously conditioned electrodermal responses were suppressed. This contradicts findings of Edmonston (1968) who found that neutral hypnosis does not influence conditioned electrodermal responses and the validity of Pavlov's (1927) conditioning (inhibition) theory of hypnosis.

Hall, H.; Minnes, L. (1989). Psychological modulation of auditory responses. International Journal of Psychosomatics, 36 (1-4), 59-63.

Psychological modulation of auditory response, the effects of imagery and suggestion on auditory thresholds were examined in naive subjects. After a hypnosis-like induction, the subjects, who were not aware of the purpose of the study, were asked to generate and maintain a specific set of images before, during, and after which their auditory thresholds were tested. Following the imagery, which represented cooling and vasoconstriction in the cochlea, audiograms revealed a temporary auditory threshold shift (TTS) in the experimental group only. This TTS pattern was similar to that produced by exposure to loud noise. Information carried in the image is suggested as the basis for the observed auditory changes. Although a hypnosis-like induction was employed, the subjects' level of hypnotizability did not appear to be related to the findings.

Hall, Howard R. (1989). Research in the area of voluntary immunomodulation: Complexities, consistencies, and future research considerations. International Journal of Neuroscience, 47, 81-89.

It is speculated that the successful voluntary alteration of one's immune functioning is a complex phenomenon associated with a number of possible factors. Evidence suggests the importance of prior experience in self-regulation and the role of practice, the ability of subjects to become relaxed and reduce sympathetic arousal, the importance of the nature and content of images, the complex role of hypnosis and hypnotizability, the importance of individual differences, and the choice of immune measures. Conclusions are drawn about the need for more experimental attention to these variables and future research with both experienced and inexperienced subjects.

Harvey, R. F.; Hinton, R. A.; Gunary, R. M.; Barry, R. E. (1989). Individual and group hypnotherapy in treatment of refractory irritable bowel syndrome. Lancet, 1 (8635), 424-425.

Thirty-three patients with refractory irritable bowel syndrome were treated with four 40-minute sessions of hypnotherapy over 7 weeks. Twenty improved, 11 of whom lost almost all their symptoms. Short-term improvement was maintained for 3 months without further formal treatment. Hypnotherapy in groups of up to eight patients was as effective as individual therapy.

## DISCUSSION

The mechanisms by which hypnotherapy improves symptoms of IBS remain unclear. A placebo effect alone is unlikely, because few patients who improved on hypnotherapy suffered a relapse after formal treatment ended at 7 weeks; many patients continued to improve after the end of formal treatment. There was no disproportionate improvement in the feeling of wellbeing of patients who improved, and most of the patients who became nearly symptom-free had no initial tension or anxiety, as judged by GHQ scores. This suggests that the treatment is not just producing a psychological effect.

The effects... were less striking than those reported by Whorwell and colleagues. Nevertheless, the results were encouraging because all 33 had been refractory to conventional medical treatment."

Holroyd, Jean; Maguen, Ezra (1989). And so to sleep: Hypnotherapy for lagophthalmos. American Journal of Clinical Hypnosis.

We used hypnosis to facilitate eye closure during sleep for a 44-year-old woman whose nocturnal lagophthalmos prevented use of a contact lens following cataract surgery and could have resulted in severe corneal damage. On three separate occasions the symptoms remitted following a very brief course of treatment. We discuss the results in terms of alternate theories of hypnotic performance.

The Discussion section notes, "There was an excellent correlation between the onset of hypnotherapy and the cessation of the recurrent corneal erosion secondary to nocturnal lagophthalmos. Healing of corneal erosion, disappearance of the superficial punctate keratopathy, and alleviation of ocular foreign body sensation occurred promptly following hypnotherapy (with two separate therapists)" (pp. 267-268). The authors present the view that "heightened suggestibility, more vivid imagery, and more specific influence of thoughts upon organ systems probably came into play (Brown & Fromm, 1986; Holroyd, 1987). Social influence explanations (role taking, expectancy, compliance) seem less relevant as explanations. This highly motivated patient had not been able to keep her eyes closed during sleep despite her conscious efforts, her "good-patient" role, her positive expectations about the benefits of standard treatments, and respectful incorporation of the assistance provided by her ophthalmologist" (p. 268).

Jirout, J. (1989). Reaction of the cerebral vertebrae in imagined changes in the shape of the cervical spine. Ceskoslovenska Neurologie a Neurochirurgie, 52, 75-77.

Postural reaction of the cervical vertebrae on imagined, but actually not performed, changes in the shape of the cervical spine in the sagittal plane are described. The percentage of reacting vertebrae is relatively high. The findings seem to indicate that, (1) the described phenomena belong to the constant features of the spinal dynamics, (2) that there probably exist residual traces of preceding activities, and (3) that these changes are due to the activation of the polymetameric system of the intrasegmental muscles. Abstracted in *American Journal of Clinical Hypnosis*, 1990, v. 32, p. 213.

Klein, Kenneth B.; Spiegel, David (1989). Modulation of gastric acid secretion by hypnosis. *Gastroenterology*, 96, 1383-1387.

"The ability of hypnosis to both stimulate and inhibit gastric acid secretion in highly hypnotizable healthy volunteers was examined in two studies. In the first, after basal acid secretion was measured, subjects were hypnotized and instructed to imagine all aspects of eating a series of delicious meals. Acid output rose from a basal mean of 3.60 to 6.80 ... with hypnosis, an increase of 89% ( $= .0007$ ). In a second study, subjects underwent two sessions of gastric analysis in random order, once with no hypnosis and once under a hypnotic instruction to experience deep relaxation and remove their thoughts from hunger. When compared to the no-hypnosis session, with hypnosis there was a 39% reduction in basal acid output ... and an 11% reduction in pentagastrin-stimulated peak acid output ...  $p < .05$ . We have shown that different cognitive states induced by hypnosis can promote or inhibit gastric acid production, processes clearly controlled by the central nervous system. Hypnosis offers promise as a safe and simple method for studying the mechanisms of such central control."

Meyer, H. K.; Diehl, B. J.; Ulrich, P. T.; Meinig, G. (1989). Changes in regional cortical blood flow in hypnosis. *Zeitschrift für Psychosomatische Medizin und Psychoanalyse*, 35, 48-58.

Regional cerebral blood flow (rCBF) was measured by means of the <sup>133</sup>Xenon inhalation method in 12 healthy male volunteers who had several months of experience in doing self-hypnosis (autogenic training). During hypnotically suggested right arm levitation, as compared to resting conditions, they found an increase in cortical blood flow and an activation of temporal areas; the latter finding was considered to reflect acoustical attention. In addition, a so-far-unexplained deactivation of inferior temporal areas was observed during successful self hypnosis and hypnosis. While there was a global absolute increase of cortical blood flow bilaterally, they could not observe a relative increase of the right as compared to the

left hemisphere during hypnosis. Several subjects successfully performed the levitation of the right arm, despite a relative left hemispheric activation, provided the absolute right hemispheric activation remained dominant.

Murphy, A. I.; Lehrer, P. M.; Karlin, R.; Swartzman, L.; Hochron, S.; McCann, B. (1989). Hypnotic susceptibility and its relationship to outcome in the behavioral treatment of asthma: Some preliminary data. Psychological Reports, 65, 691-698.

Twelve subjects from an experiment on relaxation therapy for asthma were given the Harvard. Hypnotizability was positively correlated, at a borderline significance, with improvement in the methacholine challenge test, a measure of asthma severity. Performance on the amnesia item of the Harvard was correlated with improvement in self-reported symptoms of asthma.

Reid, S. (1989). Recalcitrant warts: Case report. British Journal of Experimental and Clinical Hypnosis, 6, 187-189.

Recalcitrant warts which persisted for 5 years despite treatment cleared in 51 days with hypnotherapy. A cause/effect relationship between hypnotherapy and resolution was shown by at first excluding and then including the left hand from the suggestions given.

Rossi, Ernest L. (1989). Mind-body healing, not suggestion, is the essence of hypnosis: Invited discussion of Cohen's 'Clinical uses of measures of hypnotizability'. American Journal of Clinical Hypnosis, 32 (1), 14-15.

Initially, the 'classical' hypnotic phenomena were observed as part of normal or abnormal behavior, and then later it was noted that these phenomena could often be elicited with 'suggestion.' Therefore suggestion is not a necessary cause for the classical hypnotic phenomena. The mind-body connection has in recent years been under-emphasized by those who developed scales of hypnotizability, whereas James Braid (who originated the word 'hypnosis') wrote about 'psychophysiological' phenomena, and Wetterstrand (1902) distinguished between suggestibility and mind-body interaction (p. 14).

wrote about 'psychophysiological' phenomena, and Wetterstrand (1902) distinguished between suggestibility and mind-body interaction (p. 14).

"Wetterstrand (1902), who was one of Bernheim's foremost students, made a careful distinction between suggestibility and mind-body communication (what he termed the 'ideo-plastic faculty') that has been ignored by the makers of hypnotic susceptibility scales:

'Suggestion, or rather suggestibility, is composed of two elements: an ability to receive an impulse from without and the ideo-plastic faculty. As these are absolutely independent of each other, we must distinguish between them. There are patients who are very impressionable and who accept a suggested idea with absolute confidence; the influence, however, of the idea upon their physiological functions is feeble. They do not realize the suggestions and their morbid symptoms yield with

great difficulty, as their ideoplastic conception is small. Others, on the contrary, accept suggestions slowly, are incredulous, and even resist them. Nevertheless, we find that the physiological and pathological processes are easily modified by the psychic influence, sometimes by auto-suggestions''' (Wetterstrand, 1902, p. 14). The author suggests that clinicians need a way of measuring (and facilitating) this type of mind-body communication and healing, which is an interpersonal process, just as suggestibility is an interpersonal process.

1988

Anderson, Edgar L.; Frischholz, Edward J.; Trentalange, Mark J. (1988). Hypnotic and nonhypnotic control of ventilation. American Journal of Clinical Hypnosis, 31, 118-128.

The present study examined the effects of: 1) breathing air versus breathing 5% CO<sub>2</sub>; 2) waking versus self-hypnotic conditions; and 3) neutral versus reduced respiratory rate instructions on four measures of ventilatory functioning (respiratory rate, tidal volume, expired minute ventilation, and end-tidal Pco<sub>2</sub>). Twelve high-hypnotizable normal volunteer subjects were studied in a repeated-measures, multivariate analysis of variance design; Significant main effects were observed for each experimental condition, whereas none of the two or three way interactions proved noteworthy. Breathing 5% CO<sub>2</sub> produced increased ventilatory functions (e.g., increased respiratory rate, tidal volume, expired minute ventilation, and end-tidal Pco<sub>2</sub>). Being in a state of self-hypnosis is associated with reduced respiratory rate, with a significant increase in expired minute ventilation and end-tidal Pco<sub>2</sub>, but with no significant increase in tidal volume. Finally, reduced respiratory rate instructions were effective in significantly reducing respiratory rate and expired minute ventilation when breathing 5% CO<sub>2</sub> as evidenced by increases in end-tidal Pco<sub>2</sub> levels that were used to monitor ventilation outcomes.

Azuma, Nagato; Stevenson, Ian (1988). 'Psychic surgery' in the Philippines as a form of group hypnosis. American Journal of Clinical Hypnosis, 31, 61-67.

Psychic surgeons and their patients were observed in the Philippines during a variety of procedures of 'minor surgery.' In six cases, subcutaneous tissues (cysts and benign tumors) were removed. Histological examination confirmed the gross diagnoses and left no doubt that the skin had been penetrated. Although the psychic surgeons used no analgesics or anesthetics, the patients appeared to experience little or no pain and only slight bleeding. The authors believe that a supportive group 'atmosphere' enables the patients to enter a quasi-hypnotic state that reduces pain and facilitates healing.

Evans, C.; Richardson, P. H. (1988). Improved recovery and reduced postoperative stay after therapeutic suggestions during general anesthesia. Lancet, 2 (8609), 491-493.

The clinical value of suggestions during general anesthesia was assessed in a double-blind randomized placebo-controlled study. 39 unselected patients were allocated to

suggestion (N = 19) or control (N = 20) groups who were played either recorded suggestions or a blank tape, respectively, during hysterectomy. The patients in the suggestion group spent significantly less time in the hospital after surgery, suffered from a significantly shorter period of pyrexia, and were generally rated by nurses as having made a better-than-expected recovery. Patients in the suggestion group, unlike the control group, guessed accurately that they had been played an instruction tape.

Goldmann, Les; Ogg, T. W.; Levey, A. B. (1988). Hypnosis and daycase anaesthesia. A study to reduce preoperative anxiety and intraoperative anesthesia requirements. Anesthesia, 43, 466-469.

52 female patients having gynecological surgery as day cases received either a short preoperative hypnotic induction or a brief discussion of equal length. Hypnotized patients who underwent vaginal termination of pregnancy required significantly less methohexitone for induction of anesthesia and were significantly more relaxed as judged by their visual analogue scores for anxiety. Less than half the patients were satisfied with their knowledge about the operative procedure even after discussions with the surgeon and anesthetist. A significant correlation was found between anxiety and perceived knowledge of procedures. Results suggest that preoperative hypnosis can provide a quick and effective way to reduce preoperative patient anxiety and anesthetic requirements for gynecological daycase surgery.

Morrison, J. B. (1988). Chronic asthma and improvement with relaxation induced by hypnotherapy. Journal of the Royal Society of Medicine, 81, 701-704.

After one year of hypnotherapy, 16 chronic asthmatic patients inadequately controlled by drugs had a fall in admissions from 44 in the year before starting therapy to 13 in the year after. Duration of stay was reduced for 13 patients by 249 days; prednisone was withdrawn in 6, reduced in 8, and increased in none. Side effects of drugs were reduced. Although 62% reported improvement on a visual analogue scale, observations of air flow gave variable results.

1987

Frankel, Fred H. (1987). Significant developments in medical hypnosis during the past 25 years. International Journal of Clinical and Experimental Hypnosis, 35, 231-247.

Selected significant investigative studies on the use of hypnosis in the medical context over the past 25 years are discussed. The topics covered include anxiety and pain, asthma, migraine, skin disease, burns, nausea and vomiting, surgery, haemorrhagic disorders, and cancer and immunity. The importance of hypnotizability ratings in the methodology is emphasized.

Holroyd, Jean (1987). How hypnosis may potentiate psychotherapy. American Journal of Clinical Hypnosis, 29, 194-200.

Hypnotherapy is defined as doing psychotherapy in the hypnotic state. This article reviews cognitive, affective, and motivational changes associated with hypnotic trance, attempting to demonstrate how the hypnotic state might influence ordinary psychotherapy processes. Nine characteristics of trance probably potentiate psychotherapy: (1) changes in attention and awareness, (2) imagery enhancement, (3) increase in dissociation, (4) decrease of reality orientation, (5) increase in suggestibility, (6) increased accessibility of mind-body interactions, (7) diminution of initiative resulting in a sense of nonvoluntariness, (8) increased availability or manipulability of affect, and (9) development of a fusional relationship (rapport). This article touches upon the psychotherapeutic implications of these hypnosis attributes.

Kotses, H.; Rawson, J. C.; Wigal, J. IK.; Creer, T. L. (1987). Respiratory airway changes in response to suggestion in normal individuals. Psychosomatic Medicine, 49, 536-541.

Thirty normal individuals were told they were inhaling a substance that would either cause breathing difficulty (N - 15) or not affect breathing (N - 15). Total respiratory resistance was measured prior to and during inhalation. In reality, the subjects inhaled no substances; inhalation consisted of breathing normally into a respiratory resistance recorder. Individuals who received the former suggestion exhibited increased total respiratory resistance, whereas individuals who received the latter suggestion did not. These observations demonstrated that the ability of suggestion to affect the respiratory airway is not limited to asthmatic individuals

Locke, Steven E.; Ransil, Bernard J.; Covino, Nicholas A.; Toczydlowski, Janice; Lohse, Christopher M.; Dvorak, Harold F.; Arndt, Kenneth A.; Frankel, Fred H. (1987). Failure of hypnotic suggestion to alter immune response to delayed-type hypersensitivity antigens. Annals of the New York Academy of Sciences, 496, 745-749.

The ability to alter delayed-type hypersensitivity via hypnotic suggestion was tested in 12 highly hypnotizable, untrained subjects and 30 non-hypnotized controls. Subjects were skin tested bilaterally with a standardized panel of delayed hypersensitivity antigens and instructed either to enhance or suppress the skin test response (STR) unilaterally. Compared to controls, STR's showed no effect of hypnotic suggestion with regard to either the area of induration or the degree of inflammation assessed histologically

Makarec, K.; Persinger, M. A. (1987). Electroencephalographic correlates of temporal lobe signs and imaginings. Perceptual and Motor Skills, 64, 1124-1126.

Significant correlations (0.50) were observed between scores for the Wilson-Barber Inventory of Childhood Memories and Imaginings and the experiences that are indicative of temporal lobe lability. In addition, positive correlations (0.42) occurred between temporal lobe EEG measures (scalp electrodes) and numbers of temporal

lobe signs. The numbers of alpha seconds per minute from the occipital lobes were correlated (0.57) with the Wilson-Barber cluster that indicated interests in 'altered states'. Scores on the childhood imaginings section of the Wilson-Barber Inventory were correlated (0.44) with the numbers of spikes per minute over the temporal lobes when the eyes were closed.

"Persinger and DeSano (1986) found that people who display temporal lobe signs were also more likely to have more imaginings (as defined by Wilson and Barber's (1983) Inventory of Childhood Memories and Imaginings) and to be more suggestible as indicated by Spiegel's Hypnosis Induction Profile" (p. 1124).

Subjects in this investigation were 12 male and 18 female students, ages 18-39 (M = 25 years) Bipolar measures were taken from just above the ears (approximately T3-T4) and the occipital lobe (01-02). Number of alpha seconds per minute and number of spikes per minute from each lobe was taken for 10 minutes (5 successive pairs of 1 minute eyes- open, 1 minute eyes-closed).

"The total Wilson-Barber score was significantly ( $p < .01$ ) correlated ... with the major (0.46) and minor (0.50) temporal lobe clusters but not with two clusters of control items: normal psychological experiences (0.21) and mundane proprioceptive experiences (0.29). These correlations are similar to those in the Persinger and DeSano study (0.60, 0.50, 0.13, and 0.14, respectively). Like the first study (0.53), the items that were most associated with dissociation (depersonalization) were best correlated with the Wilson- Barber scores (0.60). The Wilson-Barber subcluster: adults' extreme experiences (Items 44 through 52, that indicate physiological changes associated with thinking) was again most strongly correlated with the major (0.55) and minor (0.65) temporal lobe clusters; these values were 0.42 and 0.52 in the first study" (p. 1125).

"The only statistically significant ( $p < .01$ ) correlations between the Wilson-Barber scales and the EEG measures were between the number of alpha seconds from the occipital lobe (with the eyes closed) and the [Wilson-Barber] 'altered state' cluster ( $r = 0.57$ ; Items 33, 41, 42, 43). A weaker correlation (0.36) occurred between the number of alpha seconds per min. (eyes closed condition) and childhood vestibular experiences (items 1, 2, 3, 10, 24)" (p. 1126).

Pastorello, E. A. (1987). The role of suggestion in asthma. I. Effects of inactive solution on bronchial reactivity under bronchoconstrictor or bronchodilator suggestion. Annals of Allergy, 59, 336-338.

Twenty-eight Ss affected by perennial asthma were selected in order to investigate the possibility of inducing or relieving an asthmatic attack by means of suggestion. 25 were positive to a methacholine challenge test, and among them, 11 reacted to an ultrasonic nebulized distilled water test. The effect of suggestion on airway response was assessed by 8 inhalations of normal saline at 32 degrees Centigrade alternately presented as a bronchoconstrictor or as a bronchodilator drug. 8 inhalations of the same diluent without any psychic stimulus were used as a control test. 7 patients reacted with bronchoconstriction to both positive and negative suggestion and to the control test. Further, this group of patients showed a lower methacholine PD10 when compared with the other Ss. In this study, the effects of suggestion on

bronchial reactivity were not observed and bronchoconstriction belonged to an individual hyperactivity of the airways.

Pastorello, E. A.; Codecasa, L. R.; Gerosa, A.; Buonocore, E.; Sillano, V.; Zanussi, C. (1987). The role of suggestion in asthma. II. Effects of a bronchoconstrictor drug on bronchial reactivity under bronchoconstrictor or bronchodilator suggestion. Annals of Allergy, 59, 339-340.

Previous studies have shown that suggestion may modify bronchial reactivity to both inactive diluents and pharmacologically bronchoconstrictor or dilator substances. In our study, 14 patients were subjected to 2 methacholine -tients were subjected to 2 methacholine challenge tests presented, respectively, as a bronchoconstrictor or as a bronchodilator drug. Forced expiratory volumes in one second were recorded and a PD20 was determined. No significant differences were reported in PD20 values of each patient after the 2 kinds of suggestion.

Patterson, David R.; Questad, Kent A.; Boltwood, Michael D. (1987). Hypnotherapy as a treatment for pain in patients with burns: Research and clinical considerations. Journal of Burn Care and Rehabilitation, 8 (3), 263-268.

Hypnotherapy has increasingly been included in the management of burn patients, particularly in the area of acute pain. To better understand such issues as (1) overall efficacy of hypnotherapy to alleviate acute burn pain, (2) instances in which hypnotherapy is contraindicated, (3) interaction of hypnotherapy with medication, (4) standard induction techniques to use with various age groups, (5) role of nursing and other staff in facilitating hypnotic effects, and (6) future methodological directions, they examined the clinical and methodological merits of recent studies of hypnoanalgesia. A literature search found 17 studies in which hypnotherapy was applied to the management of burns. The literature generally supports the efficacy of this approach to reduce burn pain; however, little else can be concluded from these studies. Several recent studies have applied hypnotherapy to aspects of burn care other than pain using excellent experimental designs. It is suggested that future studies of acute pain management follow suit.

Brink, Nicholas E. (1986-87). Three stages of hypno-family therapy for psychosomatic problems. Imagination, Cognition and Personality, 6, 263-270.

In dealing with psychosomatic complaints it has been found useful and necessary to bring together three stages or techniques of psychotherapy. First, along with teaching relaxation, the therapist directs the client to define the symptom in a symbolic or figurative way describing size, shape, color, consistency, smell, and sound. These descriptors assess intensity and, over time, change in intensity of the symptom. Second, several hypnotic techniques are used to determine the dynamic pattern that has created the symptom. Such uncovered patterns have been found to invariably involve family dynamics. Third, hypnotic and family therapy techniques assist the client in changing the pattern. Examples are presented.

Cerny, M. (1986). Hypnosuggestive interventions in emotional stress and in stress disorders. Activitas Nervosa Superior, 2, 141-143.

This paper represents a review of results using the PSA technique (Posthypnotic Suggestion evoked by Autostimulation) as a means of protection against stress. The best results were obtained in Ss with high susceptibility. This fact limits the practical use of the PSA method. However, this method can serve as a model approach in another more exact study of psychophysiological self-regulatory mechanisms in relation to coping with stress.

Olness, Karen N. (1986, March). Hypnotherapy in children: New approach to solving common pediatric problems. Postgraduate Medicine, 79 (4), 95-105.

Hypnotherapy, once thought of as magical and mysterious, is rapidly becoming accepted as an appropriate form of treatment for a wide range of disorders. Some primary care physicians are beginning to discover the value of hypnotherapy in controlling chronic disease and pain, in changing negative behavior, and in facilitating self-regulation of autonomic responses. Dr. Olness explores such use of hypnotherapy in children, the age-group that most readily acquires self-hypnosis skills and in which this technique has had dramatic results.

1986

Omer, Haim; Friedlander, Dov; Palti, Zvi (1986). Hypnotic relaxation in the treatment of premature labor. Psychosomatic Medicine, 48, 351-361.

Hypnotic relaxation was used as an adjunct to pharmacologic treatment with 39 women hospitalized for premature contractions in pregnancy. The control group received medication alone and consisted of 70 women. Treatment was started at the time of hospitalization and lasted for 3 hr on the average. patients were also given cassettes with a hypnotic - relaxation exercise for daily practice. The rate of pregnancy prolongation was significantly higher for the hypnotic - relaxation than for the medication- alone group. Infant weight also showed the advantage of the hypnotic - relaxation treatment. Background variables of the two groups were compared and it was shown that they could not have explained the treatment effect obtained

1985

Bolocofsky, David N.; Spinler, Dwayne; Coulthard-Morris, Linda (1985). Effectiveness of hypnosis as an adjunct to behavioral weight management. Journal of Clinical Psychology, 41 (1), 35-41.

109 17-67 year olds completed a behavioral treatment for weight management either with or without the addition of hypnosis. Results show that, at the end of the 9-week program, both interventions resulted in significant weight reduction. However, at 8-month and 2-year follow-ups, the hypnosis Ss showed significant additional weight loss, while those in the behavioral-treatment-only group exhibited little further

change. More Ss who used hypnosis also achieved and maintained their personal weight goals. It is suggested that hypnosis may have been an effective motivator for Ss to continue practicing the more adaptive eating behaviors acquired during treatment. Findings support the utility of employing hypnosis as an adjunct to a behavioral weight management program. (25 ref)

Finer, B. (1985, August). Altered substance P concentrations in CSF during hypnotic analgesia. [Paper] Presented at the 10th International Congress of Hypnosis and Psychosomatic Medicine, Toronto, Canada.

Substance P is present at many sites of endorphins or enkephalons. Sometimes a strange sleepiness follows triggerpoint stimulation. Acupuncture also may lead to similar changes (e.g. feeling groggy; having difficulty standing - lasts 1-4 hours). If you inject 4 mgms (10 times the ordinary dose) of Naloxone into Ss it leads to groggy sleepiness, for Naloxone-reversed hypnotic analgesia.

Olness, Karen N.; Conroy, Mary Margaret (1985). A pilot study of voluntary control of transcutaneous PO<sub>2</sub> by children: A brief communication. International Journal of Clinical and Experimental Hypnosis, 33, 1-5.

This pilot study took place to determine whether or not children could voluntarily change tissue oxygen as measured by a transcutaneous oxygen monitor. It tested 2 hypotheses: (a) children can voluntarily change tissue oxygen as reflected by a transcutaneous oxygen monitor and (b) children, experienced in use of self-hypnosis exercises, will be able to change tissue oxygen to a greater degree than children unfamiliar with such exercises. 11 children between the ages of 7 and 17 year were studied. 8 children were previously experienced in the use of self-hypnosis; 3 were not. A Novamatrix transcutaneous O<sub>2</sub>/CO<sub>2</sub> monitoring system provided a constant read-out of PO<sub>1</sub>, PCO<sub>1</sub> and local perfusion. After stabilization, children were asked to attempt increases of oxygen. 9 children increased tissue oxygen significantly. Of those, 8 children had previous self-hypnosis training. 1 had not. Only 2 children with no previous self-hypnosis training were unable to change oxygen values. This pilot study upholds both hypotheses; however, it does not conclude that self-hypnosis mediated the changes noted or that self-hypnosis would be essential to success in voluntary control of tissue oxygen.

1984

Achterberg, J. (1984, October). Cancer, immunology, psychological factors, and imagery. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

Author developed a way of scoring imagery (which will be published in Imagery and Disease.). In terms of predicting who will die and who will survive, the content of the images doesn't seem to be as important as the quality (strength, vividness, etc.), which supports Bernauer Newton's (1984) findings. "The image seems to be a basic pre-verbal component of our species that has survival value."

Bishay, Emil; Stevens, Grant; Lee, Chingmuh (1984). Hypnotic control of upper gastrointestinal hemorrhage: A case report. American Journal of Clinical Hypnosis, 27, 22-25.

The use of hypnosis for control of bleeding during and after surgical procedures is common practice. It has also been a useful tool for control of bleeding in hemophiliac children, especially during dental procedures, and in traffic accidents. This paper presents the successful treatment with hypnosis of a patient with upper gastrointestinal tract bleeding. After treatment, the patient was discharged from the hospital without the need for surgical intervention.

The physician explained to the patient that nothing would hurt her and that nobody would do anything against her will, that if she could "relax," then her unconscious mind would help her control her bleeding. [Gives script used in the hypnosis.] Trance terminated after 20 minutes. "One hour later, endoscopy performed under local anesthesia revealed 'non-bleeding gastritis, no ulcers seen.' She had no bleeding following the hypnotherapy" (p. 23).

Brown, Erick L.; Kinsman, Robert A. (1984). Resolving intractable medical problems through psychological intervention: A clinical report. Psychotherapy, 21, 452-455.

Treatment of chronic physical illness is often complicated by psychological factors that maintain and exacerbate the illness. Hypnotic techniques, coupled with insight-oriented psychotherapy comprised an effective strategy for favorably influencing medical outcome. A clinical report illustrates how psychological intervention initiated the resolution of severe medical problems in an asthmatic patient.

Conn, Lois; Mott, Thurman, Jr. (1984). Plethysmographic demonstration of rapid vasodilation by direct suggestions: A case of Raynaud's Disease treated by hypnosis. American Journal of Clinical Hypnosis, 26, 166-170.

Raynaud's Disease is a painful vasospastic disorder of the fingers and toes precipitated by cold or emotional stimuli. Treatment has usually included protection from cold stimuli and vasodilators. Biofeedback, imagery, relaxation, and hypnosis have also been used. The relationship between response to treatment and hypnotizability has been inconclusive. A case of Raynaud's Disease was treated using hypnosis. The patient was highly hypnotizable and responded rapidly to direct suggestion with a fourfold increase in her blood volume. The implications of this rapid response and its relationship to hypnotizability are discussed with suggestions for further studies.

The authors review experimental literature on the usefulness of hypnosis in modifying peripheral circulation, finding both positive (Barabasz and McGeorge, 1978, Roberts, Kewman, and MacDonald, 1973) and negative (Peters, Lundy, and Stern, 1973; Black, Edholm, Fox, and Kidd, 1963) outcomes. Experiments relating

outcome to hypnotizability also have positive (Block, Levitsky, Teitelbaum, and Valletta, 1977) and negative (Crosson, 1980; Roberts et al, 1973) results.

Clinical literature found that peripheral circulation could be influenced (Crasilneck & Hall, 1975; Norris & Huston, 1956; Jacobson et al., 1973) but none of those studies reported the hypnotizability of the patients. In the Crasilneck and Hall (1975) investigation, 60% of their 48 Raynaud's patients experienced marked improvement in symptoms or remission.

Hypnotizability has been investigated with respect to biofeedback results, finding both no relationship (Holroyd et al., 1982) and a positive relationship (Andreychuk and Skriver, 1975).

In this investigation, the highly hypnotizable (Stanford Hypnotic Susceptibility Scale, Form A, score = 11) female patient was treated with hypnosis when the blood vessels in her hands were constricted. Either she had arrived at the office with poor circulation, or a Raynaud's attack was induced with ice water. Hypnosis involved progressive relaxation followed by suggestions to visualize the blood vessels in her hand opening up, the blood warming and nourishing her hands. "With each beat of your pulse your hand becomes warmer as more blood reaches your fingers. It is as though you are lying in the warm sun. Try to visualize the blood vessels in your hand opening up...." (P. 168).

The patient was asked to use self hypnosis and a cassette of the office session twice a week between sessions, but in fact she either failed to practice or did the exercise once between weekly sessions.

With neutral hypnosis (no specific suggestions about circulation) there was little change in pulse volume; with suggestions to open up her blood vessels, there was an increase in blood volume that began within 20 seconds, reaching four times the baseline in 45 seconds. This increase was reproduced in later sessions, and a somewhat lesser degree of change could be produced with self hypnosis.

In their Discussion, the authors question whether the positive results depend on someone who is high in hypnotizability, and/or on someone with a labile vascular system. They refer to a model of biological information processing to explain how suggestions might have been incorporated by the patient. "Bowers (1977) has speculated that hypnotized patients process information in a way different from when they are not hypnotized. He presents a number of different studies which have shown a significant relationship between hypnotizability and treatment response in patients with illnesses with a clear cut physiological component, including asthma, warts, and ichthyosis. He then speculates that 'suggestions delivered to deeply hypnotized subjects can be transduced into information that is somatically encodable, thereby producing a selective and specific impact on body function and structure.' This kind of processing of information could explain the very rapid response described in the patient presented here.

"In reviewing the cases in which blistering has been produced by hypnotic suggestion, Chertok (1981) states, 'It therefore clearly emerges that these experiments have all been conducted with highly hypnotizable subjects, including a very large proportion of true somnambulists. Inversely, there is not a single

known case where a blister has been produced without the subject having been deeply hypnotized beforehand''' (p. 169).

Elkins, Gary R. (1984). Hypnosis in the treatment of myofibrositis and anxiety: A case report. American Journal of Clinical Hypnosis, 27, 26-30.

A 38-year-old woman with chronic myofibrositis pain was treated by the use of hypnosis and psychotherapy. Hypnotherapeutic techniques, including symptom alteration, relaxation, and insight, are described. This regimen resulted in reduction in pain and emotional distress, which was maintained at three months and one year after treatment.

Gould, Sol S.; Tissler, Doreen M. (1984). The use of hypnosis in the treatment of herpes simplex II. American Journal of Clinical Hypnosis, 26, 171-174.

Hypnosis training was used to treat the painful lesions and emotional symptoms associated with Herpes Simplex II in two females, ages 32 and 26. Three weekly sessions of hypnosis and daily practice sessions were initiated in the first case. During this time, the patient experienced a decline in the subjective level of pain and severity of the lesions, as well as an elevation in mood level. On three-month followup, she reported no pain or skin eruptions and significantly less feelings of stress and anxiety. The second case utilized two sessions of hypnosis and daily practice sessions, and similar results were obtained. A traumatic event caused a relapse in the latter patient, but she was again able to use hypnosis to bring the virus back under control and to experience an elevation in mood level as well. A seven-month follow-up indicated no eruptions and an improvement in self-esteem.

In the first case the tape included ego-strengthening suggestions (Hartland, 1971); another tape used the patient's fantasy of water and snow skiing. The patient felt that hypnosis helped her acquire a more positive attitude toward herself and relief of guilt and blame, as well as an improved ability to cope with the unpleasant sensations.

In treatment session, ego strengthening suggestions were followed by 2 minutes of quiet for integration of suggestions, then visualization used in cancer therapy (Simonton): suggestions of a strong cell structure, perfect skin, hormonal balance, cleanliness, and a cooling refreshed feeling in the area of the vagina and perineum; imagery of internally controlled friendly white sharks was used to "devour" the virus; of water and snow skiing, imagery of cool breezes, white refreshing snow, clean fresh water; visualized herself forgiving and releasing her previous boyfriend of guilt, thereby allowing her anger to abate.

For second patient it was similar, plus visualization of being bathed in white lights and traveling through concentric circles radiating peace and protection, being purified as she traveled through the circles until she emerged as flawless as a diamond, reflecting only clarity and light. Both patients scored 4 on Spiegel's Hypnotic Induction Profile (HIP).

Hall, Howard R. (1984, October). Hypnosis, imagery, and the immune system. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

Studied the relationship of hypnosis to immune functions, using imagery methods like the Simontons did with their cancer patients. Twenty normal volunteers were hypnotized and asked to imagine their white blood cells (WBCs) attacking weak germs like strong sharks would attack something, and they were told that the sharks would continue working after they came out of hypnosis (a post-hypnotic suggestion). They were asked to "feel it and experience it any way you can," to avoid emphasizing visual imagery too much. Then they were taught self hypnosis and sent home to practice twice a day for a week.

Three blood measures increased after hypnosis: --B-cells increased with pokeweed stimuli (an allergen) for younger Ss, not older Ss --WBC's increased for highly hypnotizable Ss who were young, not for poor hypnotizable Ss or for any older Ss (Age range was 22-80.) --Lymphocyte count increased, approaching significance for highly hypnotizable Ss who were young but not for poor hypnotizable Ss or for older Ss. A personality test administered before the hypnosis, the SLC-90, suggested that the higher the distress level, the lower the lymphocyte count before hypnosis training. Two scores that summed up the distress level correlated -.49 and -.53, respectively. The psychological distress measured by the personality test decreased after the week of self-hypnosis practice. Of the two scores that summed up distress, one decreased for everyone (General Severity Index) and the other decreased only for highly hypnotizable Ss (Positive Symptom Total). Thus, a week of self hypnosis with imagining one's WBC's eating up weak germs in the blood led to both an increase in immune response indicators and a decrease in psychological distress. Psychological distress decreased as lymphocytes increased.

Dr. Hall repeated these procedures with a small number of Ss who were told just to "lie down and rest" rather than being hypnotized and given instructions to imagine their WBC's increasing. None of the above changes occurred. However, he cautions that his research doesn't indicate whether the positive effects are due to relaxation, imagery, or hypnosis since all three were involved.

Krenz, Eric W. (1984). Improving competitive performance with hypnotic suggestions and modified autogenic training: Case reports. American Journal of Clinical Hypnosis, 27, 58-63.

Although traditionally trainers of athletes have emphasized physiological refinements for the optimal performance of complex motor skills, research has revealed that heightened levels of stress and anxiety may adversely affect performance. As a result, many athletic training programs, taking into consideration the complex interrelationship of the mind and the body, include "mental training" in an attempt to reduce the negative effects of excess stress. These programs have incorporated various psychological interventions such as post hypnotic suggestions, sensory conditioning, and mental imagery and rehearsal. Modified Autogenic Training, a teaching model based on Standard Autogenic

Training, synthesizes the strengths of hypnotic techniques to achieve optimal athletic performance. Athletes trained in these concepts can manage unexpected incidences during competition. The concepts of Modified Autogenic Training are described and four case studies are reported.

Lewith, G. T.; Kenyon, J. N. (1984). Physiological and psychological explanations for the mechanism of acupuncture as a treatment for chronic pain. Social Science & Medicine, 1367-1378.

Many suggestions have been made about the possible mechanism of acupuncture as an analgesic therapy. This review provides a comprehensive account of the neurological, neurohumoral and psychologically-based hypotheses put forward. Although the exact mechanism of this treatment remains unclear, it is apparent that reproducible neurological and chemical changes occur in response to acupuncture, and that these changes almost certainly modify the response to, and perception of, pain. The mechanism of chronic pain is incompletely understood, but within this framework we understand acupuncture as completely as most other types of analgesic treatment.

Newton, Bernauer (1984, October). The use of imagery in the treatment of cancer patients. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

Several hundred cancer patients were treated with the Simonton visualization method, with the additional factor that they were hypnotized for the visualization. In a long term follow-up study, those patients who were treated for at least 6 months and are still alive had imagery that was vivid, persistent, positive, and passive ("passive" here meaning an underlying sense of calm). Those who died had the opposite kind of images, and retrospective review of clinical notes indicates their aggressive images reflected desperation. Of the patients who were treated less than six months, a few lived. Their images also were vivid, persistent, and positive.

Raynaud, Jeanne; Michaux, Didier; Bleirad, Guilhem; Capderou, Andre; Bordachar, Janine; Durand, Jacques (1984). Changes in rectal and mean skin temperature in response to suggested heat during hypnosis in man. Physiology and Behavior, 33, 221-226.

Rectal temperature, mean skin temperature and heart rate were recorded in 7 subjects during hypnosis, induced either alone or while sensations of heat were suggested. During hypnosis alone, a fall in the heart rate of about 10 beat-min<sup>-1</sup> was the only autonomic response observed; body temperatures were unaltered. In contrast, during hypnosis with suggestion of heat, the following changes occurred: (1) Mean rectal temperature decreased 0-.20 degrees C. (p<.05) within 50 min. Its mean time course differed significantly from that for hypnosis alone (p<0.001). (2) Comparison of individual rectal temperature time sequences showed that in fact this temperature only declined in 4 subjects out of 7, and tended to form a plateau

located 0.35 degrees C below the value of the preceding waking state. Despite reinforcement of heat suggestion, the plateau continued until the end of the hypnotic trance. (3) Mean skin temperature tended to rise. (4) When hypnosis with suggestion ceased, both rectal and skin temperatures very slowly returned to their levels during the preceding waking state.

1981

Chen, Andrew C.; Dworkin, Samuel F.; Bloomquist, Dale S. (1981). Cortical power spectrum analysis of hypnotic pain control in surgery. International Journal of Neuroscience, 13, 127-136.

Cortical power spectrum (CPS) of brain potentials was recorded from the scalp between prefrontal and parietal regions in both right hemisphere (RH) and left hemisphere (LH). A pattern of laterality shift in CPS occurred at different stages during an extensive oral surgery, performed under hypnosis, in a young female patient. Video and audio recordings as well as psychophysiological recordings were obtained through the following 6 stages: Baseline, Hypnosis, Surgery (1 hr, no cortical recording), Immediate Postsurgery Procedure, Hypnotic Re-experience, Hypnotic Rest, and Posthypnotic Baseline. Indications of anxiety and pain scores were reported in writing by the patient through verbal command by the hypnotist. In each stage, 10 min of CPS (10 spectrum/stage, 8 epochs/spectrum, 6 seconds/epoch) were analyzed by a PDP-11 computer. The results of CPS analysis demonstrated significant large total power reduction at different stages. There was significant correlation between both hemispheres at baseline, but dissociation of hemispheric power output occurred during hypnosis stages. LH was more dominant than RH during baseline and presurgery hypnosis, but both were leveled-off immediately following the surgery procedure. However, RH became more dominant during all postsurgery hypnosis stages. Interestingly, this pattern shifted back to the original relationship during the posthypnotic baseline stage. Specific changes of spectral power in theta and alpha of EEG activities in both hemispheres also occurred in conjunction with hypnosis.

Subject was a 25 year old woman, described as only medium in hypnotizability. She scored 3 on the 5-point Stanford Hypnotic Clinical Scale, 7 on the 12-point Stanford Hypnotic Susceptibility Scale, and 3 on up-gaze, between 2 and 3 on eye roll, on the Spiegel eye roll test.

The principal hypnotic approach was a suggestion of dissociation, i.e. that the patient "experience herself swimming freely and powerfully, in a deep cold mountain lake, pre-occupied with the intensity of the blue-black color of the water, the shimmering of light from above, and the possibilities of exploration of rock formations, caves, etc. It was suggested that while she was experiencing the exhilaration and strenuous stimulation of the cold water and the vigorous exercise, an 'observing-self' would remain on the shore, watching and ensuring that no harm would come to the person. The suggestion was reinforced that any stimulation experienced was experienced in the body, not in the person" (p. 129).

harm would come to the person. The suggestion was reinforced that any stimulation experienced was experienced in the body, not in the person" (p. 129).

The patient was trained in inductions and dissociation first in the therapist's office, then with two sessions in the research laboratory (where tooth pulp stimulation pain thresholds were measured), and then two sessions in the hospital dental operatory.

The results of the computerized CPS were analyzed by hemispheres. "Large reductions in total power occurred at different stages associated with hypnosis and these reductions in power output of the CPS showed significant left-right differences" (p. 130).

"The total energy output of LH [left hemisphere] continued to diminish as hypnosis continued by as much as 80% of baseline value, while RH [right hemisphere] power output tended to be stabilized from the initial hypnosis recording stage until the awake baseline stage" (p. 130).

"Those stages involving hypnosis were characterized by dominant RH energy output in the alpha spectrum. ...

"Alpha output for the LH decreased an average of 65% between awake baseline levels and postsurgery hypnosis stages, while RH alpha only decreased approximately 50% of resting levels. This resulted in a relative shift of alpha output which was approximately equal in both hemispheres prior to surgery, to a 2:1 shift in favor of RH alpha output as hypnosis progressed. This differential shift in laterality of alpha was reversed when the subject awakened from hypnosis.

"Of interest was the observation that total power reductions and laterality shifts associated with hypnosis were not altered by the profound instrumentation of surgery and postoperative pain, nor were observed laterality shifts affected by hypnotic suggestions aimed at recreating the surgical experience (see Stage 5)" (p. 130).

During the experiment when the investigators used hypnotic suggestion to recreate the surgical experience, LH output continued to diminish while RH output did not change, making the LH-RH contrast highly significant. "This suggests that the RH is active during deep stages of hypnosis and can remain so despite hypnotic suggestions which are presumed to be intensely aversive" (p. 131).

In their Discussion, the authors reinforced the conclusion that overall cortical functioning is reduced during hypnosis, and that the left cerebral hemisphere shows a greater reduction than the right. They discuss the increased theta density in RH and LH during the postsurgery hypnosis stage in terms of reports that theta is associated with altered states of consciousness (Tebecis et al., 1975; Ulett et al., 1972; Anad, China, & Singh, 1961; Banquet, 1973; Kasamatsu & Hirai, 1966; Wallace, 1970) and with cognitive tasks like mental arithmetic (Dolce et al., 1974).

The authors note that their results are congruent with Hilgard's neodissociation theory of hypnosis, and add that since their suggestions were dissociative in nature rather than of local anesthesia, the EEG may reflect the brain physiology of dissociation.

Finally, they comment on the implications for pain neurophysiology. "The total power changes and shifting patterns in laterality of cortical functioning observed more closely tracked the hypnosis experience than the pain experience; this is, in

fact, a very puzzling issue. It appears on the face of it that the EEG measurements recorded are not reflective of EEG-related pain phenomenology despite the strenuous and invasive surgical procedures used. The observations that overall power output continued to decrease during the several hypnosis stages after strenuous surgery and then increased as the patient came out of hypnosis makes reasonable the possibility that \_hypnosis\_ has some functional brain correlates; we cannot conclude from the present cortical power spectrum analysis that any brain correlates of surgical \_pain\_ were revealed. We are well aware that EEG recordings were not available during actual surgery itself, because of artifacts resulting from head movements, etc. Nevertheless, it can be fairly claimed that recordings obtained immediately after such oral surgery of one hour duration, could reasonably be expected to be associated with a person in pain. But, both by verbal report and available objective data, any surgically induced traumatic pain was of brief duration under hypnosis" (p. 135).

well aware that EEG recordings were not available during actual surgery itself, because of artifacts resulting from head movements, etc. Nevertheless, it can be fairly claimed that recordings obtained immediately after such oral surgery of one hour duration, could reasonably be expected to be associated with a person in pain. But, both by verbal report and available objective data, any surgically induced traumatic pain was of brief duration under hypnosis" (p. 135).

Elkind, Leonard (1981). Effects of hypnosis on the aging process. Journal of the American Society of Psychosomatic Dentistry and Medicine, 28 (4), 132-137. (Also presented at the annual meeting of the Am Soc of Psychosomatic Dentistry and Medicine in San Francisco, CA)

This study investigated the possibility of altering physiological measures associated with aging through the use of posthypnotic suggestions of increased youthfulness and vitality. Subjects were 20 women ranging in age from 39 to 56 years old. They were tested individually on Morgan's Adult Growth Examination, the AGE. Test-retest scores of the Control group were not significantly different, the median change being zero. The Experimental group, however, showed a decrease in Body Age for all of the subjects, the range of change from -3 to -18 years with a median change of -11 years.

Barber, Theodore Xenophon (1978). 'Hypnosis,' suggestions, and psychosomatic phenomena: A new look from the standpoint of recent experimental studies. In Fosshage, J. L.; Olsen, P. (Ed.), Healing: Implications for psychotherapy (pp. 269-297). New York: Human Sciences Press.

"The first part of this chapter summarizes recent experiments that indicated that suggestions (1) can prevent the skin reaction (contagious dermatitis) that is produced by plants such as poison ivy, (2) can give rise to a localized inflammation of the skin, (3) can stimulate the remission of warts, (4) can ameliorate congenital ichthyosis (fish skin disease), and (5) can stimulate additional growth of the

mammary glands in adult women. The underlying theme throughout the first part of the paper is that "suggestions" (statements that something is occurring or will occur) affect cutaneous and glandular functions when subjects accept the suggestions and incorporate them into their own ongoing cognitions (their ongoing thoughts, images, and feelings). The second part of the paper (1) summarizes recent psychophysiological experiments and biofeedback studies that indicated that our thoughts, images, and feelings affect blood flow to the skin and other organs, and (2) postulates that the aforementioned phenomena produced by suggestions (e.g., the prevention of dermatitis, the production of inflammation, and the remission of warts) may be partly due to the localized alterations in blood flow that occur when the suggestions are accepted and become part of ongoing cognitions" (pp 269-270).

Davidson, R. J.; Goleman, D. J. (1977). The role of attention in meditation and hypnosis: A psychobiological perspective on transformations of consciousness. International Journal of Clinical and Experimental Hypnosis, 25, 291-308.

A temporally based scheme for investigation of changes in consciousness, applicable to areas such as meditation and hypnosis, is proposed and is divided into 3 basic epochs: before -- predispositional variables that affect response to consciousness altering techniques; during -- the state effects of the particular technique; and after -- the trait effects of the practice.

Research is surveyed which indicates the role of attentional processes during each of these 3 basic epochs in both meditation and hypnosis. Attentional flexibility is a predispositional variable affecting response to both meditation and hypnosis. The state effects of concentrative meditation involve alterations in stimulus set while the state effects of hypnosis may reflect primarily response set. The trait effects elicited by meditation depend critically on the psychobiological systems which are called into play. Evidence is discussed which suggests that concentrative meditation shares with relaxation an autonomic quiescence, but in addition enhances some attentional skills. A mindfulness technique involving the adoption of a particular attentional stance toward all objects of awareness appears to enhance cortical specificity, but a concentration technique does not. Some implications of attentional self-regulation are discussed.

Barber, Theodore Xenophon (1976). Introduction. Self-control: Temperature biofeedback, hypnosis, yoga, and relaxation. In Barber, Theodore Xenophon (Ed.), Biofeedback and self-control: 1975/76 (pp. xiii-xxix). Chicago: Aldine.

Discusses control of skin temperature, hypnosis, yoga, relaxation, and biofeedback. Concludes that hypnosis is not unique in producing somatic effects.

Dugan, Michelle; Sheridan, Charles (1976). Effects of instructed imagery on temperature of hands. Perceptual and Motor Skills, 42, 14.

Sixteen college student volunteers were involved in the research. Subjects were randomly assigned to two groups, either to warm or to cool their hands. All 10 subjects attempting to cool their hands were able to cool at least one hand, and six people cooled both hands. For those trying to warm their hands, five warmed at least one hand and one was able to warm both hands. Four people were able to cool their hands without hypnosis, conditioning, or feedback.

**1974**

**Galín, David (1974). Implications for psychiatry of left and right cerebral specialization: A neurophysiological context for unconscious processes. Archives of General Psychiatry, 31 (4), 572-583.**

A brief review is presented of hemispheric specialization for different cognitive modes, and of the symptoms that follow disconnection of the two hemispheres by commissurotomy. Our present knowledge of the hemispheres' cognitive specialization and potential for independent functioning provides a framework for thinking about the interaction of cognitive structures, defensive maneuvers, and variations in awareness. Parallels are noted between some aspects of the mental processes of the disconnected right hemisphere and some aspects of primary process thinking and repression. The hypothesis is proposed that in normal intact people mental events in the right hemisphere can become disconnected functionally from the left hemisphere (by inhibition of neuronal transmission across the cerebral commissures), and can continue a life of their own. This hypothesis suggests a neurophysiological mechanism for at least some instances of repression and an anatomical locus for the unconscious mental contents.

**Hilgard, Ernest R. (1974, October). Visceral control through hypnosis. [Paper] Presented at the International Congress of Physiological Sciences, New Delhi.**

The author reviews evidence of hypnosis and/or suggestion effects on skin: removal of warts, raising blisters, controlling chemically induced inflammation, modifying temperature. He concludes that although there may be dramatic results, the contributions of suggestion and hypnosis 'remain ambiguous.'

**1973**

**Roberts, Alan H.; Kewman, Donald G.; Macdonald, Hugh (1973). Voluntary control of skin temperature: Unilateral changes using hypnosis and feedback. Journal of Abnormal Psychology, 82 (1), 163-168**

To demonstrate the ability of human Ss to achieve control over specific autonomic functions, hypnosis and auditory feedback were used to train a select group of hypnotically talented subjects to produce a difference in skin temperature in one hand relative to the other in a direction specified by the experimenter. Large and reliable effects were shown demonstrating that some individuals are capable of achieving a high degree of voluntary control over the autonomic processes involved

in peripheral skin temperature regulation. Individual differences between subjects were noted, and variables that might account for these are discussed.

All Ss felt hypnosis helped (p. 167). However there were no waking control subjects. The study confounds hypnosis with auditory feedback (p. 168). They observed a relationship between hypnotic depth and physiological control.

**1970**

**Bowers, Kenneth S.; Kelly, P. (1970). Stress, disease, psychotherapy, and hypnosis. Journal of Abnormal Psychology, 490-505.**

Presents evidence for the importance of suggestion and hypnotic ability in the healing or amelioration of various somatic disorders. It is argued that even in some treatment interventions that are not explicitly hypnotic, suggestion and hypnotic ability may be hidden factors that help to promote successful healing. Consequently, hypnotic ability may be an individual difference variable that influences treatment outcome in a manner not heretofore recognized by many investigators and clinicians involved in helping the psychologically and physically ill.

**1964**

**Black, Stephen (1964). Mind and body. London: Kimber**

Defines psychosomatic disease as one that responds to psychotherapy. Believes only 5% are highly hypnotizable, that hypnosis is learnable in 1/2 hour, that hypnosis is not a useful treatment for psychosomatic disorders because you can't use interpretation [of unconscious]. The 'unconscious' is "... a complex of informational systems derived from such primaevial mechanisms" (p. 133). "Primaevial mind is involved in these mechanisms of genetics and immunology" (p. 133). "There is thus a 'somatic mind' which is unconscious and presumably without any means of verbalization of experience--and a 'cerebral mind' which is conscious" (p. 133). The dividing line is not clear.

"There is thus a 'somatic mind' which is unconscious and presumably without any means of verbalization of experience--and a 'cerebral mind' which is conscious" (p. 133). The dividing line is not clear.

Rapport is discussed on pp. 160, 169 as one of the spontaneous characteristics of hypnosis, in the absence of suggestion. The same for posthypnotic suggestion (rapport and amnesia). Spontaneous physiological changes in hypnosis relate to mind-body relationships (p. 169)

Conditioned reflex is discussed on p. 161

"...the subjective evidence indicates that a perceptual change involving any sensory modality can be produced by DSUH" [direct suggestion under hypnosis] p. 178. Suggestion can selectively affect different parts of the body p. 197.

Research: "Hypnosis is not only the most important and practical way of proving the existence of the unconscious--which is still in doubt in some circles--but is in fact the only way in which unconscious mechanisms can be manipulated under repeatable experimental conditions for purposes of investigation" (p. 152).

Mind-body is "amenability to control" Catatonia, which characterizes both animal and human hypnosis, seen in hypnosis, is induced by constriction (i.e. disorientation). The Cartesian concept of mind and body tends to confuse the issue p. 157.

Rapport is discussed (p. 157).

Suggestion (p. 159) "It was this concept of 'suggestion'--which so obviously parallels 'amenability to control' in animals--that eventually established hypnosis in the French schools of psychiatry as a state of increased suggestibility. ... still the standard definition of hypnosis in most medical psychiatric textbooks and in lay dictionaries" (p. 159).

Black (1969) did some biochemical sleuthing to learn how information transmitted by words becomes information encoded somatically, as when psychosomatic allergies flare and recede or disappear. What accounts for suggestion "curing" an allergic skin reaction in one part of the body while another part not included in the suggestion remains reactive? What accounts for the instantaneous skin allergy cure which sometimes occurs with suggestion (in 24 hours)?

Skin sensitivity tests in highly hypnotizable Ss who were also very allergic were inhibited by direct suggestion under hypnosis under highly controlled experimental conditions--and in one subject the effect (inhibition) was relatively permanent--ruling out (he suggests) a neurological mechanism. He did further experiments to examine whether the result was due to an instant neurological mechanism and a long-term endocrinal mechanism.

p. 212 He ruled out peripheral blood flow as the cause of diminished skin sensitivity (there was no change in blood flow with suggestions of heat or cold). Therefore decrease in blood flow couldn't explain in neurovascular terms the 'instant' inhibition of skin sensitivity (allergy) tests. Was it due to systemic--especially adrenal-- changes? He demonstrated increases in plasma cortisol under hypnosis with suggestions of fear. On p. 230 he summarizes the facts he established by skin sensitivity tests, plasma- cortisol studies, and histology - endocrinological.

1963

Black, Stephen; Edholm, O. G.; Fox, R. H.; Kidd, D. J. (1963). The effect of suggestion under hypnosis on the peripheral circulation in man. Clinical Science, 26, 223-230.

"Summary. 1. The effects on the circulation in the forearm and hand of both direct and indirect suggestion under hypnosis of thermal stimuli have been studied. 2. The induction of hypnosis did not significantly alter the forearm blood flow, but a small reduction in hand blood flow was usually observed. Pulse rate in general slowed slightly as did respiration rate. 3. The effect of body heating on forearm and hand blood flow was not modified by hypnosis. 4. Direct suggestion under not modified by hypnosis. 4. Direct suggestion under hypnosis of body heating or body cooling, with and without body heating, produced only small changes. 5. The changes associated with suggestion were not related to the thermal suggestion. Whatever the suggestion, the usual response was a reduction in hand blood flow and an increase in forearm blood flow. 6. The rise of body temperature with heating was

not modified by direct suggestion, under hypnosis, of body cooling. 7. No change in body temperature could be elicited by suggestion. 8. In a few experiments marked changes in forearm blood flow occurred. These appeared to resemble the changes in the circulation produced by emotional stimuli. 9. The smaller changes more frequently observed were also similar to those produced by mild emotional stimuli" (p. 229). [N.B. The Subjects were normal, healthy adults, N = 9, between 21-45 years old; highly hypnotizable, amnesic for trance.]

Paul, Gordon L. (1963). The production of blisters by hypnotic suggestion: Another look. Psychosomatic Medicine, 25 (3), 233-244.

Presents a critical evaluation of reported attempts to produce nonherpetic skin blisters through hypnotic suggestion. Even though the majority of these reports are grossly lacking in controls, experimental design, etc., and are subject to alternative explanations, the author concludes that skin anomalies have been produced by suggestion in some instances. Additional studies of psychogenic vascular changes add credence to the possibility of central control of these phenomena. It is also concluded that these reactions do not appear to be limited only to hypnotized Ss.

1954

Howarth, Edgar (1954). Postscript to a new theory of hypnosis. Journal of Clinical and Experimental Hypnosis, 2, 91-92.

Referring to a theory of internal and external signalling systems, the author describes situations in which an individual's behavior comes under other than willed control by virtue of external circumstances. "In normal behavior the individual provides his own 'will' and may, to some extent, choose among a variety of alternative action sequences on the basis of guiding integrations between the second (externally directed) signalling system and the primary (internally directed) signalling system. ... it appears that a considerable degree of control may be obtained by the 'top' semantic command system over internal process, particularly those 'inhibited' by the cranial and sacral subdivisions of the 'autonomic' nervous system. .. [In anecdotal case reports] control was gained over breathing, heart rate and bladder and the person may feign death for several days. In such cases surface wounds do not exude other than lymph. The method for such control remains for experimental examination, but a necessary part of the procedure seems to be the use of mild occasional reward during a prolonged period of fasting. Solitary confinement is also necessary and both deserts and prison cells are reported ... to have been used" (pp. 91-92).

Modeling

1986

Gorassini, Donald R.; Spanos, Nicholas P. (1986). A social-cognitive skills approach to the successful modification of hypnotic susceptibility. Journal of Personality and Social Psychology, 50, 1004-1012.

Subjects low and medium in hypnotic susceptibility were administered cognitive strategy and instructional set information and also practiced responding to test suggestions in order to enhance susceptibility. Those in one modification treatment received this information both from the experimenter and by observing a videotaped female model who responded successfully to suggestions and reported on the cognitive strategies she used to do so. Those in a second modification treatment received the information and practice but were not exposed to the model. Low and medium susceptibles in a third condition (practice alone) received a hypnotic induction procedure and practice suggestions but neither modification information nor modeling. No-treatment controls performed a filler task. All subjects were posttested on two different susceptibility scales. Information plus modeling produced significantly greater increments on all objective and subjective indices of susceptibility on both posttests than did practice- alone or control treatments. Susceptibility increments in the information without model treatment always fell between those of the model and practice-alone treatments. In the modeling treatment, over half of the initial low susceptibles and over two thirds of the initial medium susceptibles scored as high susceptibles on both posttests. These findings provide strong support for a social-cognitive skill formulation of hypnotic susceptibility.

Spanos, Nicholas P.; Cross, Wendi P.; Lepage, Mark; Coristine, Marjorie (1986). Glossolalia as learned behavior: An experimental demonstration. Journal of Abnormal Psychology, 95, 21-23.

60 Ss listened to a 60-s sample of glossolalia (defined to them as pseudolanguage) and then attempted to produce glossolalia on a 30-s baseline trial. Afterward, half of the Ss received two training sessions that included audio- and videotaped samples of glossolalia interspersed with opportunities to practice glossolalia. Also, live modeling of glossolalia, direct instruction, and encouragement were provided by an experimenter. Both the trained subjects and untreated controls attempted to produce glossolalia on a 30-s posttest trial. About 20% of subjects exhibited fluent glossolalia on the baseline trial, and training significantly enhanced fluency. Seventy percent of trained subjects spoke fluent glossolalia on the posttest. Our findings are more consistent with social learning than with altered state conceptions of glossolalia.

1983

Council, James R.; Kirsch, Irving; Vickery, Anne R.; Carlson, Dawn (1983). 'Trance' versus 'skill' hypnotic inductions: The effects of credibility, expectancy, and experimenter modeling. Journal of Consulting and Clinical Psychology, 31 (3), 432-440.

A hypnotic induction procedure based on social learning principles (skill induction) was compared with a traditional eye-fixation/relaxation trance induction, a highly credible placebo induction, and a no-induction base-rate control

The trance induction surpassed the skill induction only on the Field Inventory, a measure of hypnotic depth that contains items corresponding to suggestions contained in the trance induction. Experimenter modeling was not found to enhance the effectiveness of the skill induction. Skill and trance inductions elicited slightly higher behavioral scores on the Stanford Hypnotic Susceptibility Scale: Form C than did the placebo induction. However, this difference was not obtained on other measures of hypnotic responsibility and depth. Significant correlations were found between expectancy, absorption, and responsiveness on all dependent measures. Multiple regression analyses indicated that the relationship between absorption and responsiveness was mediated by expectancy. The results are interpreted as supporting the hypotheses that hypnotic responses are elicited by the expectancy for their occurrence and that induction procedures are a means of increasing subjects' expectancies for hypnotic responses.

1) Trance induction resulted in a higher score on subjective experiences (cognitive & perceptual distortions) but not higher suggestibility scores than cognitive-behavioral skill induction. 2) Trance and cognitive-behavioral inductions got slightly higher scores in suggestibility than placebo biofeedback induction. 3) All inductions did better than a "no induction" control group on subjective and behavioral indices of hypnosis.

One of the goals of this research was to examine the contribution of experimenter modeling to the behavioral skill induction that "trains the subject in hypnosis skills and requires the subject's conscious cooperation in learning cognitive strategies that will enhance hypnotic responsiveness" (p. 432). Another goal was to assess the contribution of "a subject's expectancies for the occurrence of behaviors perceived as being involuntary" (p. 433). A third goal was to determine whether congruence between a subject's beliefs about hypnosis and the rationale for a particular induction would increase expectancy. Two different skill inductions were employed (one with, one without a model). Subjects were asked to predict their performance, based on a description of the induction that they would receive. The contributions of credibility and expectancy were assessed using a highly credible placebo (pseudo biofeedback of EEG theta rhythm).

The investigation used only subjects who had never experienced hypnosis.

Independent variables included Rotter's (1966) Internal-External Locus of Control Scale, Rotter's (1967) Interpersonal Trust Scale, and Tellegen's Absorption Scale (Tellegen & Atkinson, 1974). Mediating variables included a measure of induction credibility based on Borkovec and Nau (1972), and a 20-item inventory measuring expectancies for hypnotic performance. Dependent variables included 20 standard hypnotic suggestions taken from the Stanford Hypnotic Susceptibility Scale, Form C; the Creative Imagination Scale; ratings of the 'realness' or experienced intensity of each suggestion; and the Field Inventory of Hypnotic Depth (Field, 1965).

The authors conclusion reads as follows: "The results of this study may be summarized as follows: (a) Traditional trance hypnotic inductions and cognitive-behavioral skill inductions were shown to be equally effective in eliciting experiential and behavioral responses to hypnotic suggestions, although trance subjects reported a somewhat greater alteration in conscious experience. (b)

Experimenter modeling was not found to be an effective component of the skill induction package. (c) Subjects' expectancies for hypnotic responses, reported prior to hypnotic induction, bore a very strong relationship to hypnotic responsiveness. (d) A highly credible placebo induction resulted in levels of expectancy and hypnotic responsiveness generally comparable to those produced by trance and skill hypnotic inductions. (e) Absorption was significantly correlated with expectancy, but was not found to be significantly related to responsiveness once variance due to expectancy was taken into account. Thus the relationship between absorption and hypnotic responsiveness appears to be mediated by expectancies.

"In sum, these results suggest that various hypnotic inductions elicit expectancies for responding to hypnotic suggestions and that these expectancies are sufficient to elicit hypnotic responses. Further studies are needed to determine the nature of the relationship between absorption and hypnotic response expectancies" (p. 439).  
hypnotic response expectancies" (p. 439).

Harris, Gina M.; Johnson, Suzanne Bennett (1983). Coping imagery and relaxation instructions in a covert modeling treatment for test anxiety. Behavior Therapy, 14, 144-157.

The present study compared the efficacy of instructing test anxious subjects to use personalized coping imagery based on nonacademic experiences of competence with coping imagery based on academic experiences of competence. The effect of relaxation was also examined and the relationship of imagery elaborateness and content to treatment effectiveness was assessed. Sixty-three subjects were randomly assigned to one of four treatments or a waiting list control group. Test anxiety as measured by a self-report instrument significantly decreased in all treatment groups. Improvement in grade point average occurred for all treatment groups except for academic coping imagery without relaxation which was also the least efficient treatment. The waiting list control group significantly deteriorated in academic performance. Relaxation training did not appear to enhance treatment effectiveness or influence the elaborateness or content of the imagery used. Test anxiety scenes elicited highly response-oriented images by all subjects. However, the stimulus/response content of the subjects' images was not influenced by treatment outcome. In contrast, successful treatment was primarily associated with reduction in negative coping imagery descriptions, although an increase in positive coping statements cured as well.

1980

Bornstein, Philip H.; Devine, David A. (1980). Covert modeling-hypnosis in the treatment of obesity. Psychotherapy: Theory, Research and Practice, 17 (3), 272-276.

Investigated the efficacy of a covert modeling/hypnosis treatment package in the control of obesity. 48 overweight female volunteers (who had been administered the Harvard Group Scale of Hypnotic Susceptibility, Eating Patterns Questionnaire, and Rotter's Internal-External Locus of Control Scale) were randomly assigned to 1

of the following groups: (a) covert modeling/hypnosis, (b) covert modeling, (c) no-model scene control, and (d) minimal treatment (where Ss received a shortened version of the covert modeling/hypnosis procedure following an 8-wk no-treatment period.) Results indicate a significant effect for weight loss from pretreatment to follow-up across all groups combined. Proportion weight loss measures indicated significantly greater weight loss only for the covert modeling/hypnosis group as compared to the no-model controls. Implications for combining behavior therapy and hypnotic techniques are discussed. (30 ref).

Diamond, Michael Jay (1980). The client-as-hypnotist: Furthering hypnotherapeutic change. International Journal of Clinical and Experimental Hypnosis, 28, 197-207.

A novel hypnotic induction technique is described wherein the client reverses roles and serves as hypnotist for the therapist. Relevant theoretical processes are discussed as are mutual hypnosis, modeling, and the uncommon techniques of Erickson (1964). 3 case illustrations are presented and implications discussed. It is hypothesized that the 'client-as-hypnotist' may in certain special situations further hypnotherapy by: (a) increasing client motivation; (b) enhancing therapeutic rapport; (c) increasing both client trust and skills in utilizing unconscious processes; (d) overcoming resistance and increasing hypnotizability; (e) providing a useful psychodiagnostic and behavior assessment index; (f) presenting a role 'model' for dealing with feelings, alterations in consciousness, and self-control; (g) providing a client-centered framework for subsequent therapeutic interventions; (h) increasing client self-esteem, mastery, and ego strength; and (i) increasing client self-control skills. Potential risks and contraindications for use of the technique are also discussed.

and behavior assessment index; (f) presenting a role 'model' for dealing with feelings, alterations in consciousness, and self-control; (g) providing a client-centered framework for subsequent therapeutic interventions; (h) increasing client self-esteem, mastery, and ego strength; and (i) increasing client self-control skills. Potential risks and contraindications for use of the technique are also discussed.

1977

Botto, R. W.; Fisher, S.; Soucy, G. P. (1977). The effect of a good and a poor model on hypnotic susceptibility in a low demand situation. International Journal of Clinical and Experimental Hypnosis, 25, 175-183.

A review of recent studies reveals that there has yet to be a clear demonstration of a behavioral model affecting hypnotic levels. Two studies were conducted to test whether a peer model who portrayed deep or light hypnosis could affect S hypnotizability under minimal demand conditions. Using a low demand version of the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962), the first study showed a difference (Good Model scoring higher than Poor Model) that only approached significance. A replication on a larger sample,

however, showed significantly higher scores for those Ss observing a good model rather than a poor model. Although base scores were not obtained on these Ss, norms from comparable populations suggest that the poor model seems more effective than the good model; but this difference does not appear attributable to differential attitudes created by the models.

Havens, Ronald A. (1977). Using modeling and information to modify hypnotizability. International Journal of Clinical and Experimental Hypnosis, 25, 167-174.

Ss were 117 college students divided into 3 groups. 1 group observed a model being reinforced for hypnotizable behavior, 1 observed a model being punished for hypnotizable behavior, and the third did not observe a model. Previously, each S had completed 1 of 3 randomly-distributed programmed learning texts containing facilitative information about hypnosis, non-facilitative information, or information unrelated to hypnosis. Hypnotizability was subsequently determined by the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962). Significantly higher HGSHS:A scores were obtained from Ss exposed to the reinforced model than from Ss exposed to the punished model. Facilitative information yielded higher HGSHS:A scores than non-facilitative or unrelated information. No interaction effects were obtained. In order for individuals to obtain maximum hypnotic responsiveness, it is desirable that members of the general population not be exposed either to hypnotic Ss being punished or ridiculed and that non-facilitative statements be avoided. Facilitative information presented in a programmed-learning-text format may be a useful technique for enhancing hypnotizability.

1974

Chaves, John F.; Barber, Theodore Xenophon (1974). Cognitive strategies, experimenter modeling, and expectation in attenuation of pain. Journal of Abnormal Psychology, 83 (4), 356-363.

Verbal reports of pain were obtained from 120 subjects during a base-level pretest and also during a posttest conducted under one of several experimental treatments. The pain stimulus was a heavy weight applied to a finger for two minutes. During the posttest, subjects who had been asked to utilize cognitive strategies for reducing pain (to imagine pleasant events or to imagine the finger as insensitive) showed a reduction in pain as compared to uninstructed control subjects. Subjects led to expect a reduction in pain, but not provided with cognitive strategies, also showed reduced pain during the posttest as compared to control subjects, but the reduction was smaller than for subjects using cognitive strategies. An experimenter modeling procedure, used with one half of the subjects under each experimental treatment, was effective in reducing verbal reports of pain only for subjects with high pretest levels who were asked to imagine pleasant events.

Motivation

**2000**

**Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)**

**This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; (3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.**

**1999**

**Bargh, John A.; Chartrand, Tanya L. (1999). The unbearable automaticity of being. American Psychologist, 54 (7), 462-479.**

**What was noted by E. J. Langer (1978) remains true today: that much of contemporary psychological research is based on the assumption that people are consciously and systematically processing incoming information in order to construe and interpret their world and to plan and engage in courses of action. As did E.J. Langer, the authors question this assumption. First, they review evidence that the ability to exercise such conscious, intentional control is actually quite limited, so that most of moment-to-moment psychological life must occur through nonconscious means if it is to occur at all. The authors then describe the different possible mechanisms that produce automatic, environmental control over these various phenomena and review evidence establishing both the existence of these mechanisms as well as their consequences for judgments, emotions, and behavior. Three major forms of automatic self-regulation are identified: an automatic effect of perception on action, automatic goal pursuit, and a continual automatic evaluation of one's experience. From the accumulating evidence, the authors conclude that these various nonconscious mental systems perform the lion's share of the self-regulatory burden, beneficently keeping the individual grounded in his or her current environment.**

Wegner, Daniel M.; Wheatley, Thalia (1999). Apparent mental causation: Sources of the experience of will. American Psychologist, 54 (7), 480-492.

The experience of willing an act arises from interpreting one's thought as the cause of the act. Conscious will is thus experienced as a function of the priority, consistency, and exclusivity of the thought about the action. The thought must occur before the action, be consistent with the action, and not be accompanied by other causes. An experiment illustrating the role of priority found that people can arrive at the mistaken belief that they have intentionally caused an action that in fact they were forced to perform when they are simply led to think about the action just before its occurrence.

In the section on the principle of consistency ("the thought should be compatible with the action"), the authors discuss motor automatisms, including the Chevreul pendulum. "The perceived involuntariness of the movement seems to derive from thought-action inconsistency arising in the sheer unwieldiness of the pendulum. Moving the hand in one direction produces an impulse to the pendulum in the opposite direction, so the control of the movement is like trying to write while looking at one's hand in a mirror. ... The involuntariness of a variety of the motor automatisms appears traceable to movement confusion that interferes with perceptions of consistency (Wegner, in press)" (p. 485). The authors go on to discuss how people in hypnosis come to think that they are automatically doing what the hypnotist suggests. "The development of involuntariness in hypnosis may occur, then, through the learning of a causal interpretation for one's action that leaves out any role for one's own thoughts. This view is consistent with the longstanding notion that hypnosis is an interpretive exercise in which people are encouraged to view their actions as events caused by the hypnotist rather than by their own thoughts (Bowers, 1992; Kihlstrom, 1985; Kirsch & Lynn, 1997). As suggested by Spanos (1982), 'Interpreting behavior as an action involves attributing causality to the self (e.g., I did it), while interpreting it as a happening requires that causality be attributed to sources other than the self (e.g., It happened to me)' (p. 200)" (p. 487).

1997

Barsby, Michael (1997). Hypnosis in the management of denture intolerance. In Mehrstedt, Mats ; Wikstrom, Per-Olof, (Eds.) (Ed.), Hypnosis international monographs : Number 3 : Hypnosis in dentistry (pp. 71-78). Munich Germany: M.E.G.-Stiftung.

Intolerance of dentures may have dental or psychological causes. It is within the latter group of patients, provided that they are genuinely motivated to wear a denture, that the use of hypnosis may be helpful. The importance of careful patient assessment and exploration of appropriate treatment strategies with the patient is emphasised. Principles of treatment including relaxation, controlled breathing, visual imagery and reframing are described. All of these techniques may be used in conjunction with conditioning / desensitisation and a gradual progression to denture wearing.

**Council, James R. (1997). Context and consistency: The Canadian connection. International Journal of Clinical and Experimental Hypnosis, 45 (3), 204-211.**

Issues related to context effects in hypnosis research are briefly reviewed. The contributions of Canadian hypnosis researchers to current theory and research on context effects are acknowledged. Bowers and colleagues at the University of Waterloo emphasized the scope and subtlety of contextual influences on correlates of hypnotic suggestibility, and they promoted the development of a consistency motivation theory of context effects. Spanos and colleagues at Carleton development of a consistency motivation theory of context effects. Spanos and colleagues at Carleton University generalized context effects within the domain of hypnosis, prompting extension of this work to general personality measurement. Implications of findings on consistency motivation for hypnosis research are discussed in terms of person-by-situation interactions. -- Journal Abstract

**Patterson, David R.; Adcock, Rebecca J.; Bombardier, Charles H. (1997). Factors predicting hypnotic analgesia in clinical burn pain. International Journal of Clinical and Experimental Hypnosis, 45 (4), 377-395.**

The use of hypnosis for treating pain from severe burn injuries has received strong anecdotal support from case reports. Controlled studies provide less dramatic but empirically sound support for the use of hypnosis with this problem. The mechanisms behind hypnotic analgesia for burn pain are poorly understood with this patient population, as they are with pain in general. It is likely that, whatever the mechanisms are behind hypnotic pain analgesia, patients with burn injuries are more receptive to hypnosis than the general population. This article postulates some variables that may account for this enhanced receptivity, including motivation, hypnotizability, dissociation, and regression.

**Ready, David J.; Bothwell, Robert K.; Brigham, John C. (1997). The effects of hypnosis, context reinstatement, and anxiety on eyewitness memory. International Journal of Clinical and Experimental Hypnosis, 45 (1), 55-68.**

The effects of hypnosis, context reinstatement, and motivational instructions on accuracy of recall for factual information and facial recognition accuracy following a stressful event were assessed. None of the three techniques had a significant effect on factual memory or susceptibility to suggestion as assessed by true-false and multiple-choice tests. However, participants high in hypnotic susceptibility showed somewhat better memory on the true-false test, and hypnosis affected performance on the two photograph line-ups. In addition, hypnosis appeared to enhance facial recognition accuracy for participants who were low in anxiety, but not for those high in anxiety. Finally, there was evidence of a curvilinear relationship between self-reported anxiety at time of retrieval and facial recognition accuracy. -- Journal Abstract

Ruehle, Beth L.; Zamansky, Harold S. (1997). The experience of effortlessness in hypnosis: Perceived or real. International Journal of Clinical and Experimental Hypnosis, 45 (2), 144-157

Hypnotized individuals who successfully respond to a suggestion typically report that the response requires little or no cognitive effort. It is important, however, to distinguish between whether this effect occurs in actual effort or is only perceived. In addition, the authors distinguish between cognitive effort expended to initiate a response and that required to maintain it. The authors examine the different predictions of four theories-compliance theory, sociocognitive theory (Lynn & Rhue, 1991), Hilgard's (1986) neodissociation theory, and Bowers's (1992) theory of dissociated control-regarding both of these distinctions. Experimental evidence bearing on the various predictions is examined. Additionally, the authors propose a number of design modifications that may help sort out the variables contributing to the effortlessness of the hypnotic response. -- Journal Abstract

1994

Barsby, Michael (1994). The use of hypnosis in the management of 'gagging' and intolerance to dentures. British Dental Journal, 176, 97-102.

Hypnosis is not a therapy but can provide the clinician with a set of techniques which may be used to augment or facilitate a particular course of treatment. The importance of the patient's history and clinical findings in the diagnosis of intolerance to dentures and the selection of patients for hypnosis is discussed. Principles of treatment using relaxation, anxiety control, conditioning / desensitisation and confidence boosting techniques are described. Some examples of typical case histories are used to illustrate the application of a variety of techniques that have been found to be successful.

Wagstaff, Graham F.; Royce, C. (1994). Hypnosis and the treatment of nail biting: A preliminary trial. Contemporary Hypnosis, 11, 9-13.

A clinical trial was conducted examining the relative efficacy of therapeutic suggestions preceded by and without a hypnotic induction in the treatment of nail biting in 17 students. Outcomes showed a hypnotic induction added significantly to therapeutic benefits and was the only condition that resulted in symptom improvement. Results from only one session showed that 7 of 11 hypnosis subjects stopped nail biting compared to only 1 of 6 control subjects. Reports of "believed in efficacy" predicted treatment success better than ratings of motivation, hypnotic induction per se, or scores on the Creative Imagination Scale. However, within the group receiving hypnotic induction, hypnotic- depth scores significantly correlated with treatment success, suggesting that state factors such as dissociation might be involved.

The hypnotized Ss were given the T. X. Barber (1969) induction, a request for their depth estimate on a scale of 0-10, and then a set of suggestions to discourage nail

biting. The suggestions were of four types: (1) to have a positive attitude, that nail biting is a habit that can be broken and that stopping will enhance attractiveness and self esteem; e.g., 'With just a little self control you will stop biting your nails and feel better about yourself.' (2) to stop the habit; e.g. to say to themselves, 'I will not bite my nails today/tomorrow,' five times each morning and at night, and whenever the temptation arose. (3) to improve feelings of self-efficacy; e.g., 'If you ever feel the urge to bite your nails tell yourself that you want to break the habit and that you are perfectly capable of doing so. You are not weak.' (4) that the results would be outstanding; e.g. 'After only ten days or so ... you will have no desire to bite your nails, indeed the very thought of doing so will repulse you.'

Control subjects received the same instructions, without a hypnotic induction; the procedure was labeled a 'positive attitude for self discipline' technique

Judges rated improvement without being aware of the Ss' self-report on whether they had stopped biting their nails. Judges' ratings correlated  $r = .94$  with Ss' statements about whether they had stopped the habit. Improvement scores also correlated significantly with belief the treatment would be effective ( $r = .60$ ) and Creative Imagination Scale scores ( $r = .53$ ), but not with motivation. The hypnosis group had significantly higher belief scores than the control group. Within the hypnosis group itself, hypnotic depth was the only variable to correlate significantly with improvement.

-nificantly with improvement.

The Discussion stated, "However, taken together, the findings indicate that hypnotic induction added significantly to the therapeutic benefits of suggestions for the cessation of nail biting, and that Johnson and Barber's (1978) concept of 'believed-in efficacy' was more important in accounting for therapeutic success than motivation (at least as measured here), hypnotic induction per se, or the subject's proclivity for imaginative involvement. Nevertheless, belief still accounted for less than 40% of the variance in improvement. This may have been due to measurement error or insensitivity in the measures. Alternatively, or additionally, other factors may have been influential. For example, if CIS scores are considered to be indirect measures of hypnotic susceptibility, then belief was more influential than hypnotic susceptibility; however, from a hypnotic state theory perspective, the significant correlation between hypnotic depth (LSS scores) and improvement within the hypnosis group might suggest that some further feature of the 'hypnotic state' could still have been at work, such as a dissociative process (Hilgard, 1986). On the other hand, from a non-state perspective, perhaps subjects receiving hypnotic induction and reporting high depth scores might have felt more obliged to respond to the demand characteristics of the study, and tried harder to please the experimenter (Wagstaff, 1981); the general motivation questions used here could have been insensitive to such an effect" (p. 12).

1993

Page, Roger A.; Handley, George W. (1993). The use of hypnosis in cocaine addiction. American Journal of Clinical Hypnosis, 36, 120-123.

An unusual case is presented in which hypnosis was successfully used to overcome a \$50-0 (five grams) per day cocaine addiction. The subject was a female in her twenties. Six months into her addiction, she acquired a commercial weight-control tape that she used successfully to stop smoking cigarettes (mentally substituting the word "smoking"), as well as to bring her down from her cocaine high and allow her to fall asleep. After approximately 8 months of addiction, she decided to use the tape in an attempt to overcome the addiction itself. Over the next 4 months, she listened to the tape three times a day, mentally substituting the word "coke." At the end of this period, her addiction was broken, and she has been drug free for the past 9 years. Her withdrawal and recovery were extraordinary because hypnosis was the only intervention, and no support network of any kind was available.

Spiegel, David; Frischholz, Edward J.; Fleiss, Joseph L.; Spiegel, Herbert (1993). Predictors of smoking abstinence following a single-session restructuring intervention with self hypnosis. American Journal of Psychiatry, 150, 1090-1097.

Examined the relation of smoking and medical history, social support, and hypnotizability to outcome with Spiegel's smoking-cessation program. A consecutive series of 226 smokers were treated with the single-session approach and followed up for 2 years. With a total abstinence criterion, 52% success was found after 1 week, and 23% abstinence at 2 years. Hypnotizability and having been previously able to quit smoking for at least a month significantly predicted the initiation of abstinence. Hypnotizability and living with a significant other person predicted 2-year maintenance. The results are superior to those of spontaneous efforts to stop smoking and suggest it is possible to predict which patients are most likely to respond and which patients are least likely to respond to such a brief intervention.

1992

Kunzendorf, Robert; Carrabino, Carlene; Capone, Daniel (1992-93). 'Safe' fantasy: The self-conscious boundary between wishing and willing. Imagination, Cognition and Personality, 12, 177-188.

This experiment tested the hypothesis that a fantasy will impel people to 'act out' only if they fail to distinguish the fantasy from the anticipated reality. In the experiment, one task obtained a baseline measure of how long subjects could resist eating popcorn, then measured how long subjects could resist popcorn while fantasizing its taste. Another task instructed subjects to merge three circular images with three circular percepts of equal vividness, then presented subjects unexpectedly with only two of the three circular percepts. Some subjects thought that there were three circular percepts during the merger, and for these subjects, the length of resistance to popcorn was significantly shorter during the popcorn fantasy. But for subjects who self-consciously differentiated the two real circles from the three merging images, the normal 'boundary' between wishful fantasy and willful eating was intact.

This research investigated whether people can fantasize without acting out. The authors place the study in the context of theories proposed by Freud and William James. Kunzendorf's source monitoring theory of self-consciousness suggests that "self-consciousness that one is imaging is the phenomenal consequence of neurally monitoring the central source of one's imaged sensations, and self-consciousness that one is perceiving is the subjective quality of neurally monitoring the peripheral source of one's perceived sensations" (p. 178).

The ability to carry out source monitoring varies. Those who have difficulty monitoring whether they are imaging or perceiving may also have trouble distinguishing wishful fantasy from anticipatory imagery, and therefore they might act on it.

This research "identified subjects with poor source monitoring--nondiscerners of reality--and investigated the effect of fantasy on their impulse control" (p. 179).

#### **METHODS.**

Subjects sat in front of a computer monitor for all tests; they completed Eysenck's seventh impulsivity questionnaire for measures of impulsivity, venturesomeness, and empathy, Marks' Vividness of Visual Imagery Questionnaire (VVIQ).

The study used a test in which subjects maintained in mental imagery a red, green, and yellow filled circle that had been on screen, with eyes closed; were instructed to open eyes and merge their 3 imaginary circles with the 3 on the screen (but when they opened eyes only 2 were there), and they were then asked questions about how many circles they saw when they opened their eyes.

Then they were given a taste of popcorn, told to resist eating any more (but could press a key to receive a little if they couldn't resist), and then were told to resist by imagining that they were eating popcorn.

#### **RESULTS.**

Those who discerned the two real circles while imaging a third circle of equal vividness (the Discerners), could resist eating popcorn for 137 sec in the baseline condition and 132 sec in the fantasy condition. Those who could not discern two real circles while imagining a third (Nondiscerners) could resist eating popcorn for 127 sec in the baseline treatment but only 95 sec in the fantasy treatment.

Discerners could identify the missing circle as the red one, whereas nondiscerners could not do so with any certainty; there was no effect of "image vividness".

"Vivid imagers" whose imagery matched real yellow circles of greater illuminance, exhibited more vivid imagery on the VVIQ as well.

more vivid imagery on the VVIQ as well.

In their Discussion, the authors suggest that "fantasy impels people to 'act out' only if they fail to distinguish fantasized sensations from perceived sensations. ... [the theory] is applicable to sexual fantasy and aggressive fantasy as well. This theory--Kunzendorf's 'source monitoring' theory of self-consciousness--implies that fantasies of the sensory consequences of a behavior should not lead to the behavior, so long as the fantasies are self-consciously known to be imaginal and are not expected to be perceptual... But for people who cannot self-consciously distinguish between wishful images of pure fantasy and anticipatory images of perceptual

reality, between wishing and willing, fantasies of gastronomical, sexual, or aggressive sensations are implicitly unsafe.

"Indeed, as Baars notes, 'the issue of voluntary control is at the very core of human psychopathology' [31, p. 254]. But recently, Baars' and others' theories of volition have emphasized the computer-metaphoric distinction between conscious 'willful' behavior and unconscious 'automatic' action [31, 39-40], and have neglected James' distinction between conscious willing and conscious wishing. Decades ago, when pre-computational theorists like Janet used the term 'automatism' to describe psychopathological behavior, they meant that an abnormally behaving patient was \_consciously 'possessed' by a fantasy\_--a wishful image, a hypnotic suggestion, or a fantasized personality [41]. In reemphasizing the phenomena of wishing, willing, and possession by fantasies, the present article redefines the latter phenomenon as possession by 'unmonitored' fantasies, which are distinguishable from anticipatory images impelling action" (pp. 184-185).

1992

Spanos, Nicholas P.; Simulates, Ann; de Faye, Barbara; Mondoux, Thomas J.; Gabora, Natalie J. (1992-93). A comparison of hypnotic and nonhypnotic treatments for smoking. Imagination, Cognition and Personality, 12, 23-43.

Three experiments administered variants of Spiegel's (1970) smoking cessation procedure to smokers in hypnotic and nonhypnotic treatments. Follow-up periods were from twelve to twenty-four weeks depending on the experiment. Complete abstinence was an infrequent outcome in all three experiments. Greater-than-control reductions in smoking for treated subjects were obtained in two of the experiments but, in both cases treatment and control subjects failed to differ significantly before the end of the follow-up period. Hypnotic and nonhypnotic treatments produced equivalent smoking reductions in all studies, and neither hypnotizability nor questionnaire assessments of motivation to quit correlated significantly with treatment outcome. Implications are discussed.

When the experimenters compared number of treatments they simply compared two sessions of Spiegel's one-session treatment with four sessions of it. The authors make the point that perhaps they should vary the four sessions.

"In all three of the present experiments the abstinence rates associated with the Spiegel treatment were very low. Our abstinence rates were similar to those reported in one earlier study [4 - Perry et al.], but substantially lower than those reported in three other studies [2, 22, 25]. The reasons for these discrepancies between studies remains unclear, but experiment 3 suggests that these discrepancies cannot be accounted for simply in terms of whether the subjects were drawn from a university or nonuniversity population, and experiment 2 suggests that the discrepancies are unrelated to the number of treatment sessions administered to subjects.

"The finding that hypnotic and nonhypnotic subjects in all three experiments attained equivalent reductions in smoking is consistent with other comparison studies in this area which indicate that hypnotic treatments are no more effective than various nonhypnotic procedures at inducing reductions in smoking [22, 25, 30].

More generally, these findings are consistent with comparison studies on a wide variety of clinical disorders (headache pain, warts, phobias, obesity) which indicate that hypnotic treatments are no more effective than nonhypnotic ones at producing therapeutic change (see [3] for a review).

1991

Sheehan, Peter W. (1991). Hypnosis, context, and commitment. In Lynn, S. J.; Rhue, J. W. (Ed.), Theories of hypnosis: Current models and perspectives (pp. 520-541). New York: Guilford Press.

"There are several different ways to classify the model that is expounded in this chapter. One may view it ... as an individual-differences model of hypnosis, because it emphasizes the significance of intragroup differences in the pattern of hypnotic performance. Alternatively, one may view it as a phenomenologically based model... Invariably, however, single categories fail to do justice to the nature of theories, and hence it is perhaps wisest to view this theory as a means of exploring particular hypotheses about hypnotic phenomena that focus primarily on the meaning of suggestion as perceived by susceptible subjects. This model focuses, in a way that most other theories do not, on the motivational implications of the cognitive involvement of the susceptible subject in the events of the hypnotic setting. It offers a variant of contextual theories of psychological functioning, but is experiential in its emphasis rather than simply behavioral" (p. 537).

1988

Pavia, M.; Stanley, R. O. (1988). Effect of defining induction as hypnosis or relaxation. Australian Journal of Clinical and Experimental Hypnosis, 16, 11-21.

Previous studies have shown that the perceived definition of an induction may sometimes affect the subject's responses to the induction. These variations in the effect of induction definition may be due to interactions between a subject's motivations and expectations of the induction technique and the way the induction is defined. These authors explored this interaction with groups of clinical and student subjects. Differing definitions of induction as 'hypnosis' or 'relaxation' did not result in significant differences in response among either group, though subjects in neither group were found to have high expectations of motivation (sic).

1986

Markus, Hazel; Nurius, Paula (1986). Possible selves. American Psychologist, 41 (9), 954-969.

The concept of possible selves is introduced to complement current conceptions of self-knowledge. Possible selves represent individuals' ideas of what they might become, what they would like to become, and what they are afraid of becoming, and thus provide a conceptual link between cognition and motivation. Possible selves are the cognitive components of hopes, fears, goals, and threats, and they give the specific self-relevant form, meaning, organization, and direction to these dynamics.

Possible selves are important, first, because they function as incentives for future behavior (i.e., they are selves to be approached or avoided) and second, because they provide an evaluative and interpretive context for the current view of self. A discussion of the nature and function of possible selves is followed by an exploration of their role in addressing several persistent problems, including the stability and malleability of the self, the unity of the self, self- distortion, and the relationship between the self-concept and behavior

**Bolocofsky, David N.; Spinler, Dwayne; Coulthard-Morris, Linda (1985). Effectiveness of hypnosis as an adjunct to behavioral weight management. Journal of Clinical Psychology, 41 (1), 35-41.**

**109 17-67 year olds completed a behavioral treatment for weight management either with or without the addition of hypnosis. Results show that, at the end of the 9-week program, both interventions resulted in significant weight reduction. However, at 8-month and 2-year follow-ups, the hypnosis Ss showed significant additional weight loss, while those in the behavioral-treatment-only group exhibited little further change. More Ss who used hypnosis also achieved and maintained their personal weight goals. It is suggested that hypnosis may have been an effective motivator for Ss to continue practicing the more adaptive eating behaviors acquired during treatment. Findings support the utility of employing hypnosis as an adjunct to a behavioral weight management program. (25 ref)**

**Pajntar, Marjan; Jeglic, Anton; Stefancic, Martin; Vodovnik, Lojze (1980). Improvements of motor response by means of hypnosis in patients with peripheral nerve lesions. International Journal of Clinical and Experimental Hypnosis, 28 (1), 16-26.**

**In order to accelerate rehabilitation of patients with peripheral nerve lesions, hypnosis was employed to encourage them voluntarily to move those muscles with weak re-innervation and to achieve the best possible activity of the affected muscle groups. By measuring muscle force and endurance and by observing the electrical activity of the affected muscles, it was found that the activity of the affected muscles was much better while patients were in hypnosis than when they were in the waking state. The patients were able to contract even paretic muscles having only weak re-innervation with such strength, that clinically perceptible contraction of the muscles and movement of paretic extremities occurred. Such early and improved activation is very important for prevention of much permanent damage.**

**Jackson, J. Arthur; Gass, Gregory C.; Camp, Elizabeth M. (1979). The relationship between posthypnotic suggestion and endurance in physically trained subjects. International Journal of Clinical and Experimental Hypnosis, 27, 278-293.**

55 male Ss were assigned to 5 groups: control, hypnosis alone, motivation alone, low susceptible hypnosis with motivation, or high susceptible hypnosis with motivation. Ss performed 2 runs on a treadmill to their maximum capacity, as measured by oxygen consumption, blood lactate concentration, and respiratory quotient. Groups involving hypnosis performed in the posthypnotic state. A significant increase in endurance performance was revealed in the motivation alone Ss and in high susceptible hypnosis Ss who were given motivational suggestions. Maximum ventilation was significantly increased in high susceptible hypnosis Ss when compared with control Ss and significant increases in blood lactate concentrations were revealed when the high susceptible hypnosis Ss were compared with low susceptible hypnosis and motivation alone Ss. The reasons for the changes in metabolic variables are discussed. Findings demonstrated that in achieving greater endurance performance, motivational suggestions alone are as effective as identical suggestions given to high susceptible Ss.  
identical suggestions given to high susceptible Ss.

Perry, Campbell; Gelfand, Robert; Marcovitch, Phillip (1979). The relevance of hypnotic susceptibility in the clinical context. Journal of Abnormal Psychology, 88 (5), 592-603.

Despite experimental evidence that hypnotic susceptibility is a relatively stable characteristic of the individual, and one that is very difficult to modify, clinical investigators tend to see susceptibility as irrelevant to therapeutic outcome. Such investigators view motivational and interpersonal variables as more essential to the therapeutic change. The evidence for the clinical relevance of hypnotizability is sparse and contradictory. Most existing studies stem from medical hypnosis and indicate that susceptibility plays an important role in the successful treatment of such conditions as clinical pain, warts, and asthma. Two studies are reported that seek to pursue a contrary finding reported by Perry and Mullen, who found that susceptibility was unrelated to the successful treatment of a socially learned behavior (cigarette smoking). Both studies confirmed the earlier finding of a lack of relation. In Study 1, however, stepwise multiple regression analysis located three inventory items concerning the motivation of cigarette smokers. The combination of items was found to predict outcome for 67.39% of 46 clients treated either by hypnosis or by rapid smoking. The finding was replicated in Study 2, which utilized a combined hypnosis - rapid smoking technique and employed a different therapist. The outcome for 9 of the 13 quitters and 37 of the 62 nonquitters across the two studies could be predicted by the three motivational questionnaire variables.

Jackson, T. L.; Barkley, R. A.; Pashko, S. M. (1976). The effects of hypnotic induction versus high motivation on oral temperature. International Journal of Clinical and Experimental Hypnosis, 24, 22-28.

The hypothesis that changes in oral temperature are associated with neutral hypnotic induction was investigated using neutral hypnosis and a high motivation

condition as controls. 33 Ss were assigned to 3 experimental conditions: (1) neutral hypnotic induction, (2) high motivation control, and (3) no treatment control. Ss in all 3 conditions received pre- and post-treatment oral temperature measurements after a 20-minute temperature stabilization showed a significantly greater increase in oral temperature as compared to Ss in both the high motivation and no treatment control conditions. Ss in the latter 2 conditions did not differ from each other in this regard. The methodological considerations of future research in this area are also discussed.

London, Perry (1976). Kidding around with hypnosis. International Journal of Clinical and Experimental Hypnosis, 24 (2), 105-121.

This paper reviews a long term research project relating hypnotic susceptibility to performance and personality variables. Several experiments indicated that people who are low in hypnotic susceptibility try harder than high susceptibles for maximum performances on strength, endurance, psychomotor coordination, and cognitive tests, though high susceptibles are generally more pleased with their own performances. Other experiments indicated that people of high hypnotic susceptibility have slower brain-wave patterns under relaxed, nonhypnotic conditions, than do low susceptibles. These findings, together with a third set of findings on the developmental character of hypnotic susceptibility, led to the theory that

-mental character of hypnotic susceptibility, led to the theory that hypnotic susceptibility and brain-wave patterns are both inversely correlated with achievement motivation and with its developmental roots in childhood independence training. An elaborate research program was initiated to investigate the hypothesized relationships.

Aletky, Patricia J.; Carlin, Albert S. (1975). Sex differences and placebo effects: Motivation as an intervening variable. Journal of Consulting and Clinical Psychology, 43 (2), 278.

" ... the present findings would suggest that future studies of placebo effects should take into account the nature of the dependent variable and the pertinent differential sex-role expectations" (p. 278). The performance measure was a dynamometer pull task. The placebo was a jelly applied to the forearm "and alleged to relieve muscular fatigue" (p. 278). The motivational instructions were telling Subjects that "individuals in good health and with normal muscle tonus would be expected to show improved performance on the posttreatment trial" (p. 278).

Lick, John R. (1975). Expectancy, false galvanic skin response feedback, and systematic desensitization in the modification of phobic behavior. Journal of Consulting and Clinical Psychology, 43 (4), 557-567.

This study compared systematic desensitization and two pseudotherapy manipulations with and without false galvanic skin response feedback after every session suggesting improvement in the modification of intense snake and spider fear. The results indicated no consistent differences between the three treatment groups, although all treatments were significantly more effective than no treatment in modifying physiological, behavioral, and self-report measures of fear. A 4-month follow-up showed stability in fear reduction on self-report measures for the three treatment groups. Overall, the results of this experiment were interpreted as contradicting a traditional conditioning explanation of systematic desensitization. An alternate explanation for the operation of systematic desensitization emphasizing the motivational as opposed to conditioning aspects of the procedure is discussed.

Crasilneck, Harold B.; Hall, James A. (1970). The use of hypnosis in the rehabilitation of complicated vascular and post-traumatic neurological patients. International Journal of Clinical and Experimental Hypnosis, 18 (3), 152-158.

Hypnotherapy has been found of value in rehabilitation of many patients experiencing difficulty in the usual procedures which follow cerebrovascular or traumatic brain injury. 3 cases are reported to illustrate the approach taken. Of 25 similar cases seen over a 9-year period, 4 were unresponsive to hypnosis. Although an increase in motivation for recovery seemed to be the major change elicited by hypnotherapy, other theoretical possibilities are mentioned. Hypnosis may be a useful way of approaching motivational problems in rehabilitating patients who manifest negativism toward conventional treatment.

1969

Secter, Irving I.; Tremaine, Donahue L. (1969). The psychology of learning applied to hypnosis. American Journal of Clinical Hypnosis, 11, 191-194.

Some generally held principles of learning have been stated. The statements hold even when the word 'hypnosis' is substituted for the word 'learning.' Teaching does not guarantee learning. A hypnotic induction verbalization does not guarantee the development of hypnotic states. The process and the learner would seem to be of greater importance than the teacher or hypnotist. The latter's main function should be to create a favorable environment for learning and to help remove the obstacles to learning. When the resistances to learning are inoperative, induction of hypnosis takes place rapidly

Thorne, D. Eugene (1969). Amnesia and hypnosis. International Journal of Clinical and Experimental Hypnosis, 17, 225-241.

Explored the relative effects of 2 factors on short-term memory for a paired-associate learning task. 36 undergraduate and graduate paid volunteers were stratified, according to their Harvard Group Scale of Hypnotic Susceptibility, Form A scores, into 3 groups of 12 Ss each. The Ss within each of the 3 groups were then

evenly but randomly assigned to 3 treatment conditions, which differed in terms of the kind of motivational procedure in which suggestions of amnesia for a recently learned paired-associate task were given. Results did not directly support or were sometimes contrary to predictions derived from popular hypnosis theories, which assert that posthypnotic amnesia is a reliable behavioral criterion for the "hypnotic state." **1965**

Evans, Frederick J.; Orne, Martin T. (1965). Motivation, performance, and susceptibility to hypnosis. International Journal of Clinical and Experimental Hypnosis, 13 (2), 103-116.

Earlier reports found that the waking base level performance of Ss who are relatively insusceptible to hypnosis is higher than the waking base level of highly susceptible Ss on tasks of muscular strength, endurance, coordination, and verbal learning and that any increment in performance under hypnosis tends to be at least as great with insusceptible Ss as with highly susceptible Ss. These previous studies were carefully replicated, but the results were not confirmed. No differences in base level or hypnosis performance were found, except for poorer hypnosis performance of Ss of medium susceptibility to hypnosis, arising in part from the emphasis on relaxation in the induction procedure, and in part because of subtle demand characteristics present in the counterbalanced experimental design. Furieux, W. D. (1963). Neuroticism, Extraversion, answer suggestibility: A comment. International Journal of Clinical and Experimental Hypnosis, 11, 201-202.

Author develops hypotheses about the relationships between scores on the Maudsley Personality Inventory (MPI) and suggestibility.

"(a) The effective-drive experienced by a S in a suggestibility test, or hypnosis situation, is positively correlated with both neuroticism and with extraversion, as measured by the MPI.

(b) Effective-drive is also a function of the "press" of the test situation, and of the S's previous experience.

(c) Within the range of values of effective-drive lower than the Yerkes-Dodson optimum for the test being studied, the magnitude of response to a suggestibility test (or hypnosis) is a positive function of drive.

(d) For values of effective-drive greater than the Yerkes-Dodson optimum, response is a negative function of drive" (p. 201).

Fowler, William L. (1961). Hypnosis and learning. International Journal of Clinical and Experimental Hypnosis, 9, 223-232.

3 studies are reported in which hypnotic suggestion was used for the purpose of increasing the motivation and self-confidence of college students suffering reading difficulties. While the subjects reported a variety of benefits, objective tests provided no evidence that hypnosis did improve reading performance. From *Psyc Abstracts* 36:04:4II23F. Furneau, W. D. (1961). Neuroticism, extroversion, drive, and suggestibility. *International Journal of Clinical and Experimental Hypnosis*, 9, 195-214. (Abstracted in *Psychological Abstracts*, 62: 4 II 95F)

In the group studied, the body-sway scores of stable extraverts and neurotic introverts tended to be large, whereas they were smaller for stable introverts and neurotic extraverts. This result was explained in terms of a theoretical model in which the effective drive produced in a S by a test-situation is a function of both his neuroticism and his extraversion. The author believes that the theoretical model generates a number of predictions and suggestions which can serve to guide future experimental work in this field. From *Psyc Abstracts* 36:04:4II95F. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Pearson, R. E. (1961). Response to suggestion given under general anesthesia. *American Journal of Clinical Hypnosis*, 4, 106-114.

Employed a double-blind design with placebo control. Audio tapes containing therapeutic suggestions were played to 43 experimental patients during anesthesia. The main theme of the suggestions was that the patient would cope better and recover faster if he could become relaxed. Placebo tapes (music or blank tapes) were played to the 38 control patients. Only E, who had no contact with the patients, knew which tape was played to a given patient. Three postoperative variables were studied: (a) number of doses of narcotics in the first 5 postoperative days; (b) a numerical rating by the surgeon of the postoperative course; and (c) number of postoperative days until release. Although no significant differences were found between the suggestion group and placebo group on need for narcotics or rated course of recovery, patients receiving suggestions were discharged an average of 2.42 days sooner ( $p < .05$ ).

Schneck, Jerome M. (1961). Hidden determinants in deceptive requests for hypnoanalysis. *International Journal of Clinical and Experimental Hypnosis*, 9, 261-267. (Abstracted in *Psychological Abstracts*, 62: 4 II 61S)

Evaluation of the motives underlying the request for hypnoanalysis leads to the conclusion that often these patients do not wish for this form of treatment at all. Thus, requests for hypnoanalysis are often deceptive (a method of changing therapists during a period of negative transference). The implications of these hidden determinants are discussed and brief case references are given. From *Psyc*

Salzberg, Herman Carl (1960). The effects of hypnotic, posthypnotic, and waking suggestion on performance using tasks varied in complexity. International Journal of Clinical and Experimental Hypnosis, 8, 251-258.

This article probably is based on the dissertation, reported as follows in the PsychInfo database:

An experimental investigation of the differential effects of hypnotic, post-hypnotic and waking suggestion on learning, with tasks varied in complexity

AU: Salzberg, Herman Carl

SO: Dissertation Abstracts. 21, 1961, pp. 2017-2018

AB: 5 Ss were instructed to respond with a reaction time key to colors and figures presented tachistoscopically. In the 1st series of experiments a steady reaction to figures (with the right hand) and to colors (with the left hand) was established. In the 2nd series figures and colors were presented 1 by 1 at random, and the Ss had to react according to the previously established habit. In the 3rd series combinations of figures and colors were shown and the Ss had to react with both hands at the same time. 4 different types of reactions were observed in the last series depending upon the shifting or the distribution of attention. Conn, Jacob H. (1958). Meanings and motivations associated with spontaneous hypnotic regression. Journal of Clinical and Experimental Hypnosis, 6 (1), 21-44.

"The motivational influences and meanings associated with spontaneous regression have been discussed. It is postulated that when a patient spontaneously regresses he has the wish to recreate a previous life situation --one in which he was completely helpless. The clinical material indicates that the patient can be brought out of regression without any attempt being made to re-orient him to the present, and during spontaneous regression the patient can discuss topics which are subsequent to the regressed age level. The patient does not revive old memories but 'memory romances' which are rationalizations and wish fulfilling fantasies.

"The patient in the hypnotic trance is not passive, but is an active agent, who uses the therapist as a means of restoring the patient's feeling of mastery and control. A painful, baffling life situation which formerly had been the source of conflict, guilt or self-depreciation is in this manner mastered, so that the patient can start all over again as if he were 'reborn,' and can go on to a normal, healthy way of life.

"This is in keeping with Whitehorn's view (16) that 'symptoms have meaning in a motivational sense, that morbid patterns of reaction are part of an adaptational struggle, that one of the main tasks in psychiatric work is to conduct an

individualized study of each patient to point up the main recurrent theme of dissatisfaction and conflict and to assess the individual's currently unused potentialities for dealing with this issue ..." (p. 42).

Rosenberg, M. J.; Gardner, C. W. (1958). Some dynamic aspects of posthypnotic compliance. Journal of Abnormal and Social Psychology, 57, 351-366.

Within the context of a general, psychoanalytically-oriented theory of hypnosis there were presented two hypotheses on the nature of compliance with posthypnotic suggestions. According to the first, such compliance is viewed as facilitated by the subjects being able to interpret the posthypnotic suggestion in a manner consistent with the mechanisms and affective reactions that, for him, characterize and maintain the hypnotic relationship. In the second, compliance with a posthypnotic suggestion is viewed as facilitated if that suggestion permits the subject safely to express and indulge a previously warded-off and conflicted drive. Case record data drawn from a recent experimental study were presented which tend to confirm these two hypotheses.

1955

Meares, Ainslie (1955). A note on the motivation for hypnosis. Journal of Clinical and Experimental Hypnosis, 3 (4), 222-228. (Abstracted in Psychological Abstracts 57: 1129)

"Summary. The logical reasons of the patient for desiring hypnosis, and of the therapist in advising it, operate on a background of unconscious mechanisms. These mechanisms are important factors in determining whether or not the logical reasons become effective. An understanding of such motivation helps the therapist in the selection of cases and the choice of the particular form of hypnotherapy to be used" (p. 228).

Patient motivations for hypnosis include magical expectations, paranoid belief that one is under the control of a malevolent influence, a (paradoxical) belief that hypnosis will be ineffective with neurotic symptoms and therefore justify continuation of the symptoms, latent aggression ("hypnotize me if you can" attitude) or an excess of passivity ("humiliate me"), erotic motivation or a wish for a more intimate relationship with the therapist, search for new or unusual experiences in life, a last ditch effort to cope with chronic pain and illness, etc.

Patient motivations against hypnosis include fear of being overpowered or the threat of authority, aggressive feelings that would be motivated if the hypnotist seems to be an authority, or association of hypnosis with the erotic. The author has observed "a surprising number of people" with the latter association. "With these people, it is more of an attitude of mind in which any close or intimate relationship is regarded as erotic. They see in hypnosis an intimate relationship with the therapist, and they avoid it without being aware of their reasons for doing so" (p. 226).

Therapist motivations for hypnosis include unconscious mechanisms as well, such as a drive for power (sometimes manifested in desire to demonstrate the technique to a wider audience than simply colleagues in a workshop). When tinged with eroticism the drive can become sadistic. Also, erotic drives can find vicarious expression as "The intensity of the rapport between patient and psychotherapist in waking psychotherapy, is increased many times in hypnosis" (p. 227).

Therapist motivations against hypnosis include fear of failure (which is more obvious when a patient doesn't follow a suggestion than in lack of response to medicine), fear of erotic involvement, fear of one's own aggression, etc.

Kirkner, Frank J.; Dorcus, R. M.; Seacat, Gloria (1953). Hypnotic motivation of vocalization in an organic motor aphasic case. Journal of Clinical and Experimental Hypnosis, 1 (3), 47-49.

Authors' Summary - A 41 year old male patient with a history of mutism on an organic basis for a year and a half failed to respond to speech retraining efforts. Comprehension was good and motivation poor. With the aid of hypnosis, he was induced to vocalize. Following vocalization, oral speech retraining progress was steady. Retraining efforts in writing met with repeated failure.

The patient had suffered a cerebral vascular accident, attributed at the time to an embolism.

Movement

1997

Jasiukaitis, Paul; Nouriani, Bitia; Hugdahl, Kenneth; Spiegel, David (1997). Relateralizing hypnosis: Or, have we been barking up the wrong hemisphere?. International Journal of Clinical and Experimental Hypnosis, 45 (2), 158-177.

Research and theory over the past couple decades have suggested that the right cerebral hemisphere might be the focus of brain activity during hypnosis. Recent evidence from electrodermal responding, visual event-related potentials, and Stroop interference, however, can make a case for a role of the left hemisphere in some hypnotic phenomena. Although hemispheric activation on hypnotic challenge may depend in large part on the kind of task the challenge might involve, several general aspects of hypnosis might be more appropriately seen as left-rather than right-hemisphere brain functions. Among these are concentrated attentional focus and the role of language in the establishment of hypnotic reality. A left-hemisphere theory of hypnosis is discussed in light of recent findings and theories about a left-hemisphere basis for synthetic or generational capabilities (Corballis, 1991) and a neuro-evolutionary model of a left-hemisphere dopaminergic activation system for the implementation of predetermined motor programs (Tucker & Williamson, 1984). -- Journal Abstract

1996

**Dane, Joseph R. (1996). Hypnosis for pain and neuromuscular rehabilitation with multiple sclerosis: Case summary, literature review, and analysis of outcomes. International Journal of Clinical and Experimental Hypnosis, 44 (3), 208-231.**

Videotaped treatment sessions in conjunction with 1-month, 1-year, and 8-year follow-up allow a unique level of analysis in a case study of hypnotic treatment for pain and neuromuscular rehabilitation with multiple sclerosis (MS). Preparatory psychotherapy was necessary to reduce the patient's massive denial before she could actively participate in hypnosis. Subsequent hypnotic imagery and posthypnotic suggestion were accompanied by significantly improved control of pain, sitting balance, and diplopia (double vision), and a return to ambulatory capacity within 2 weeks of beginning treatment with hypnosis. Evidence regarding efficacy of hypnotic strategies included (a) direct temporal correlations between varying levels of pain relief and ambulatory capacity and the use versus nonuse of hypnotic strategies, (b) the absence of pharmacological explanations, and (c) the ongoing presence of other MS-related symptoms that remained unaltered. In conjunction with existing literature on hypnosis and neuromuscular conditions, results of this case study strongly suggest the need for more detailed and more physiologically based studies of the phenomena involved. - Journal Abstract

**Montgomery, Guy; Kirsch, Irving (1996). The effects of subject arm position and initial experience on Chevreul pendulum responses. American Journal of Clinical Hypnosis, 38 (3), 185-190.**

Some clinicians maintain that responses to the Chevreul pendulum illusion are facilitated by resting one's elbow on a table. Others claim the reverse. We compared these two methods in a counterbalanced crossover design by having 32 counterbalanced crossover design by having 32 university students perform the Chevreul pendulum illusion with their elbows supported on a table and with their elbows unsupported. Although there was no main effect for method (elbow supported versus elbow unsupported), subjects who rested their elbows on a table on the first trial were more successful in responding on both trials. This suggests that supporting the elbow does facilitate responding, but only on the initial trial. Performance on subsequent trials is determined by degree of success on the first trial. Similar data from a previous study comparing different hypnotic inductions suggests that this phenomenon is generalizable beyond the Chevreul pendulum illusion and supports the hypothesis that the test-retest reliability of suggestibility scales may be due to a stabilization of response expectancy by a person's first experience of imaginative suggestions.

**Weitzenhoffer, Andre M. (1996). Catalepsy tests: What do they tell us?. International Journal of Clinical and Experimental Hypnosis, 44 (4), 307-323.**

In a survey of 200 clinicians regarding their use of catalepsy tests, three fourths of the respondents indicated that they used these tests. In light of this response, and considering both the scientific importance of being able to identify the presence of

hypnosis and the fact that catalepsy may account for up to eight of the other indications of hypnosis in use, it is relevant to inquire into the reliability and validity of catalepsy tests. It was found that of the three tests of catalepsy currently in use, only one has the potential for being a test of hypnosis proper and can also justifiably be said to be "of catalepsy." This one test, however, has many serious weaknesses that need to be eliminated if it is to be truly useful. - Journal Abstract

1993

Gruzelier, John; Warren, Kristen (1993). Neuropsychological evidence of reductions on left frontal tests with hypnosis. Psychological Medicine, 23, 93-101.

Individuals with high and low susceptibility to hypnosis were compared in a baseline condition and after instructions of hypnosis on tests of anterior left and right hemispheric functions of word fluency to letter categories, word fluency to semantic categories, design fluency and bilateral finger tapping dexterity. With hypnosis high susceptibles showed a reduction in word generation to letter categories, no significant change in word generation to semantic categories, an improvement in design fluency, and bilateral reductions in finger tapping dexterity. Low susceptibles showed the opposite changes except for the improvement in design fluency. These results, together with correlational results, were interpreted as evidence of central inhibitory processes, particularly of the left hemisphere, in response to instructions of hypnosis in high susceptibles.

The authors discussion of their study includes the following statements. "The main result of the study was the differential influence of instructions of hypnosis on high and low susceptibles for word fluency to letter designated categories, as distinct from semantic categories, and design fluency" (p. 98).

"The absence of effects of hypnosis on word generation to semantic categories (left fronto-temporoparietal) versus letter categories (left frontal) has a bearing on evoked potential evidence (Gruzelier et al. 1987). Bilateral comparisons at temporal lobe and central locations showed that high susceptibles were characterized by asymmetric changes in evoked

potential amplitude (N116 component) with hypnosis. Activity at the central electrodes was compatible with a left-to-right hemispheric shift of function, but this was not the case at the temporal electrodes. Instead of an inhibition of left temporal activity with hypnosis activation was maintained. Maintenance of activity in the left temporal lobe follows consideration of the fact that hypnosis requires sustained attention to the voice of the hypnotist, which is predominantly a left temporal function" (p. 99).

"The absence of differences in the pre-hypnotic condition between high and low susceptibles indicates that hemisphericity per se may not be a factor that characterizes susceptibility. The fact that lateral differences were found in some experiments (e.g. Gruzelier et al. 1984; Gruzelier & Brow, 1985) but not others (e.g. Cikurel & Gruzelier, 1990; McCormack & Gruzelier, 1993) may indicate that such effects, when apparent, were secondary to another factor such as cognitive flexibility as conceptualized by Crawford (1989)" (p. 99).

Lyskov, E.; Juutilainen, J.; Jousmaki, V.; Hanninen, O.; Medvedev, S.; Partanen, J. (1993). Influence of short-term exposure of magnetic field on the bioelectrical processes of the brain and performance. International Journal of Psychophysiology, 14, 227-231.

The influence of an extremely-low-frequency (ELF) magnetic field on the bioelectrical processes of brain and performance was studied by EEG spectral analysis, auditory-evoked potentials (AEP), reaction time (Roletaking) and target-deletion test (TDT). Fourteen volunteers were exposed for 15 min to an intermittent (1 s on/off) 45- Hz magnetic field at 1000 A/m (1.26 mT). Each person received one real and one sham exposure. Statistically significant increases in spectral power through alpha- and beta- bands, as well as in mean frequency of the EEG spectrum were observed after magnetic field exposure. Field-dependent changes of N100 were also revealed. No changes in the amplitudes or latencies of the earlier peaks were observed. No direct effects on Roletaking, nor on TDT performance were seen. However, practice effects on Roletaking (decrease of Roletaking in the course of the test-sessions) seemed to be interrupted by exposure to the magnetic field.

Morgan, William P. (1993, October). Use of hypnosis in exercise and sport psychology. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Performance of exercise is rated as equal effort with hypnosis and waking conditions; but with hypnotic suggestion they will perceive it as more or less effortful (uphill exercise vs going down the hill). When they think they are going up hill both cardiac and respiratory response increase physiologically, with catecholamine differences.

Mitchell (1981) suggests that respiration changes with exercise do not result from muscle feedback, but that central motor brain signals go to both the cardiovascular centers and to exercising muscle. Actually, it appears that both muscle and cortex give signals, and their synergy governs whether ventilation or heart rate increase.

Wang & Morgan, Psychophysiological responses to imagined exercise, Sport Psychology Lab, University of Wisconsin-Madison. Reported that both external (watching someone else) and internal (imagining oneself) visualizing give responses similar to actual exercise.

We have done research on the prediction of respiratory distress (dyspnea) - work we have done with fire fighters. The best predictor of this on treadmill with air supply is trait anxiety. Sometimes the firefighters who took off face mask even though they had air did not know why they did. It is an opportunity to use hypnotic age regression. SCUBA divers described in Lynn & Rhue also were age regressed to obtain information that was repressed. They have demonstrated stress responses like panic in a 12 foot tank also.

Sometimes the firefighters who took off face mask even though they had air did not know why they did. It is an opportunity to use hypnotic age regression. SCUBA

divers described in Lynn & Rhue also were age regressed to obtain information that was repressed. They have demonstrated stress responses like panic in a 12 foot tank also.

For active people and athletes there is an "iceberg" profile on the POMS, below average on tension, depression, anger, fatigue, and confusion, but higher on vigor. But the divers who panic have a flat profile, around the 50th percentile on all POMS scales.

Middleman et al used Navy divers in 25 degree C. water and used hypnosis to increase and decrease their body temperature--one of the best papers on the topic. Ss who were best able to use imagery, to think of a beach, had the poorest responses; the ones who could relax did poorest, because shivering produces heat and keeps you warm. It is opposite of what is needed.

In our work, we took 5 highest and 5 lowest anxiety Ss; the latter had higher rates of respiration than the former.

All Ss are similar in oxygen use whether volunteers or not. When people volunteer for research before they know hypnosis will be used, the males are lower than females [on hypnotizability?] when they finally volunteer. [He presents a lot of different tests on which volunteers do not differ from nonvolunteers personality wise.]

Ikai & Steinhaus is a classic study of Disinhibition of Inhibitory Mechanisms. Taking Ss up to their maximum (in weight training) to a plateau, Ikai & Steinhaus said this is a pseudomaximum. They showed that strength increases if - you fire a starter pistol behind them - you ask them to shout just as they do it - they have alcohol - they have amphetamine sulfate - they have hypnosis It is disinhibition of the inhibitory mechanisms.

[He referred to the book Mind of the Marathoner.]

In Tibet an anthropologist was amazed to see a man running into their camp, and he ran straight through--a monk carrying messages. He created a non-cultic form of meditation in the laboratory (trained to visually "fix" on mountaintop, to have respiration in synchrony with locomotion, and to use a pseudo mantra "down" each time they put their foot down). Placebo condition was used also. Ss were tested by blinded lab assistants. Endurance time increased from 16 minutes to 20, while controls decreased a minute.

Now we can predict who will win a race. Elite runners do not dissociate; they use association strategy. They pay close attention to race strategy, they monitor themselves constantly (they slow down when they feel bad), and attempt informally to stay loose, not get tight, and relax. Dissociation has, however, been used for the last 300 meters of a marathon (New Zealander Dixon).

1992

Appel, Philip R. (1992). Performance enhancement in physical medicine and rehabilitation. American Journal of Clinical Hypnosis, 35, 11-19.

Performance enhancement or mental practice is the "symbolic rehearsal of a physical activity without any gross muscular movements" to facilitate skill acquisition and to increase performance in the production of that physical activity.

Performance- enhancement interventions have been well known in the area of sports psychology and medicine. However, clinical applications in physical medicine and rehabilitation have not flourished to the same extent, though the demand for improved physical performance and the acquisition of various motor skills are as important. In this paper I will describe how hypnosis can potentiate mental practice, present a model of mental practice to enhance performance, and describe how to help patients access an ideal performance state of consciousness.

a model of mental practice to enhance performance, and describe how to help patients access an ideal performance state of consciousness.

**Goodman, Linda; Holroyd, Jean (1992). Ego receptivity and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 40 (2), 63-67.**

Ego receptivity has been described as important for the psychotherapy process and as a characteristic of hypnosis (Deikman, 1974; Dosamantes-Alperson, 1979; Fromm, 1979). Receptivity also has been associated with a measure of absorption (Tellegen, 1981). In the first pilot study with 6 dance/movement therapy students, higher observer ratings of receptivity were associated with greater hypnotizability ( $r = .79$ ,  $df = 4$ ,  $p < .05$ , 2-tailed test). In the second pilot study, the correlation was replicated ( $r = .51$ ,  $df = 12$ ,  $p = .06$ , 2-tailed test) with 14 dance/movement therapy students. In the second pilot study, receptivity did not correlate with absorption. Receptivity and absorption, however, accounted for 54% of hypnotizability population variance in a step-wise multiple regression. Receptivity accounted for a unique part of the variance after the effects of absorption were removed. It was concluded that receptivity should be explored as a potential predictor of hypnotizability, and that a reliable scaled measure of receptivity should be developed.

Receptivity was rated by dance instructor on the following scale. "TABLE 1 Criteria for Ranking Ss on Receptivity A. Individuals were rated high if they could consistently do the following most of the time:

1. If they moved with emotional involvement.
  2. If they could readily verbally describe their movement experience in terms of sensations or feelings.
  3. If they were able to image while moving. That is, their movement experience could be transformed into representational visual images.
  4. In their describing their movement experience verbally, if they readily alluded to the images which were generated from their body movement.
  5. If they could relate their movement experiences to other contexts outside of the therapeutic one.
  6. If they could develop a working alliance with the therapist (based on students' capacity to risk experiencing self with increased emotional depth).
- B. Individuals were rated low, if they were not able to do the above most of the time. C. Individuals were rated in the mid-range if they were able to do the above some of the time" (p. 65).

Herbert, James D.; Mueser, Kim T. (1992). Eye movement desensitization: A critique of the evidence. Journal of Behavior Therapy and Experimental Psychiatry.

The scientific evidence supporting the efficacy of eye movement desensitization (EMD), a novel intervention for traumatic memories and related conditions, is reviewed. The sparse research conducted in this area has serious methodological flaws, precluding definite conclusions regarding the effectiveness of the procedure. Clinicians are cautioned against uncritically accepting the clinical efficacy of EMD.

Lohr, Jeffrey M.; Kleinknecht, Ronald A.; Conley, Althea T.; Dal Cerro, Steven; Schmidt, Joel; Sonntag, Michael E. (1992). A methodological critique of the current status of eye movement desensitization (EMD). Journal of Behavior Therapy and Experimental Psychiatry.

Eye Movement Desensitization (EMD) has been recently advocated as a rapid treatment for the elimination of traumatic memories responsible for the maintenance of a number of anxiety disorders and their clinical correlates. Despite a limited conceptual framework, EMD has attracted considerable interest among clinicians and researchers. The popularity and interest generated by EMD will likely result in wide usage. We present a methodological critique of it with reference to assessment, treatment outcome, and treatment process. We also provide guidelines for judging the methodological adequacy of research on EMD and suggest intensive research to assess effectiveness, treatment components, and comparisons with other procedures.

1991

Brown, Jason W. (1991). Self and process: Brain states and the conscious present. New York: Springer-Verlag.

Author, from the Department of Neurology at New York University Medical School, presents a theory about the genetic unfolding of mental content (mind) through stages, from mental state into consciousness or into behavior. He relates the genesis of mind to brain development but avoids assuming that there is a straightforward correlation between brain development (e.g. myelination) and cognitive development or perception. To some degree, the theory is based on subjective report data and psychological symptoms. The author discusses issues that bear on the phenomena of nonvoluntary responding and dissociation that are reported or described by hypnotized persons.

"The nature of the mental state will determine the relation between self and world, and thus the interpretation given to agency and choice. ... The crossing of the boundary from self to world is a shift from one level in mind to another" (pp. 10-11).

"... if we begin with mind as primary and seek to explain objects from inner states and private experience, the discontinuity between inner and outer evaporates: mind is everywhere, a universe. ... Whereas before we thought to perceive objects, now we understand that we think them" (p. 19).

**"The concept of a stratified cognition is central to the notion of a mental state ... This entails an unfolding from depth to surface, not from one surface to the next, a direction crucial to agency and the causal or decisional properties of consciousness" (p. 52). By unfolding from depth to surface, he means from Core, through Subconscious, then Conscious Private Events, and finally Extra-Personal Space.**

**He goes on to provide a definition of mental states. "A mental state is the minimal state of a mind, an absolute unit from the standpoint of its spatial and temporal structure. ... The state also has to include the prehistory of the organism. ... The concept of a mental state implies a fundamental unit that has gestalt-like properties, in that specific contents-- words, thoughts, percepts--appear in the context of mind as a whole (p. 53).**

**"The entire multitiered system arborizes like a tree, with levels in each component linked to corresponding levels in other components. For example, an early (e.g., limbic) state in language (e.g., word meaning) is linked to an early stage in action (e.g., drive, proximal motility) and perception (e.g., hallucination, personal memory) ... In sum, a description of the spatial and temporal features of a single unfolding series amounts to a description of the minimal unit of mind, the absolute mental state" (p. 54).**

**The author's discussion of an individual's physical movement relates to the concept of nonvoluntary movement (or movement without awareness of volition) in hypnosis. "More precisely, levels in the brain state constitute the action structure. As it unfolds, this structure generates the conviction that a self-initiated act has occurred. This structure--the action representation--does not elaborate content in consciousness. ... As with the sensory-perceptual interface, the transition to movement occurs across an abrupt boundary. In some manner, perhaps through a translation of cognitive rhythms in the action to kinetic patterns in the movement, levels in the emerging act discharge into motor (physical) events" (p. 57).**

**The author's discussion of an individual's physical movement relates to the concept of nonvoluntary movement (or movement without awareness of volition) in hypnosis. "More precisely, levels in the brain state constitute the action structure. As it unfolds, this structure generates the conviction that a self-initiated act has occurred. This structure--the action representation--does not elaborate content in consciousness. ... As with the sensory-perceptual interface, the transition to movement occurs across an abrupt boundary. In some manner, perhaps through a translation of cognitive rhythms in the action to kinetic patterns in the movement, levels in the emerging act discharge into motor (physical) events" (p. 57).**

**"The self has the nature of a global image or early representation within which objects-to-be are embedded. ... The self is the accumulation of all the momentary cognitions developing in a brain configured by heredity and experience in a particular way (p. 70).**

**"The deposition of a holistic representation ... creates the deception of a self that stands behind and propagates events. The feeling of the self as an agent is reinforced by the forward thrust of the process and the deeper locus of the self in relation to surface objects. The self appears to be an instigator of acts and images when in fact**

it is given up in their formation. The self does not cause or initiate, it only anticipates (p. 70).

The foregoing notes cover only the first five chapters, less than half the book. Other chapters relevant to hypnosis would be those titled 'The Nature of Voluntary Action,' 'Psychology of Time Awareness,' 'From Will to Compassion,' and 'Mind and Brain.'

Hinshaw, Karin E. (1991). The effects of mental practice on motor skill performance: Critical evaluation and meta-analysis. Imagination, Cognition and Personality, **11**, 3-35.

21 studies that met the criteria of having both an adequate control and a mental practice alone group were included. The 44 separate effect sizes resulted in an overall average effect size of .68 (SD = .11) indicating that there is a significant benefit to performance of using mental practice over no practice. A series of General Linear Models revealed that the use of "internal" imagery produced a larger average effect size than the use of "external" imagery, and that mental practice sessions of less than one minute or between ten and fifteen minutes in length produced a larger average effect size than sessions of three to five minutes in length. These findings suggest the complexity of the relationship between variables that influence mental practice

Lucic, Karen S.; Steffen, John J.; Harrigan, Jinni A.; Stuebing, Roger C. (1991). Progressive relaxation training: Muscle contraction before relaxation?. Behavior Therapy, **22** (2), 249-256.

Demonstrated support for E. Jacobson's (1938) position that tensing muscle groups prior to relaxation is physiologically detrimental to the relaxation process. 48 undergraduates participated in 1 of 3 conditions: muscle contraction (MC) relaxation, relaxation without muscle contraction (WMC), and self-induced relaxation control. Ss participated in a single session of progressive relaxation. Ss had no previous relaxation training and had moderate trait anxiety scores. A significant main effect for group resulted for the electromyograph (EMGH) measures. The mean EMGH measures identified the WMC group as most relaxed (i.e., experiencing the least amount of muscle tension), followed by the control group and then the MC group.

Marzi, C. A.; Bisiacchi, P.; Nicoletti, R. (1991). Is interhemispheric transfer of visuomotor information asymmetric? Evidence from a meta-analysis. Neuropsychologia, **29**, 1163-1177.

Using a meta-analytic procedure we have analysed 16 studies employing a simple unimanual reaction time (RT) paradigm and lateralized visual stimuli to provide an estimate of interhemispheric transfer time in normal right-handed subjects. We found a significant overall RT advantage of the left visual field over the right and of the right hand over the left. These asymmetries can be explained by a superiority of

the right hemisphere for the detection of simple visual stimuli and by a corresponding superiority of the left hemisphere for the execution of the manual response, respectively. Alternatively, they may be interpreted as related to an asymmetry of interhemispheric transmission of visuomotor information, with transfer from the right hemisphere (side of stimulus entry) to the left (side of response generation) faster than in the reverse direction. Although a direct test of these hypotheses is still lacking, we think that the evidence available is more in keeping with the latter possibility.

This research relates to issues of hemispheric dominance during hypnosis, for high hypnotizable subjects

1990

McAleney, Patrick J.; Barabasz, Arreed; Barabasz, Marianne (1990). Effects of flotation restricted environmental stimulation on intercollegiate tennis performance. Perceptual and Motor Skills, 72, 1023-1028.

The study investigated the effects of flotation Restricted Environmental Stimulation (REST) with an imagery message on the competitive performance of intercollegiate tennis players (10 men, 10 women). Pre- and posttreatment athletic performance was measured during intercollegiate competition. Posttreatment results indicated that subjects exposed to flotation REST with an imagery message performed significantly better than subjects exposed to imagery only on a measure of first service accuracy. Findings suggest that flotation REST can be used to enhance the performance of a well learned skill by athletes of high ability

Wain, Harold J.; Amen, Daniel G.; Jabbari, Bahmann (1990). The effects of hypnosis on a Parkinsonian tremor: Case report with polygraph/EEG recordings. American Journal of Clinical Hypnosis, 33, 94-98.

Although Parkinsonian tremors typically disappear during sleep and are reduced during relaxation periods, the effects of hypnosis on this type of movement disorder have been generally ignored. We observed a patient's severe Parkinsonian tremor under hypnosis and monitored it with EEG and EMG studies. The patient was taught self-hypnosis and performed it three to four times daily in conjunction with taking medication. The results suggest that daily sessions of self-hypnosis can be a useful therapeutic adjunct in the treatment of Parkinsonian tremors.

The patient scored low on the Hypnotic Induction Profile scale of hypnotizability and was unable to experience any classical hypnotic phenomena, but was motivated to learn self-hypnosis. For self hypnosis he visualized a relaxing scene.

1989

Snodgrass, M.; Lynn, Steven Jay (1989). Music absorption and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 37, 41-54.

The present study investigated differences between high (N = 15), medium (N = 20), and low (N = 16) hypnotizable Ss' involvement in imaginative versus nonimaginative music. Ss were first screened for hypnotizability with the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962). In a second session presented as a study of music appreciation, Ss listened to classical music of high- and low-rated music imaginativeness. Ss' involvement was indexed by absorption, imagery elaboration reported in open-ended essays, and reaction time to a pure tone. High hypnotizable Ss reported more absorption than low hypnotizable Ss, regardless of the imaginativeness level of the music. Ss reported more imagery elaboration in the imaginative than in the low-imaginative passages. High hypnotizable Ss tended to differ in their imagery elaboration in response to the imaginative passages but not in response to the nonimaginative passages. Reaction time results were nonsignificant. No sex differences were found. Medium hypnotizable Ss were indistinguishable from both high- and low-hypnotizable Ss. The findings are generally compatible with J. R. Hilgard's (1970, 1974) construct of imaginative involvement.

Yousufzai, N. M. (1989). Rheumatoid arthritis and hypnosis: Case report. British Journal of Experimental and Clinical Hypnosis, 6 (3), 178-181.

[http://www.imp-muenchen.de/The\\_effect\\_of\\_hypnos.698.1.html](http://www.imp-muenchen.de/The_effect_of_hypnos.698.1.html)

From: Psychology and Health, 2000, vol 14, p. 1089.

Horton-Hausknecht J, Mitzdorf U, Melchart D: The effect of hypnosis therapy on the symptoms and disease activity in rheumatoid arthritis .

In this study we aimed to assess the effectiveness of clinical hypnosis on the symptoms and disease activity of rheumatoid arthritis (RA). 66 RA patients participated in a controlled group design. 26 patients learnt the hypnosis intervention, 20 patients were in a relaxation control group, and 20 patients were in a waiting-list control group. During hypnosis , patients developed individual visual imagery aimed at reducing the autoimmune activity underlying the RA and at reducing the symptoms of joint pain, swelling, and stiffness. Subjective assessments of symptom severity and body and joint function, using standardized questionnaires and visual analogue scales, were obtained. Objective measures of disease activity via multiple blood samples during the therapy period and at the two follow-ups were also taken. These measurements were of erythrocyte sedimentation rate, C-reactive protein, hemoglobin, and leukocyte total numbers. Results indicate that the hypnosis therapy produced more significant improvements in both the subjective and objective measurements, above relaxation and medication. Improvements were also found to be of clinical significance and became even more significant when patients practiced the hypnosis regularly during the follow-up periods.

"The effect of hypnotic suggestion on pain and mobility of joints was remarkable. On the fifth session there was hardly any pain, and shoulder movements were almost normal" (p. 179).

1988

Houge, Donald R.; Hunter, Robert E. (1988). The use of hypnosis in orthopaedic surgery. Contemporary Orthopaedics, 16, 65-68.

Some patients postpone or refuse indicated orthopaedic surgery because of fear or a medical contraindication to anesthesia. Clinical hypnosis previously has been used mainly as an adjunct to chemical anesthesia. However, hypnosis was shown to be entirely effective when used as the sole anesthesia in three of four orthopaedic cases. These four procedures included a radical head resection, the removal of a sideplate and Richard's screw from the hip, and two cases of arthroscopic knee surgery. The preparation required for the surgery and the experiences of the patients during these procedures are described, and the kinds of patients most likely to benefit from the use of hypnosis in orthopaedic surgery are reviewed.

Jones, Lynette A. (1988). Motor illusions: What do they reveal about proprioception. Psychological Bulletin, 103 (1), 72-86.

Five illusions involving distortions in the perception of limb position, movement, and weight are described in the context of their contribution to understanding the sensory processes involved in proprioception. In particular, these illusions demonstrate that the position sense representation of the body and the awareness of limb movement results from the cross-calibration of visual and proprioceptive signals. Studies of the vibration illusion and phantom-limb phenomenon indicate that the perception of limb movement and position are encoded independently and can be dissociated. Postural aftereffects and the illusions of movement induced by vibration highlight the remarkable lability of this sense of limb position, which is a necessary feature for congruence between the spatial senses. Finally, I discuss the role of corollary discharges in the central processing of afferent information with respect to the size-weight and vibration illusions.

Neiss, Rob (1988). Reconceptualizing arousal: Psychobiological states in motor performance. Psychological Bulletin, 103 (3), 345-366

This review of research dealing with psychologically induced arousal and motor performance focuses on the hypothesized inverted-U function relating arousal to performance. The inverted-U hypothesis is supported only in a weak and psychologically trivial fashion. More useful research in human motor performance would investigate discrete psychobiological states, which include affect and cognition as well as physiology. Examination of profound individual differences in response to incentive and threat suggests that psychobiological states have their genesis in response expectancies and hypnotic-like self-inductions. The cognitive and affective components of these states are highly interactive and perhaps not profitably separated. Because performance anxiety is a central problem in the motor realm, it is carefully delineated and the test anxiety literature is scrutinized. Psychophysiological test batteries and other investigations in the area are described, and guidelines for future research are provided.

Neiss, Rob (1988). Reconceptualizing relaxation treatments: Psychobiological states in sports. Clinical Psychology Review, 8 (2), 139-159.

Reviews studies relating relaxation treatments to motor performance and attempts to explain these treatments from a psychological perspective. The inverted-U hypothesis is based on arousal, which has construct validation problems and is a physiological, rather than a psychological, construct. Arousal cannot distinguish among fear, anger, sexuality, and other psychobiological states; predictive validity is low in the area of motor performance. The inverted-U hypothesis is effectively refutable in current usage, and empirically weakly supported. Relaxation treatments are reconceptualized as relatively nonspecific psychological therapies, potentially useful in alleviating dysphoric, debilitating psychobiological states. These treatments are particularly apt for athletics, where performance anxiety is a pervasive problem.

1987

Jacobs, Sharon B.; Salzberg, Herman C. (1987). The effects of posthypnotic performance-enhancing instructions on cognitive-motor performance. International Journal of Clinical and Experimental Hypnosis, 35, 41-50.

The effects of performance-enhancing instructions on a cognitive-motor task (typing) was assessed using 3 groups: hypnosis and control groups with performance-enhancing instructions, and a control group without instructions. Unlike previous hypnosis research, the performance-enhancing instructions were given after substantial learning had occurred. Results indicated that posthypnotic performance-enhancing instructions, or performance-enhancing instructions alone, did not have a facilitative effect on performance. The results also suggested potential negative performance effects following hypnotic induction, depending on Ss' initial typing ability. The implications of these findings are discussed.

The research investigated whether hypnotic suggestions could influence various factors thought to inhibit peak performance by increasing confidence, increasing motivation, and decreasing performance anxiety. 84 undergraduates of varying levels of typing ability were recruited, not mentioning in advance that the research involved hypnosis (in order to avoid selection bias). The experimental materials included a modified version of the Apple Typing Tutor program, which measures words per minute (WPM), key strokes missed (KM), and net words per minute (NWPM, which was obtained by subtracting 2 (KM) from WPM). These measures were obtained for the average of every 9 paragraphs.

Subjects received nine practice sessions and then were assigned to Experimental or Control group based on NWPM and sex. The hypnosis group received the Stanford Hypnotic Susceptibility Scale, Form C, minus suggestions for drowsiness, sleepiness, or posthypnotic amnesia. Additional suggestions for performance enhancement were introduced. The control group watched a film. The average of every nine paragraphs was used.

The analyses of variance for dependent measures revealed no significant effects except for one interaction effect that actually was in the unexpected or wrong

direction. That effect appeared to be spurious as it was due to extreme errors produced by one subject.

"Only speed of typing (WPM) changed from pre to posttreatment, and this effect interacted with ability level. Post hoc analyses (Scheffe) indicated that beginner typists became less proficient, intermediate typists did not change, and advanced typists became more proficient" (p. 46).

Hypnotizability on SHSS:C did not correlate with change on NWPM.

A 3 x 3 x 2 ANOVA indicated a significant change over time on KM. "Although no change occurred from pretreatment to posttreatment, there was a decrease in errors at follow-up. There was also a significant Group x Level x Time interaction for KM ( $F = 2.57, p < .05$ ). This was accounted for by post hoc analyses showing that hypnotized beginner Ss changed over time, while control beginner Ss did not. Hypnotized Ss made significantly more errors following hypnosis than at pretreatment or follow-up" (p. 46).

"There was a significant main effect for time on NWPM. ... The Ss' overall typing performance decreased from pretreatment to posttreatment, but increased at follow-up. Only the advanced Ss demonstrated significant improvement between pretreatment and follow-up.

"There was also a significant interaction between time and ability level on WPM. ... beginner Ss typed significantly slower at posttreatment than at pretreatment or follow-up" (p. 47).

In their Discussion, the authors note that the outcomes of their investigation are consonant with results obtained by other investigators studying hypnosis effects on skills (Arnold, 1971; Edmonston & Marks, 1967). In contrast, earlier studies on reaction time demonstrated that either motivational instructions and/or alert hypnotic inductions improved performance (e.g. Ham & Edmonston, 1971; Rader, 1972). They raise the question whether Ss' relaxation following hypnosis may have slowed response time and canceled the effects of motivating instructions.

"When looking at all groups combined, Ss did not improve between pretreatment and posttreatment. At follow-up, however, Ss showed significant improvement on two out of the three measures. This suggests that learning had occurred, but that temporary inhibitory factors such as S restlessness and indifference observed by Es may have affected performance at posttreatment. The length of the task (90 minutes in one sitting) may have been responsible for the fatigue and boredom that seemed to set in. It is probable that the performance-enhancing instructions were not potent enough to counteract these effects. At follow-up (which took much less time) fatigue and boredom were apparently absent, hence typing improved. In addition, other factors may have affected performance (e.g., anxiety, lack of motivation). The data indicate that Ss of different ability levels responded differently over time.

"The results of the present study cast doubt on the utility of hypnosis in improving performance on a cognitive-motor task. Although there are many anecdotal reports of hypnosis improving performance, research studies indicate that hypnosis, with motivational instructions, is effective only in improving reaction time and not more complex measures of performance. This apparent inconsistency may be explained by considering the level of motivation of participants. It is likely that a person

requesting hypnosis to help improve performance is more motivated than experimental Ss" (p. 48).

Pajntar, M.; Roskar, E.; Vodovnik, L. (1985). Some neuromuscular phenomena in hypnosis. In Waxman, D.; Misra, P.C.; Gibson, M.; Basker, M.A. (Ed.), Modern trends in hypnosis (pp. 181-206). New York: Plenum Press.

The phenomena presented here allow us to conclude that with hypnosis, the functioning of the neuromuscular system may be significantly influenced, either by increasing or decreasing the functioning of voluntary or electrically stimulated contractions, and that the function of movements may be improved. Two suggestions proved to be most efficient: 1) physical and mental relaxation, and 2) age regression. In age regression the patient recalls the ideomotor system, which is likely to result in a reconstruction of the forgotten motor contractions or in a strong intensification of these contractions under additional suggestions. With regard to relaxation, on one hand it intensifies the functioning of the voluntarily stimulated neuro-muscular systems, and on the other hand it prevents an excessive functioning of the involuntarily reflex stimulated antagonistic systems" (pp 202; 204).

Finkelstein, S. (1982). Re-establishment of traumatically disrupted finger flexor function: A brief communication. International Journal of Clinical and Experimental Hypnosis, 30 (1), 1-3.

Age regression during hypnosis and mental rehearsal while in trance, using a cassette tape for induction, enabled a patient, with disruption of flexor function of the fifth finger of her right hand, to restore full function, even though she did not have a strong belief system in hypnosis.

**1981**

Dosamantes-Alperson, Erma (1981). Experiencing in movement psychotherapy. American Journal of Dance Therapy, 4, 33-44.

Experiencing is a process variable in psychotherapy which deals with the manner with which individuals use their internal, ongoing bodily-felt flow of experience to

gain self-awareness and to communicate about themselves. A consistent finding across research process studies in psychotherapy is that successful clients start, continue, and end therapy at higher experiencing levels than do less successful clients. The implication of this finding for all therapists, irrespective of their theoretical framework, is that they need to help their clients process the content they raise in therapy at a high level of experiencing throughout the course of therapy. This paper discusses and demonstrates several body movement based procedures that enhance clients' experiencing level while working within the context of experiential movement psychotherapy, a form of psychotherapy which emphasizes the acquisition of personal meanings by clients from any of the following three experiential and expressive modalities: body movement, kinetic imagery, or verbal communication.

Wallace, Benjamin; Hoyenga, Katharine Blick (1981). Performance of fine motor coordination activities with an hypnotically anesthetized limb. International Journal of Clinical and Experimental Hypnosis, 29, 54-65.

3 experiments were conducted to determine the effects of induced hypnotic anesthesia in S's dominant arm upon the performance of various motor coordination tasks. Experiment 1 assessed the ability of Ss to tap a pencil within a 20 mm diameter circle while the limb performing the task was or was not anesthetized. Experiment 2 determined the effect of hypnotic anesthesia upon the ability to perform a hand-turn task. Experience 3 considered the effects of hypnotic anesthesia on the ability to draw and duplicate a sine- wave pattern. IN all 3 experiments, hypnotic anesthesia adversely affected task performance. Their results were interpreted as indicating a possible relationship between induced hypnotic anesthesia and mimicked cerebellar dysfunction.

-thesia on the ability to draw and duplicate a sine- wave pattern. IN all 3 experiments, hypnotic anesthesia adversely affected task performance. Their results were interpreted as indicating a possible relationship between induced hypnotic anesthesia and mimicked cerebellar dysfunction.

"Although the induction of hypnotic anesthesia in a limb appears to mimic cerebellar dysfunction or damage, the present authors are not implying that this is actually happening. In fact, there are few physiological correlates of hypnosis or hypnotic anesthesia (Evans, 1979; Sarbin & Slagle, 1979) and, to date at least, cerebellar involvement does not appear to be one of them. There appears to be a curious relationship, however, between performance on a motor task as a function of induced hypnotic anesthesia in a limb and as a function of cerebellar damage. This relationship may simply be coincidental at best but before it can be dismissed as such, further experimentation should take place to study this interesting phenomenon" (p. 61).

Pajntar, Marjan; Jeglic, Anton; Stefancic, Martin; Vodovnik, Lojze (1980). Improvements of motor response by means of hypnosis in patients with peripheral

nerve lesions. International Journal of Clinical and Experimental Hypnosis, 28 (1), 16-26.

In order to accelerate rehabilitation of patients with peripheral nerve lesions, hypnosis was employed to encourage them voluntarily to move those muscles with weak re-innervation and to achieve the best possible activity of the affected muscle groups. By measuring muscle force and endurance and by observing the electrical activity of the affected muscles, it was found that the activity of the affected muscles was much better while patients were in hypnosis than when they were in the waking state. The patients were able to contract even paretic muscles having only weak re-innervation with such strength, that clinically perceptible contraction of the muscles and movement of paretic extremities occurred. Such early and improved activation is very important for prevention of much permanent damage.

Wallace, Benjamin; Hoyenga, K. B. (1980). Production of proprioceptive errors with induced hypnotic anesthesia. International Journal of Clinical and Experimental Hypnosis, 28 (2), 140-147.

The present study assessed the ability of Ss to localize their noses with the forefinger of their dominant hands. This was accomplished while S had his eyes closed and while the limb performing the task was or was not hypnotically anesthetized. In performing this task with an anesthetized limb, 2 error types were observed. The first involved a localization error of missing the nose location. A second error involved an increased amount of time required to find the nose location. An inverse relationship was found to exist between these error types such that a large localization error was associated with a short latency period while a small localization error was associated with a long latency period. Neither error type was evident when hypnotic anesthesia was absent

Weitzenhoffer, Andre M. (1980). Hypnotic susceptibility revisited. American Journal of Clinical Hypnosis, 22, 130-146.

The concept and measurement of hypnotic susceptibility are re-examined in their relation to hypnotizability, hypnotic depth and suggestibility. The Stanford Scales and similar instruments are found to have failed to take into account essential features defining traditional hypnosis and suggestibility and to have created confusion in the scientific inquiry into hypnotism. Other available measures have not been particularly successful, but some bear further attention. Recent claims that hypnotizability can be trained have failed to distinguish between hypnotizability proper and accessory processes, leaving some question about what is actually being trained. Possible future directions of work on susceptibility are considered. Attempts to distinguish between 'clinical' and 'laboratory' hypnotizability are examined and found to have been premature and loosely based on facts.

1979

Dosamantes-Alperson, Erma (1979). The intrapsychic and the interpersonal in movement psychotherapy. American Journal of Dance Therapy, 3, 20-31.

The adaptive function of two states of consciousness and corollary movement experiences is described. Movement in which a relaxed state of attention is maintained on inner kinesthetic sensations and imagery is contrasted with movement which is characterized by conscious, active interacting with the external world of people and events. Clinical examples from individual and group psychotherapy sessions are cited to demonstrate how meaning and conflict resolution may be achieved by clients while moving in either mode.

Hilgard, Ernest R.; Crawford, Helen J.; Wert, A. (1979). The Stanford Hypnotic Arm Levitation Induction and Test (SHALIT): A six-minute hypnotic induction and measurement scale. International Journal of Clinical and Experimental Hypnosis, 27 (2), 111-124.

The Stanford Hypnotic Arm Levitation Induction and Test (SHALIT) has been designed as a short (6-minute) induction and measurement method for screening Ss according to hypnotizability for either clinical or experimental purposes. In Experiment 1 conducted with college students in two institutions, SHALIT was substituted for the eye closure induction of the Stanford Hypnotic Susceptibility Scale, Form A (SHSS:A) of Weitzenhoffer and E. R. Hilgard (1959) and followed by the remaining SHSS:A items. The SHALIT levitation score correlated .63 (N = 64) with SHSS:A. Some Ss who participated in the study were invited back for Experiment 2. This second experiment yielded a correlation of .52 (N = 27) between SHALIT and the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & E. R. Hilgard, 1962). Alternative simplified scoring methods designed for maximal convenience also proved satisfactory. The limitations of short tests as adequate measures of hypnotizability are noted.

Jackson, J. Arthur; Gass, Gregory C.; Camp, Elizabeth M. (1979). The relationship between posthypnotic suggestion and endurance in physically trained subjects. International Journal of Clinical and Experimental Hypnosis, 27, 278-293.

55 male Ss were assigned to 5 groups: control, hypnosis alone, motivation alone, low susceptible hypnosis with motivation, or high susceptible hypnosis with motivation. Ss performed 2 runs on a treadmill to their maximum capacity, as measured by oxygen consumption, blood lactate concentration, and respiratory quotient. Groups involving hypnosis performed in the posthypnotic state. A significant increase in endurance performance was revealed in the motivation alone Ss and in high susceptible hypnosis Ss who were given motivational suggestions. Maximum ventilation was significantly increased in high susceptible hypnosis Ss when compared with control Ss and significant increases in blood lactate concentrations were revealed when the high susceptible hypnosis Ss were compared with low susceptible hypnosis and motivation alone Ss. The reasons for the changes in metabolic variables are discussed. Findings demonstrated that in achieving greater

endurance performance, motivational suggestions alone are as effective as identical suggestions given to high susceptible Ss.

-hypnotic state. A significant increase in endurance performance was revealed in the motivation alone Ss and in high susceptible hypnosis Ss who were given motivational suggestions. Maximum ventilation was significantly increased in high susceptible hypnosis Ss when compared with control Ss and significant increases in blood lactate concentrations were revealed when the high susceptible hypnosis Ss were compared with low susceptible hypnosis and motivation alone Ss. The reasons for the changes in metabolic variables are discussed. Findings demonstrated that in achieving greater endurance performance, motivational suggestions alone are as effective as identical suggestions given to high susceptible Ss.

Delprato, D. J.; Holmes, P. A. (1978). Facilitation of arm levitation by responses to previous suggestions of a different type. International Journal of Clinical and Experimental Hypnosis, 26 (3), 167-177.

This experiment tested the hypothesis that responses to suggestions (confirmations of them) facilitate responses to subsequent suggestions. Experimental Ss first received 5 different suggestions (e.g., falling forward, index fingers coming together) that included instructions designed to help them experience involuntary performance of the suggested response. Control Ss were given the suggestions without the instructions. A subsequent, identical, arm levitation test revealed significantly more involuntary responding in experimental Ss than in control Ss. 10 prior confirmations of suggestions were more effective in differentiating control from experimental treatment than was a smaller number of confirmations. Results were discussed in terms of the contribution of learning and social control factors to suggestion effects.

1977

Anderson, J. W. (1977). Defensive maneuvers in two incidents involving the Chevreul pendulum: A clinical note. International Journal of Clinical and Experimental Hypnosis, 25, 4-6.

"Hypnosis frequently facilitates increased access to the unconscious. In both of these cases, the hypnotized subject gained contact with a thought which otherwise would likely have remained out of awareness. Then the ego quickly resorted to defensive maneuvers in order to deny the thought" (p. 6).

Lazar, Billie S. (1977). Hypnotic imagery as a tool in working with a cerebral palsied child. International Journal of Clinical and Experimental Hypnosis, 25 (2), 78-87.

Hypnotic imagery was used with a moderately severe athetoid cerebral palsied 12-year-old boy who was mildly retarded and a poor hypnotic subject. Techniques included imagery, observation of the self, revivification of relaxing experiences,

proprioceptive feedback about the athetoid movements, and dealing with feelings and motivation. Athetoid movements were reduced, results extended beyond the treatment situation, and improvement was made in practical skills.

Stillman, Richard C.; Wolkowitz, Owen; Weingartner, Herbert; Waldman, Ivan; DeRenzo, Emil V.; Wyatt, Richard J. (1977, Dec 15). Marijuana: Differential effects on right and left hemisphere functions in man. Life Sciences, **21** (12), 1793-1799.

Marijuana, smoked at moderate doses, produced a differential impairment of the reaction times of right-handed males to pictorial stimuli presented to the left and right cerebral hemispheres. After smoking marijuana responses to pictorial stimuli presented to the right hemisphere were slowed significantly less than to the left hemisphere. Responses to verbal stimuli (trigrams) were slowed equally in both hemispheres, preserving an initial left hemisphere superiority for this material. This suggests that marijuana may differentially change the processing speed or relative dominance of man's two cerebral hemispheres, depending on the nature of the material being processed.

1976

Spanos, Nicholas P.; Spillane, Jeanne; McPeake, John (1976). Cognitive strategies and response to suggestion in hypnotic and task-motivated subjects. American Journal of Clinical Hypnosis, **18**, 254-262.

Thirty-two male and 32 female subjects, exposed to an hypnotic induction or task-motivational instruction, were administered either three suggestions which provided a cognitive strategy (i.e., a goal-directed fantasy, GDF) for experiencing suggested effects, or three suggestions that did not provide such a strategy. Subjects provided with GDF strategies were more responsive overtly and subjectively to two out of the three suggestions. Subjects in the No GDF Strategy treatment who spontaneously devised their own goal-directed fantasies were more responsive to suggestions than subjects who failed to devise such a strategy. These results support the contention that goal-directed fantasy helps both hypnotic and non-hypnotic subjects experience suggested effects.

1975

Bender, V. L.; Navarett, F. J.; Nuttman, D. (1975). Effects of neutral hypnosis on a conditioned physiological response. Psychological Reports, **37**, 1155-1160.

The objective of the present experiment was to determine whether hypnosis without explicit suggestion of analgesia would diminish physiological responses to an operationally defined painful shock stimulus. Muscle tension (EMG) was significantly lower during hypnosis than pre- or posthypnosis. Pulse rate remained stable throughout all conditions. Also, the question of whether a tone paired with shock might acquire some unique property because of that association was investigated. It was found that EMG response to the tone alone was significantly

greater than to the tone-shock combination, in prehypnosis and posthypnosis, but not during hypnosis.

Weitzenhoffer, Andre M. (1972). The postural sway test: A historical note. International Journal of Clinical and Experimental Hypnosis, 17-24.

Presents historical evidence disputing that the postural or body sway test of hypnotic susceptibility was originated by C. L. Hull. Excerpts from French scientific literature between 1887 and 1914 are cited indicating that the French physician Lucien Moutin should receive credit as the originator. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1970

Perry, Campbell (1970). A possible kinesic indicator of hypnotic susceptibility. International Journal of Clinical and Experimental Hypnosis, 18 (1), 52-60.

Reports a significant association between a kinesic variable and hypnotic susceptibility for 39 male undergraduate volunteers. Highly susceptible Ss tended to undergo hypnotic induction with their legs uncrossed; medium susceptible and insusceptible Ss crossed their legs. The phenomenon was present both in an experimental context in which Ss were being tested primarily for their ability to experience hypnotic analgesia and in a diagnostic hypnotic rating situation. There is some evidence to suggest that leg crossing in insusceptible Ss represents a reaction to their inability to meet the implicit demands of a hypnotic induction. (Spanish & German summaries) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

1969

Garmize, L. M.; Marcuse, F. L. (1969). Some parameters of body sway. International Journal of Clinical and Experimental Hypnosis, 17, 189-194.

Investigated the effects of 4 variables on body sway with 160 undergraduates. A 4-dimensional analysis of variance was performed on the body sway scores obtained. None of the main effects were significant. 1 of the interactions was significant, but might have been due to chance. Results are consistent with those of past researchers. (Spanish & German summaries) (16 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Hunt, Sonja M. (1969). The speech of the subject under hypnosis. International Journal of Clinical and Experimental Hypnosis, 17, 209-216.

Attempts to objectify changes taking place in the speech of 12 undergraduates under hypnosis as compared with their waking speech. A series of open-ended questions was asked in the waking and hypnotized states and the responses compared. Results indicate that the latency of response may be longer, the rate of speech slower, and the number of words in the response fewer under hypnosis. The rate of speech of E, however, also differed significantly between Ss in waking and hypnotized

conditions. It was therefore not possible to attribute the speech changes only to the hypnotized state. They could have arisen from E's differential verbal treatment of hypnotized and waking Ss. The need for future research and its nature are discussed. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

**1964**

Anderson, Milton L.; Sarbin, T. R. (1964). Base rate expectations and motoric alterations in hypnosis. International Journal of Clinical and Experimental Hypnosis, *12* (3), 147-158.

Degree of responsiveness to "suggestion" in an experiment which did not utilize hypnotic induction (the Berkeley Sample) was comparable to that obtained in an experiment which did utilize hypnotic induction (the Stanford Sample). Procedural differences between the 2 experiments--self-scoring vs. objective-scoring, and group vs. individual testing--were regarded as not crucial in making a comparison of the 2 experiments. The distribution of responses in the Berkeley Sample may be taken as the base rate. The slightly higher degree of responsiveness over the base rate in the

Stanford Sample (on some tests) may be attributed to the "degree of volunteering" that characterized the sample. The importance for experiments in the future to create equal levels of motivation and expectation to perform well under both the hypnotic and the nonhypnotic conditions is stressed, and brief mention is made of a new metaphor to be used in the conceptualization of the problems of hypnosis. Levitt, Eugene E.; Brady, J. P. (1964). Muscular endurance under hypnosis and in the motivated waking state. International Journal of Clinical and Experimental Hypnosis, *12*, 21-27.

8 female Ss scoring at least 10 on the Stanford Hypnotic Susceptibility Scale were required to hold a weight in the outstretched hand in 3 states: (a) under hypnosis, (b) under hypnosis with the upper arm and shoulder anesthetized hypnotically, and (c) in the waking state with motivation provided by a verbal exhortation and monetary payment. Order of performance in the 3 states was varied. No significant differences among states were found. The interaction between states and orders was significant, but it appears more likely to be the result of intersubject variability rather than of position or fatigue effects. Ss' expectancies and estimates of performance time, obtained postexperimentally, did not appear to be related to performance itself. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1963

Hoskovec, J.; Svorad, D.; Lanc, O (1963). The comparative effectiveness of spoken and tape-recorded suggestions of body sway. International Journal of Clinical and Experimental Hypnosis, *11*, 163-166.

The relative effectiveness of tape-recorded vs. spoken suggestions of body sway was measured. Both types of suggestion produced increased body sway. Spoken suggestions following recorded suggestions were the most effective. The expectation by Ss of a greater effectiveness of live presentation may have produced this result. **Das, J. P.; O'Connor, N. (1959). Body-sway suggestibility in paranoid and nonparanoid schizophrenics. International Journal of Clinical and Experimental Hypnosis, 7 (3), 121-128.**

**Twenty paranoid and twenty nonparanoid schizophrenics were tested for body-sway suggestibility and verbal conditioning. Paranoids showed greater sway than nonparanoids and both groups swayed more forward than backward. Forward sway was found to be a more reliable measure than backward sway. Both static ataxia and suggested sway were found to be highly reliable over short test-retest periods. The smaller sway of the nonparanoids was explained in terms of difficulty of communication. With regard to the verbal conditioning, it was found that the difficulty of inhibiting an already acquired conditioned response was positively related to the amount of sway produced by suggestion. This was tentatively interpreted as due to the degree of weakness of the capacity to inhibit responses" (p. 128).**

**1955**

**Schneck, Jerome M. (1955). Transference and hypnotic behavior. Journal of Clinical and Experimental Hypnosis, 3 (3), 132-135.**

**"Summary. This report describes an extreme posture in hypnosis, spontaneously assumed by a male patient, when the patient, seated in a chair, curved his head, neck, and upper body far forward so that his face finally was turned inward toward his body at the level of lower abdomen or pubis. This spontaneous motor**

phenomenon, aside from serving as an addition to spontaneous sensory and motor phenomena described previously, continued throughout a series of sessions and reflected symbolically a combination of broad rather than limited interest in treatment and its implications were accepted and used as a base in determining the direction and management of therapy. The constellation of events furnished an additional example of incorporation of hypnotic technique into psychotherapy" (p. 135).

1954

Koster, S. (1954). Experimental investigation of the character of hypnosis. Journal of Clinical and Experimental Hypnosis, 2, 42-54.

In waking, hypnosis, and sleep states 6 subjects were tested for knee-jerk height, key pressing to metronome signal, doing sums, recalling a story, etc. The Summary states:

"1. The height of the knee-jerk of all 6 subjects both in T and in "S" was much lower than in (W), the average height of all knee-jerks computed of the 6 subjects was both in T and in "S" only 39% of the average height in (W).

2. The [arm] catalepsy in T and in "S" continually existed.

3. The subjects in T and in "S" could hear well and perform active movements, though they reacted somewhat more slowly, and less forcibly than in (W) and sometimes only after some provocations.

4. The subjects both in T and in "S" could not only hear well, but could also present more or less complicated psychic impressions, reproducing them later again in "S" and also after the end of the experiment" (p. 50).

The author concluded, "Hypnosis is a sleeping-condition, but a special one. The specific difference consists of the fact that the subject's many impressions, which he would observe in a waking-condition, he does not observe now, and does not react to, aside from impressions coming to him through the hypnotist. It can then be said that there is not an absence but a decrease of the active relation with the outer world. This is exactly the same state as the one during sleepwalking and the writer must repeat after all his investigations, what has already been stated: Essentially there is no difference between the condition of a hypnotized person and that of a sleepwalker" (p. 51).

Guze, Henry (1953). Posture, postural redintegration and hypnotherapy. Journal of Clinical and Experimental Hypnosis, 1, 76-82. (Abstracted in Psychological Abstracts 53: 6559)

The use of postural analysis, and directives regarding posture and their importance in hypnotherapy are discussed. Theoretically, it is indicated that a chronic postural condition may act to elicit an emotional state with which it was originally associated. Such an emotional condition may have caused the posture in the first place, and then established a feed-back relationship with it. The breaking of feed-back mechanisms of this kind depends largely upon postural change when a chronic situation is established in the absence of realistic cause for the emotion. Posture may

also act redintegratively, when directly suggested, in rearousing traumatic memories. Several clinical cases are reported.

**Dane, Joseph R. (1996). Hypnosis for pain and neuromuscular rehabilitation with multiple sclerosis: Case summary, literature review, and analysis of outcomes. International Journal of Clinical and Experimental Hypnosis, 44 (3), 208-231.**

Videotaped treatment sessions in conjunction with 1-month, 1-year, and 8-year follow-up allow a unique level of analysis in a case study of hypnotic treatment for pain and neuromuscular rehabilitation with multiple sclerosis (MS). Preparatory psychotherapy was necessary to reduce the patient's massive denial before she could actively participate in hypnosis. Subsequent hypnotic imagery and posthypnotic suggestion were accompanied by significantly improved control of pain, sitting balance, and diplopia (double vision), and a return to ambulatory capacity within 2 weeks of beginning treatment with hypnosis. Evidence regarding efficacy of hypnotic strategies included (a) direct temporal correlations between varying levels of pain relief and ambulatory capacity and the use versus nonuse of hypnotic strategies, (b) the absence of pharmacological explanations, and (c) the ongoing presence of other MS-related symptoms that remained unaltered. In conjunction with existing literature on hypnosis and neuromuscular conditions, results of this case study strongly suggest the need for more detailed and more physiologically based studies of the phenomena involved. - Journal Abstract

**1991**

**Clarke, J. H.; Reynolds, P. J. (1991). Suggestive hypnotherapy for nocturnal bruxism: A pilot study. American Journal of Clinical Hypnosis, 33, 248-253.**

Although one can find many case reports of hypnotherapy for bruxism, there is a paucity of scientific research on the subject. This study describes the use of suggestive hypnotherapy and looks at its effectiveness in treating bruxism. Eight subjects who reported bruxism with symptoms such as muscle pain and complaints of bruxing noise from sleep partners were accepted into the study. An objective baseline of the bruxing was established using a portable electromyogram (EMG) detector attached over the masseter muscle during sleep. Hypnotherapy was then employed. Both self-reports and posttreatment EMG recordings were used to evaluate the hypnotherapy. Long-term effects were evaluated by self-reports only. The bruxers showed a significant decrease in EMG activity; they also experienced less facial pain and their partners reported less bruxing noise immediately following treatment and after 4 to 36 months.

**Lucic, Karen S.; Steffen, John J.; Harrigan, Jinni A.; Stuebing, Roger C. (1991). Progressive relaxation training: Muscle contraction before relaxation?. Behavior Therapy, 22 (2), 249-256.**

Demonstrated support for E. Jacobson's (1938) position that tensing muscle groups prior to relaxation is physiologically detrimental to the relaxation process. 48 undergraduates participated in 1 of 3 conditions: muscle contraction (MC) relaxation, relaxation without muscle contraction (WMC), and self-induced relaxation control. Ss participated in a single session of progressive relaxation. Ss had no previous relaxation training and had moderate trait anxiety scores. A significant main effect for group resulted for the electromyograph (EMGH) measures. The mean EMGH measures identified the WMC group as most relaxed (i.e., experiencing the least amount of muscle tension), followed by the control group and then the MC group.

EMGH measures identified the WMC group as most relaxed (i.e., experiencing the least amount of muscle tension), followed by the control group and then the MC group.

Somer, Eli (1991). Hypnotherapy in the treatment of the chronic nocturnal use of a dental splint prescribed for bruxism. International Journal of Clinical and Experimental Hypnosis, 39, 145-154.

A behavioral medicine case is described in which the patient was treated with a combined approach involving both hypnoanalytic and hypnbehavioral techniques. A 55-year-old man with bruxism was referred after 10 years of craniomandibular treatment because of his dependency on a dental splint prescribed for nocturnal use. A projective hypnoanalytic exploration helped to uncover and consequently resolve an earlier conflict that had been reactivated in the patient's work situation and which had become a constant source of mental and muscular tension. The hypnoanalytic exploration was followed by a cognitive-behavioral hypnotic intervention that was tape-recorded and prescribed for bedtime practice. Pre- and posttherapy psychological, physiological, and self-report measurements corroborated the patient's sense of well being that came with his newly found ability to sleep without the dental splint. The importance of considering multiple etiological factors in the treatment of such psychosomatic disorders as bruxism is discussed.

1988

Radil, T.; Snyderova, I.; Hacik, L.; Pfeiffer, J.; Votava, J. (1988). Attempts to influence movement disorders in hemiparetics. Scandinavian Journal of Rehab. Med. Suppl., 17, 157-161.

Step duration, measured in hemiparetic patients walking on a circular path, showed that step duration of the affected foot is usually longer. Functional electrical stimulation of the peroneal nerve in the swing phase of the step (eliminating foot drop) shortened step duration in the majority of cases. Hypnosis induced by the verbal fixation technique was used in hemiparetic patients (a) to ascertain whether the patients' mobility would increase during hypnosis and to determine (in positive cases) whether this approach might be used to predict the effect of rehabilitation

performed by classical methods; (b) to use hypnosis as a method of auxiliary treatment. The general finding was that the extent of movements of the hemiparetic upper extremity considerably improved during and immediately after hypnosis. This effect could be observed both at the level of severe impairment (at the beginning of treatment) and during the later stages when mobility greatly improved due to rehabilitation and recovery.

1986

Rudnick, David (1986). Hypnosis in movement disorders. [Paper] Presented at UCLA Neurobehavioral Seminar/Case Conference.

This case conference involved presentation of 4 cases of torticollis movement disorders and discussion of the role of hypnosis in treatment. Author asked: What are dystonias? What is hypnosis? What is the effect of movement disorders on hypnosis? He noted that the close mind-body relationship was an interest of Mesmer, and of Charcot in study of epilepsy. In one case, hypnosis was used for: 1. movement exercises (often incorporated into imagery) once the patient is hypnotized, to exercise muscles. 2. tactile and imagery-based suggestions for healing brain center and neck (e.g. imaging change and growth in atrophied muscles) 3. psychodynamic explorations of possible contributory factors (e.g. a patient who had no history of neurological insult, but talked about guilt over raising an illegitimate son). 4. Self-hypnosis tapes (specific motor exercises and nonspecific relaxation techniques) 5. simulating typing, taking dictation under hypnosis

Author notes that we are beginning to get some understanding of the neuropathology and neuroanatomy of movement disorders. They are involuntary, happen without people trying to make them happen. We used to think they all disappear during sleep, but Tourette's tics occur during sleep. Based on known syndromes (Parkinson's and Huntington's diseases), it appears that movement disorders involve extrapyramidal and basal ganglia, subthalamic nuclei, substantia nigra, red nucleus, direct connection to spinal levels and to thalamus. Neurotransmitters involved include dopamine, GABA, etc.

There is still an argument whether these movement disorders are psychogenic or neurogenic. In the past torticollis was considered psychogenic, caused by single traumatic event. Then hypnosis was used a la Freud. There were early case reports of improvement with hypnosis, but no long-term follow-up of results. The author thinks they attributed improvement with hypnosis to the wrong reasons. Hypnosis also was being applied to clearly neurogenic disorders at that time.

Various theories of hypnosis have neurological aspects: 1. Hypnosis is related to neurologic regression (exemplified by animals staying still in face of danger), involving the phylogenetically older brain. 2. Hysteria equals state of hypnosis (but hysteria itself isn't well-defined). Most hysterics have some neurological problems.

See recent articles by Bruce Miller 3. Hypnosis is a state of partial sleep (a la Pavlov), but EEG patterns during hypnosis are similar to waking EEG. There are reports of people placed into hypnosis and then given suggestions to go to sleep, and EEG changes are observed (but not sleep pattern). 4. William Kroger, M.D., theorizes that the part of brain "calling the shots" during hypnosis is an older part of the brain, with something separating out the cortex, so that memory storage is different, and reality identified is different. 5. Some evidence points to role of the reticular activating system -- which integrates afferent sensory pathways; only some neocortex projects to the system. Functionally, the reticular activating system relates to motor phenomena and especially to attention. 6. Electrophysiological changes may occur in hypnosis. Roberts (1960 NCEH) says it's a specific electrophysiological state of brain: arousal of reticular activation system, inhibition of behavioral arousal, and sensory suppression.

The author asks, How does cortical inhibition occur in hypnosis? There is a subcortical delta wave that "drives the separation of cortex (three persistent rhythmic stimuli). He asks, Is there some way to teach subcortical changes? He notes a connection between hypnosis and movement disorders. The reticular activating system and extrapyramidal connections are inhibited by hypnosis, so they are no longer responsible for decreasing the movement disorders. Finally, why do some people stop movements during hypnosis while, the movements return after hypnosis termination?

1985

Miller, Lorence S.; Cross, Herbert J. (1985). Hypnotic susceptibility, hypnosis, and EMG biofeedback in the reduction of frontalis muscle tension. International Journal of Clinical and Experimental Hypnosis, 33, 258-272.

Biofeedback and hypnosis have been used in the treatment of similar disorders. While each has been useful, it is unclear whether they involve similar or conflicting processes. Bowers & Kelly (1979) have hypothesized that high hypnotizable Ss are more likely to benefit from hypnosis and similar procedures, than moderate and low hypnotizable individuals. In contrast, Qualls & Sheehan (1979, 1981 a, b, c) have argued that hypnosis and biofeedback involve antithetical abilities. In the present study, high, moderate, and low hypnotizable individuals (N = 60) were randomly assigned to either EMG biofeedback or hypnosis conditions and instructed to relax. It was found that the mean percent reduction in frontalis muscle tension over the last 5 trials was significantly greater for the high hypnotizable Ss during hypnosis than the moderate and low hypnotizable Ss. The moderate and low hypnotizable Ss demonstrated greater reductions in frontalis muscle tension during EMG biofeedback than during hypnosis. These findings are partly supportive of the predictions of Qualls and Sheehan that hypnosis and biofeedback involve antithetical processes.

Qualls and Sheehan (1979, 1981a) "have hypothesized that biofeedback and hypnosis abilities involve antithetical or antagonistic cognitive processes. Specifically, they argued that the biofeedback signal interferes with the natural ability of high absorption Ss to 'direct their attention in an effortless manner toward

subjective, imaginal experience [1981a, p. 33],' by forcing them to attend to the external environment. In contrast, low absorption Ss, as well as moderate hypnotizable Ss, possess inadequate abilities to direct their attention in such an effortless and absorbing manner towards inner, subjective experiences, and therefore, the biofeedback signal better enables them to focus their attention. While the pattern of EMG results among the high, moderate, and low hypnotizable Ss ... was somewhat consistent with these predictions, the self-report data did not reveal differences in Ss' awareness of the biofeedback signal or hypnotic suggestions. In addition, there was only a trend for the high hypnotizable Subjects to report less effort in attempting to relax. It is, therefore, unclear whether the explanations postulated by Qualls and Sheehan (1979, 1981a) for the differences found in this study are valid" (p. 269).

Subjective relaxation response results were complex. Ss were asked how relaxed they were during the experimental session in comparison to the previous hypnosis sessions (screening tests). Biofeedback Ss rated the experimental session less favorably than hypnosis Ss. Ss were asked to what degree the feedback (or hypnotic suggestions) helped them to relax; there were significant main effects for treatment and trait, as well as a significant trait x sex interaction. Hypnosis Ss reported that this procedure was more helpful than was reported by the biofeedback Ss. Newman-Keuls comparison revealed that the main effect for trait was due to the high hypnotizable Ss reporting more help from the procedures than the low hypnotizable Ss, and moderate hypnotizable Ss. The Trait x Sex interaction was the result of the high hypnotizable female Ss indicating more help from either relaxation procedure, than was reported by the low hypnotizable male Ss and moderate hypnotizable female Ss and the high hypnotizable male Ss indicated that the procedures were significantly more helpful than was reported by the low hypnotizable male Ss

Pajntar, M.; Roskar, E.; Vodovnik, L. (1985). Some neuromuscular phenomena in hypnosis. In Waxman, D.; Misra, P.C.; Gibson, M.; Basker, M.A. (Ed.), Modern trends in hypnosis (pp. 181-206). New York: Plenum Press.

The phenomena presented here allow us to conclude that with hypnosis, the functioning of the neuromuscular system may be significantly influenced, either by increasing or decreasing the functioning of voluntary or electrically stimulated contractions, and that the function of movements may be improved. Two suggestions proved to be most efficient: 1) physical and mental relaxation, and 2) age regression. In age regression the patient recalls the ideomotor system, which is likely to result in a reconstruction of the forgotten motor contractions or in a strong intensification of these contractions under additional suggestions. With regard to relaxation, on one hand it intensifies the functioning of the voluntarily stimulated neuro-muscular systems, and on the other hand it prevents an excessive functioning of the involuntarily reflex stimulated antagonistic systems" (pp 202; 204).

**Funch, Donna P.; Gale, Elliot N. (1984). Biofeedback and relaxation therapy for chronic temporomandibular joint pain: Predicting successful outcomes. Journal of Consulting and Clinical Psychology, 52 (6), 928-935.**

Fifty-seven patients with chronic temporomandibular joint (TMJ) pain were randomly assigned to receive either relaxation or biofeedback therapy. Therapy efficacy was assessed (immediate posttreatment and 2-year follow-up), and pretherapy factors (demographic, clinical, personality) were used to predict successful outcomes for each therapy group. Although there were no significant differences in outcomes, characteristics of patients with successful outcomes were not similar for the two therapies. Successful patients in the relaxation condition tended to be younger, had experienced TMJ pain for a shorter period of time, and had reported problems with other psychophysiological disorders. Successful patients in the biofeedback group tended to be older, married, had experienced TMJ pain for a longer period of time, and had not received prior equilibration treatment. Only two of these factors, equilibration and presence of other disorders, were related to both short- and long-term outcomes, suggesting that they may be particularly useful as predictors of outcome. These findings do suggest that knowledge of pretherapy factors, particularly clinical, may allow for more optimal assignment to therapy conditions.

**Murphy, Joseph K.; Fuller, A. Kenneth (1984). Hypnosis and biofeedback as adjunctive therapy in blepharospasm: A case report. American Journal of Clinical Hypnosis, 27, 31-37.**

The efficacy of ophthalmologic, hypnotic, and biofeedback treatment procedures in a case of blepharospasm was evaluated. Manual eye rubbing and eye opening served as dependent measures which were assessed by the patient during treatment and a three month follow-up. Results indicated that ophthalmologic treatment had a limited effect. In contrast, brief hypnosis had a dramatic but short-lived effect and biofeedback had a moderate but sustained effect. Results are discussed in terms of the efficacy of psychological intervention, the limitations of the report, and the need for future research.

**Stam, Henderikus J.; McGrath, Patricia A.; Brooke, Ralph I. (1984). The effects of a cognitive-behavioral treatment program on temporo-mandibular pain and dysfunction syndrome. Psychosomatic Medicine, 46, 534-545.**

Sixty-one patients, clearly diagnosed as suffering from temporo-mandibular pain and dysfunction syndrome (TMPDS), were randomly assigned to one of three groups, (1) hypnosis and cognitive coping skills, (2) relaxation and cognitive coping skills, or (3) a no-treatment control group. All patients were evaluated with a standard hypnotic susceptibility scale prior to treatment. The two treatment groups received four weekly sessions of their respective treatments. Patients in the hypnosis and relaxation groups reported equivalent decrements in pain, abnormal sounds in the temporomandibular joint, and limitations of jaw mobility. Hypnotic susceptibility was significantly correlated with reductions in reported pain for the

treatment groups. Patients' age and the duration of pain prior to treatment were not related to treatment outcome. Patients who dropped out of treatment had fewer limitations in jaw movement but did not differ on any other variable from patients who remained in treatment. These findings are discussed in relation to the hypothesis that TMPDS is a stress related muscular pain and dysfunction.

1983

Schandler, Steven L.; Dana, Edward R. (1983). Cognitive imagery and physiological feedback relaxation protocols applied to clinically tense young adults: A comparison of state, trait, and physiological effects. Journal of Clinical Psychology, 39, 672-681.

Examined changes in targeted and general tension behaviors as well as reductions in physiological tension associated with cognitive imagery and electromyographic biofeedback relaxation procedures. Three groups of 15 female college students participated. During three weekly sessions each person received either guided cognitive imagery relaxation, frontalis muscle feedback relaxation, or a self-rest control procedure. The Anxiety Differential was administered before and after each session, while frontalis EMG, heart rate, and skin temperature were monitored continuously. A second Temperament Analysis was administered after the final session. The imagery procedure was associated with moderate reductions in physiological tension and significant reductions in state anxiety and three tension-related personality dimensions. Self-rest persons displayed lesser reductions in general tension with little physiological change. While biofeedback persons showed the largest reductions in physiological tension, they displayed only small and variable changes in state anxiety and personality dimensions. The data raise continued questions about the application of physiologically based operant relaxation procedures and support the use of cognitively mediated protocols for the treatment of specific or general anxiety behaviors.

Thakur, Kripa; Thakur, Aruna (1983, November). Hypnotherapy for dysphagia. [Paper] Presented at the annual meeting of the American Society for Clinical Hypnosis, Dallas, TX.

The authors present six cases. They describe the act of swallowing as a complex neuromuscular activity involving a series of conditioned reflexes that get mingled with the voluntary act of swallowing, resulting in an automatic functioning of the mouth, pharynx, and the esophagus.

1980

Pajntar, Marjan; Jeglic, Anton; Stefancic, Martin; Vodovnik, Lojze (1980). Improvements of motor response by means of hypnosis in patients with peripheral nerve lesions. International Journal of Clinical and Experimental Hypnosis, 28 (1), 16-26.

In order to accelerate rehabilitation of patients with peripheral nerve lesions, hypnosis was employed to encourage them voluntarily to move those muscles with weak re-innervation and to achieve the best possible activity of the affected muscle

groups. By measuring muscle force and endurance and by observing the electrical activity of the affected muscles, it was found that the activity of the affected muscles was much better while patients were in hypnosis than when they were in the waking state. The patients were able to contract even paretic muscles having only weak re-innervation with such strength, that clinically perceptible contraction of the muscles and movement of paretic extremities occurred. Such early and improved activation is very important for prevention of much permanent damage.

1967

Schubot, Errol David (1967). The influence of hypnotic and muscular relaxation in systematic desensitization of phobias (Dissertation). Dissertation Abstracts, 27 (n10-B), 3681-3682.

"15 snake phobic subjects had desensitization treatment and 15 matched subjects had desensitization treatment with a hypnotic and muscular relaxation induction. Rate of moving through the fear hierarchy was based on three variables fear report, report of body tension, and time of signaling anxiety. Analysis of results took into consideration initial approach (to snake) level of subjects. Both treatments were effective. However, hypnotic relaxation was significantly important in desensitization for the most phobic subjects (those who couldn't approach closer than 5 feet, initially) though not for less fearful subjects. In fact, the most fearful subjects did not show improved approach behavior if they did not get the hypnosis relaxation treatment, though bodily tension and fear were reported as less while working on early items in the hierarchy. The Waking group, compared to the Relaxation hypnosis group, manifested significantly less improvement in approach and slower progress in desensitization. Hypnotizability was significantly correlated with improvement for the Relaxation subjects, as was vividness of imagery. In summary, hypnosis (a relaxation induction) facilitated desensitization treatment of highly anxiety snake-phobic subjects with the hypnotic relaxation induction, treatment outcome was related both to hypnotizability and to imagery vividness" (p. 3681- 3682).

1965

Schneck, Jerome M. (1965). Hypnotherapy for vaginismus. International Journal of Clinical and Experimental Hypnosis, 13 (2), 92-95.

The literature on hypnotherapy contains few comments, usually generalizations, on vaginismus. 2 patients with this problem are presented here. Methods used and degrees of success are described. Major stress was on hypnotic relaxation with supporting, persuading, and graded, encouraging measures. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1964

Moskowitz, Arnold E. (1964). A clinical and experimental approach to the evaluation and treatment of a conversion reaction with hypnosis. International Journal of Clinical and Experimental Hypnosis, 12 (4), 218-227.

A combination of hypnotherapeutic techniques within a clinical and experimental context provided a method of understanding, evaluating, and predicting the course of a conversion reaction. During waking and hypnotic conditions, 5 trials of dynamometer presses were obtained from a patient having primary symptoms of paralysis of his left arm. Difference scores between the left and right hands during waking and hypnotic conditions were evaluated. Findings were: (a) At the beginning of treatment, significant differences were found between the waking and hypnotic conditions (b) The largest differences between the waking and hypnotic conditions occurred during the early stages of treatment, while the smallest differences occurred on the final day of treatment. (c) With a complete remission of the patient's symptoms, no significant differences between the waking and hypnotic conditions were found. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1961

Cedercreutz, Claes (1961). Hypnosis in surgery. International Journal of Clinical and Experimental Hypnosis, 9, 93-95.

(Author's Summary) "It is possible to treat painful conditions and spasms in the alimentary canal by hypnosis. In the rehabilitation of patients with limb injuries and fractures, hypnosis has also proved useful. There is seldom reason to resort to this method of inducing anaesthesia in surgery" (p. 95).

Music

1992

Blankfield, Robert; Scheurman, Kathleen; Bittel, Sue; Alemagno, Sonia; Flocke, Sue; Zyzanski, Stephen (1992, October). Taped therapeutic suggestions and taped music as adjuncts in the care of coronary artery bypass graft patients. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

18 studies have explored the issue with an experimental design; half used tapes, half didn't; majority of studies found benefits; 2 were of heart surgery patients.

This study used taped suggestions with coronary bypass patients. Used tape recorder rather than person delivering suggestions because it was more convenient; used tape intra-surgery and post-operatively for more impact.

We hypothesized: shorter length of stay, less narcotic analgesia, less anxiety, faster recovery, more positive mental outlook, resume activities sooner, have less symptoms postoperatively, etc.

Used a prospective, randomized, single-blind trial in 2 community hospitals in Cleveland with coronary artery bypass graft surgery patients. Study was done between Dec 1989 - Feb 1992.

3 groups were involved: (1) Suggestion, (2) music, and (3) tape. Control subjects had a blank tape. Tapes were played continuously and repeatedly with headphones. Postoperatively, a different tape was played.

**Excluded:** Patients with emergent surgery, hearing impairment, poor comprehension of English, patients who died in hospital, patients whose hospital stay lasted longer than 14 days (3 of them). 5% of sample were eliminated for last 2 reasons.

**Music:** Herb Ernst, Dreamflight II. **Suggestions:** Music background, permissive, based on Evans & Richardson's study.

**Outcome Measures:** Nurse assessment of anxiety and progress post operatively, Symptom scale, Depression scale.

Mean age 62, 3/4 men, 92% white, 75% married. The groups were same on a variety of preoperative variables (status of heart and arteries). Length of stay was 6.5 in all 3 groups. No difference in narcotics use, in nurse assessment of anxiety or of progress; of depression scale, or activities of daily living.

Recategorized data into patients who said the tapes were helpful (both music and suggestion) N = 33 vs the other patients N = 62. No difference in the variables evaluated.

1990

Biasutti, M. (1990). Music ability and altered states of consciousness: An experimental study. International Journal of Psychosomatics, 37, 82-85.

The relationship between music and altered states of consciousness was studied with 30 subjects divided into hypnosis and control groups. The "Test di abilità musicale" was applied. The hypnosis group did the retest after posthypnotic suggestions and the second in waking conditions. The hypnosis group had better results than the control group, especially in the rhythm test ( $p < 0.0001$ ).

Clark, Duncan B.; Agras, W. Stewart (1990). The assessment and treatment of performance anxiety in musicians. American Journal of Psychiatry, 148 (5), 598-605.

94 adults with a performance anxiety problem were recruited by mass media announcements and were seen in a university-based outpatient psychiatric clinic. Assessments were questionnaires for all 94 ss, diagnostic interview of 50 ss, and laboratory performance of 34 ss. Treatment conditions were 6 weeks of buspirone, 6 weeks of placebo, a five-session group cognitive-behavior therapy program (CBTP) with buspirone, or the CBTP with placebo. All Ss fulfilled criteria for Diagnostic and Statistical Manual of Mental Disorders-III-Revised (DSM-III-R) social phobia. Of the 15 full-time professional musicians, 10 had tried propranolol and 3 had stopped performing. Most Ss had substantial anxiety and heart rate increases during lab speech and musical performances. CBTP resulted in significant reductions in subjective anxiety, improved quality of musical performance, and improved performance confidence.

1989

Snodgrass, M.; Lynn, Steven Jay (1989). Music absorption and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 37, 41-54.

The present study investigated differences between high (N = 15), medium (N = 20), and low (N = 16) hypnotizable Ss' involvement in imaginative versus nonimaginative music. Ss were first screened for hypnotizability with the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962). In a second session presented as a study of music appreciation, Ss listened to classical music of high- and low-rated music imaginativeness. Ss' involvement was indexed by absorption, imagery elaboration reported in open-ended essays, and reaction time to a pure tone. High hypnotizable Ss reported more absorption than low hypnotizable Ss, regardless of the imaginativeness level of the music. Ss reported more imagery elaboration in the imaginative than in the low-imaginative passages. High hypnotizable Ss tended to differ in their imagery elaboration in response to the imaginative passages but not in response to the nonimaginative passages. Reaction time results were nonsignificant. No sex differences were found. Medium hypnotizable Ss were indistinguishable from both high- and low-hypnotizable Ss. The findings are generally compatible with J. R. Hilgard's (1970, 1974) construct of imaginative involvement.

**Kokoszka, Andrzej (1993). Occurrence of altered states of consciousness among students: Profoundly and superficially altered states in wakefulness. Imagination, Cognition and Personality, 12, 231-247.**

In a questionnaire survey waking altered states of consciousness (ASC) are found to be common among 174 Polish students. The experience of Superficially Altered States of Consciousness (SASC) was reported by 96 percent of subjects and more than half of them had such experiences often. Whereas an experience of Profoundly Altered States of Consciousness (PASC) was confirmed by 75 percent and about one-third of them had them often. The comparison of the experiences accompanying the ASC indicates that SASC are characterized by disturbances in experiencing the reality and oneself combined with positive, pleasant feelings and with quietness. On the other hand, PASC are accompanied by experiences related to an absolute, universal, eternal, and existential or religious matters. PASC are accompanied by extremely strong positive emotions of happiness, total love, etc. and are experienced as more rational than SASC, and with significantly less feelings of cognitive disturbances than in SASC. The comparison of circumstances of the ASC occurrence indicates that SASC occur in usual and common states and situation of everyday life, whereas PASC mainly in the context of religion and nature. The congruence of these findings with an integrated model of the main states of consciousness suggests a natural tendency for a cyclical occurrence of ASC, or more precisely, the differentiated waking states of consciousness.

**Richeport, Madeleine M. (1992). The interface between multiple personality, spirit mediumship, and hypnosis. American Journal of Clinical Hypnosis, 34, 168-177.**

The author draws parallels between multiple personality disorder (dissociative identity disorder), spirit mediumship, and hypnosis. She uses historical, anthropological, and clinical perspectives. According to the author, Milton Erickson's view of multiple personality disorder was that it was not necessarily pathological, and he employed hypnosis to gain access to personalities and to transform their behavior from involuntary to voluntary actions. "Natural trance therapies in other cultures offer a new perspective for viewing the normalcy or pathology of "other selves"" (p. 168).

**Nelson, Peter L. (1991-92). Personality attributes as discriminating factors in distinguishing religio-mystical from paranormal experients. Imagination, Cognition and Personality, 11, 389-406.**

In the first section of this article, an operationalized notion of preternatural experience is described which includes two general classes of experience: religio-mystical (Ontic) and paranormal (Perceptual). The exploratory study which follows uses the personality measures of the complete Tellegen Differential Personality Questionnaire taken from 120 subjects who reported having had spontaneous

religio- mystical and/or paranormal experiences at some time in the past. The scores on all eleven primary dimensions, three higher order affect factors, and two validity scales were used individually, in univariate ANOVAs, and together, in a Direct Discriminant Function Analysis, to successfully separate two classes of preternatural experients from non- experients and from each other.

Burnham, John C. (1984, October/1986). The fragmenting of the soul: Intellectual prerequisites for ideas of dissociation in the United States. In Quen, Jacques M. (Ed.), Split minds/split brains (pp. 63-84). New York: New York University Press. (Based on symposium in Bear Mt., N.Y., by Section on the History of Psychiatry of Cornell University Medical Center)

"Reductionism was a relentless pursuit of the idea that knowledge of components led to knowledge of causes. In this context, I propose to show how, in the psychological-medical realm, the initial concept was the soul, and the final intellectual product was dissociative phenomena" p. 64.

Decker, Hannah S. (1984, October/1986). The lure of nonmaterialism in materialist Europe: Investigations of dissociative phenomena, 1880-1915. In Quen, Jacques M. (Ed.), Split minds/split brains (pp. 31-62). New York: New York University Press. (Based on symposium in Bear Mt., N.Y., by Section on the History of Psychiatry of Cornell University Medical Center)

Janet's career paralleled an increased interest in dissociation, because he had contact with scientists studying spiritism, used hypnosis, and insisted on a scientific approach. He coined the words "subconscious" and "dissociation." As his sphere of influence declined, so did scientific interest in dissociation--especially multiple personality disorder.

Scientific study of dissociation began with investigations into religious exorcism and spirit possession. For example, at the behest of Prince Max Joseph of Bavaria, Mesmer duplicated the exorcisms of Father Gassner (causing convulsions) using hypnosis. Following Mesmer, there were reports of multiple personalities (e.g. an "exchanged personality" in Germany, reported in 1791 by Eberhardt Gmelin).

"Partly because of this growth of knowledge of multiple personality, a new model of the mind developed during the early 19th century: the mind was dual; there were conscious and unconscious mental states. Later, it was said that there was a dominant conscious personality with a group of underlying subpersonalities. Eventually it was declared that split fragments of personality could act autonomously" p. 37.

The scientific study of these phenomena continued under the leadership of Frederic Myers of The Cambridge Society for Psychical Research. According to William James, Myers was the first to consider the phenomena of hallucination, hypnotism, automatism, double personality, and mediumship as connected parts of one whole

subject. The Cambridge Society was involved in the transition from the use of automatic writing by mediums to its use for clinical purposes and experimental research in the 1880's and 1890's.

Increasing numbers of multiple personalities reported in the literature in late 19th century led to increased interest in hypnosis and to the concept of dissociation. The author details the contributions of Janet, and then explains how interest declined in dissociation and in hypnosis due to the following: 1. Experimental psychologists in Germany (e.g. Wundt) refused to deal with anything that resembled the "unconscious," and neglected the point of view of the experiencing person. 2. Those few psychologists interested in the unconscious found projective tests (Rorschach, TAT) an easier avenue than hypnosis or automatic writing. 3. Many mediums were exposed as frauds, e.g. Flournoy's popular "From India to the Planet Mars". 4. Janet himself was very critical of parapsychology. 5. When Charcot died suddenly, it was discovered that some of his assistants had rehearsed the behavior of hypnotized patients. 6. Hypnotists' extravagant claims (e.g. past life age regression) led to a wave of reaction against them. 7. Questions were raised about the iatrogenic nature of multiple personality. 8. Conscientious hypnotists discovered drawbacks

- not everyone could become good hypnotists (e.g. Freud)
- not everyone could be hypnotized
- some patients faked hypnosis
- extreme sensitivity of hypnotized patients to the hypnotist's wishes led to biased results
- hypnotist sometimes was conditioned to things in certain way by his first patient

9. Janet didn't have the personality of a leader, and he argued with the psychoanalysts about who should get credit for certain ideas

Sacerdote, Paul (1977). Application of hypnotically elicited mystical states to the treatment of physical and emotional pain. International Journal of Clinical and Experimental Hypnosis, 25, 309-324.

Mystical states by-pass usual sensory perception and logical thinking. They often represent the ultimate goal of long apprenticeships in Eastern or Western monastic practices which stress self-discipline and meditation; or they correlate with sudden religious conversions. While interest has also been revived in mystical experiences stimulated by hallucinogens within the appropriate physical, intellectual, and emotional environment, less attention has been paid to those mystical experiences which appear spontaneously during hypnosis and Transcendental Meditation. The present author facilitates the unleashing of mystical experiences by using hypnotic approaches specifically aimed at altering space and time perceptions. Case presentations illustrate the methodologies for guiding receptive subjects to mystical states with the aim of relieving or correcting organic and functional painful syndromes unresponsive to other interventions. The probable biopsychological processes are discussed.

**King, C. D. (1963). The states of human consciousness. New York, NY: University Books. (Reviewed in *American Journal of Clinical Hypnosis* 7, 1964, 96.)**

From the book review by Stanley Abrams, *AJCH*: [The book] "is more philosophical and mystical than scientific. ... [and describes] the four states of consciousness: sleep, waking, awakeness, and objective consciousness. ... For man to attain completeness and normalcy he must achieve the state of awakeness. According to the author, however, only a relatively few have approached this stage of consciousness and his description of it is quite vague. When one has reached awakeness he is able to understand and actually perceive the world in a novel and unique manner. ... The final stage of awareness, objective consciousness, is characterized as the experiencing of cosmic phenomena in the same fashion as external reality is understood in the awakened state. The author indicated that this stage has not as yet been attained by man, but it does lie within his potential. ... The only treatment of hypnosis is the author's statement that the waking state is the same as the hypnotic state because suggestibility exists in both" (p. 96).

Faymonville, M. E.; Mambourg, P. H.; Joris, J.; Vrijens, B.; Fissette, J.; Albert, A.; Lamy, M. (1997). Psychological approaches during conscious sedation. Hypnosis versus stress reducing strategies: A prospective randomized study. Pain, **73** (3), 361-367.

Stress reducing strategies are useful in patients undergoing surgery. Hypnosis is also known to alleviate acute and chronic pain. We therefore compared the effectiveness of these two psychological approaches for reducing perioperative discomfort during conscious sedation for plastic surgery. Sixty patients scheduled for elective plastic surgery under local anesthesia and intravenous sedation (midazolam and alfentanil upon request) were included in the study after providing informed consent. They were randomly allocated to either stress reducing strategies (control: CONT) or hypnosis (HYP) during the entire surgical procedure. Both techniques were performed by the same anesthesiologist (MEF). Patient behavior was noted during surgery by a psychologist, the patient noted anxiety, pain, perceived control before, during and after surgery, and postoperative nausea and vomiting (PONV). Patient satisfaction and surgical conditions were also recorded. Peri- and postoperative anxiety and pain were significantly lower in the HYP group. This reduction in anxiety and pain were achieved despite a significant reduction in intraoperative requirements for midazolam and alfentanil in the HYP group (alfentanil: 8.7 +/- 0.9 microg kg(-1)/h(-1) vs. 19.4 +/- 2 microg kg(-1)/h(-1), P < 0.001; midazolam: 0.04 +/- 0.003 mg kg(-1)/h(-1) vs. 0.09 +/- 0.01 mg kg(-1)/h(-1), P < 0.001). Patients in the HYP group reported an impression of more intraoperative control than those in the CONT group (P < 0.01). PONV were significantly reduced in the HYP group (6.5% vs. 30.8%, P < 0.001). Surgical conditions were better in the HYP group. Less signs of patient discomfort and pain were observed by the psychologist in the HYP group (P < 0.001). Vital signs were significantly more stable in the HYP group. Patient satisfaction score was significantly higher in the HYP group (P < 0.004). This study suggests that hypnosis provides better perioperative pain and anxiety relief, allows for significant reductions in alfentanil and midazolam requirements, and improves patient satisfaction and surgical conditions as compared with conventional stress reducing strategies support in patients receiving conscious sedation for plastic surgery.

1994

Brown, Gail W.; Riddell, Rodney; Summers, David; Coffman, Brent (1994, August). Use of hypnosis by practitioners in the school setting. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

Hypnosis is a therapeutic procedure that is appropriate for some school-age clients. Through the use of hypnosis that utilizes metaphors and imagery, children can be empowered to find unique solutions to their problems. Children enjoy the feeling of power and mastery that they have when able to perform hypnotic phenomena. They like to play magic and can be told that a finger or other body part will become numb. Because a major goal of hypnotherapy is to teach a child to be an active participant in his or her own behalf, the focus is on creating solutions and mastering the situation rather than enduring the problems. Four case studies demonstrate the utility of hypnosis in the treatment of phantom pain and nausea, sleep terror disorder, school phobia, and spider phobia. In each case, treatment goals were realized. Because the solutions were self-generated, the behavioral changes maintained over time and situation.

**Case #1:** Hypnosis was used to help alleviate phantom limb pain and nausea during chemotherapy following amputation of the right leg at the knee due to cancer in a thirteen-year-old male. The client had indicated that he loved nature and enjoyed the mountains. The metaphor described a young tree that has just begun to grow small silvery leaves. The spring floods tear the limbs and branches from the stump. The deep roots and stump of the tree are all that remain. The tree is not the same as before the flood. Its roots are stronger, its base more sturdy compared to the branches and limbs. The young tree has withstood the catastrophe of the torrent of waters and is even stronger than before. To counter the nausea and vomiting associated with chemotherapy a switch mechanism metaphor was used. The client was adroit with computers and had no difficulty picturing a switch located in his brain which could "turn off" the nausea from chemotherapy. A room contained all the unpleasant feelings that were being experienced. In this room is a light of a particular color that represents all the unpleasant sensations. Press the key on the computer that controls the switch to turn off the colored light in that room. Suggestions for healing were also given. Your body has known for years how to heal. Visualize the battle between good and bad cells and the victory of the good cells.

**Case #2:** Hypnosis was used to alleviate sleep terror disorder in a ten-year-old female. The onset of the subject's parasomnic symptomatology appeared to coincide with her starting kindergarten and her family's relocation shortly before. The initial treatment consisted of progressive relaxation, deep breathing, and the visual image of her "secret safe place." An induction utilizing a variety of images was presented. Hiking barefoot on a cool moss covered mountain trail, sitting in an alpine meadow on a warm summer afternoon, and flying proved most effective in facilitating trance. The participant was told to "Visualize all your anxiety and tension as hard grey rocks. Pick up these rocks and place them in your pockets. Go to the front porch of your "secret safe place and on the porch is a "magic hefty bag." Place your hard grey rocks that contain all your anxiety and tension in the magic bag. Once in the bag, the rocks will no longer weight you down, you will be free of any feelings of stress or tension. Your bed is magic; it is covered with a special glue which will keep you in a reclining position until you are fully rested and ready to awaken."

**Case #3:** Hypnosis was used in the treatment of school phobia in a nine-year-old male. The student experienced intense anxiety whenever separation from the primary caretaker occurred. The teacher stated that this boy experienced frequent absences and crying spells that were only relieved by phone calls to his mother or the presence of his mother next to him in class.

In preparation for the intervention, the student was asked to draw a picture of how he felt inside during a panic attack. He drew a fire. He also said that only his mother could put that fire out. This information was utilized in creating a metaphor that described a house in a small town. "The mother had left, and a young boy was left alone. While at home, the boy looked out the window and saw several boys trying to burn a neighbor's yard! Acting quickly, he called the fire department, grabbed the fire extinguisher and unraveled the garden hose. He was able to extinguish the fire. The neighbors and friends were very happy and praised the boy's performance. When his mother heard the good news, she quickly returned home and held a celebration in his honor." Following the metaphor, hypnotherapy continued with suggestions about fire extinguishers that the subject could use to put out emotional fires.

**Case #4:** Hypnosis was used in the treatment of spider phobia. Diagnosis of phobia was made in this eleven-year-old female when the fear or avoidance behavior was distressing. The child's strained facial expressions occurred even at the thought of seeing what she described as "a creepy, crawly creature with 8 legs." Preparatory to her first induction the participant was read the story of *Charlotte's Web* (White, 1980) to facilitate the imagery for future hypnotic work. In the following session systematic desensitization was accomplished using characters from the story of *Charlotte's Web*. During the third session the subject was age regressed to the first time she remembered seeing a spider. She recalled playing in the woods outside her family home on an island and seeing a large web stretched between two trees with a very large spider in the center of its web. She was then asked to remain at that place to look closely at that spider as it was most likely Charlotte or one of Charlotte's family. Upon closer investigation she saw not only Charlotte but "teeny-tiny babies." The event was reconstructed as a happy experience. The imagery provided by *Charlotte's Web* permitted the subject to fantasize her previous frightful experience and reframe spiders as cute little "teeny-tiny" babies with admirable human qualities.

**LaGrone, Randy G. (1993).** Hypnobeavioral therapy to reduce gag and emesis with a 10-year-old pill swallower. *American Journal of Clinical Hypnosis*, 36, 132-136.

A 10-year-old child experienced severe nausea and psychogenic vomiting that resulted in refusal to take oral medication in pill form. The youngster was treated with hypnobeavioral therapy consisting of mental imagery, relaxation, direct suggestion, adaptive self-talk, self-monitoring, and self-reinforcement. The child's parents were instructed to reinforce approximations of successful pill swallowing while withdrawing attention for avoidance, whining, gagging, and vomiting. A one-year follow-up revealed successful pill swallowing without significant distress.

1992

Levitan, Alexander A. (1992). The use of hypnosis with cancer patients. Psychiatric Medicine, 10, 119-131.

Hypnosis has proven to be extremely valuable in the treatment of cancer patients. Specific applications include: establishing rapport between the patient and members of the medical health team; control of pain with self-regulation of pain perception through the use of glove anesthesia, time distortion, amnesia, transference of pain to a different body part, or dissociation of the painful part from the rest of the body; controlling symptoms, such as, nausea, anticipatory emesis, learned food aversions, etc.; psychotherapy for anxiety, depression, guilt, anger, hostility, frustration, isolation, and a diminished sense of self-esteem; visualization for health improvement; and, dealing with death anxiety and other related issues. Hypnosis has unique advantages for patients including improvement of self-esteem, involvement in self-care, return of locus of control, lack of unpleasant side effects, and continued efficacy despite continued use.

Syrjala, Karen L.; Cummings, Claudette; Donaldson, Gary W. (1992). Hypnosis or cognitive behavioral training for the reduction of pain and nausea during cancer treatment: A controlled clinical trial. Pain, 48, 137-146.

Few controlled clinical trials have tested the efficacy of psychological techniques for reducing cancer pain or post-chemotherapy nausea and emesis. In this study, 67 bone marrow transplant patients with hematological malignancies were randomly assigned to one of four groups prior to beginning transplantation conditioning: (1) hypnosis training (Hypnosis); (2) cognitive behavioral coping skills training (CB); (3) therapist contact control (TC); or (4) treatment as usual (TAU; no treatment control). Patients completed measures of physical functioning (Sickness Impact Profile; SIP) and psychological functioning (Brief Symptom Inventory; BSI), which were used as covariates in the analyses. Biodemographic variables included gender, age and a risk variable based on diagnosis and number of remissions or relapses. Patients in the Hypnosis, CB, and TC groups met with a clinical psychologist for two pre-transplant training sessions and ten in-hospital "booster" sessions during the course of transplantation. Forty-five patients completed the study and provided all covariate data, and 80% of the time series outcome data. Analyses of the principal study variables indicated that hypnosis was effective in reducing reported oral pain for patients undergoing marrow transplantation. Risk, SIP, and BSI pre-transplant were found to be effective predictors of inpatient physical symptoms. Nausea, emesis and opioid use did not differ significantly between the treatment groups. The cognitive behavioral intervention, as applied in this study, was not effective in reducing the symptoms measured.

Hypnotizability was not measured in this study.

The authors hypothesized that "(1) patients receiving hypnosis training would report the least pain, but the cognitive behavioral group would report less pain than

the untreated group; and (2) both treatment groups would report less nausea and emesis than the control groups" (p. 138). The adult patients were undergoing their first marrow transplant, had survived at least 19 days post-transplant, and had participated in at least the first 8 of 10 possible inpatient sessions; five additional patients completed the study but had missing data.

Each patient in the TC (therapist contact), CB (cognitive behavioral coping skills), and Hypnosis groups participated in two 90 minute training sessions with a psychologist, 2-4 days apart, on an outpatient basis. Once admitted to hospital, twice each week they participated in a total of ten 30-minute sessions designed to reinforce use of the interventions. The TAU (treatment as usual) group had no psychologist contact. For the TC control group, the psychologist simply talked with the patients about whatever was on their minds.

The CB group received multiple interventions: training in relaxation (2 techniques-progressive muscle relaxation and abbreviated autogenic relaxation) with tapes provided; cognitive restructuring (Turk et al., 1983) which included training in attention redirection and restructuring self-defeating cognitions; preparing coping self-statements or affirmations, by focusing attention on neutral or pleasant events or objects, or by occupying their attention through mental repetition of affirmations, songs or prayer; encouragement to think of negative events as time limited; provision of information, especially the beneficial vision of information, especially the beneficial effects of reducing physiological arousal and attention to pain and nausea; assistance in setting short-term progress-related goals for self-care such as exercise, caloric intake, and mouth care; exploration of the meaning of their illness and of bone marrow transplant.

For the Hypnosis group, individually tailored Ericksonian inductions (Lankton & Lankton, 1983) with relaxation and multi-sensory imagery were taped and given to the patient to use in daily practice, in between sessions. The suggestions were directed at reducing pain, nausea, and the emotional reactions to those symptoms; there also were suggestions about health, well-being, self-control and enhanced coping capabilities.

The results were analyzed by ANCOVA (except where non-parametric analysis was required with the opioid data). Due to gender differences in reported pain (men experiencing more) and the fact that the TAU group had an over-representation of men, the TAU group could not be used in the pain analyses. However, there were no gender differences in nausea reports, so that all four groups could be used for nausea outcome analyses.

The Hypnosis group evidenced the lowest amount of post-transplant pain, and used (nonsignificantly) less opioids than the other groups. No significant treatment effects were observed for either nausea or emesis.

In their discussion, the authors noted that "The hypnosis group's peak pain was lower and of a shorter duration than the other three groups. Opioid use closely followed the course of pain intensity. ... The gender effect may be characteristic of this particular sample [since it was unexpected].

"Nausea and emesis followed a less predictable course than pain. ... nausea fluctuated dramatically from day to day within treatment groups. As nausea

moderated after completion of conditioning, the day to day fluctuations remained striking. This lack of symptom predictability may have contributed to the difficulty patients had in using the interventions effectively" (p. 143).

"The lack of significant differences between treatment groups in opioid use indicates that lower pain report in the hypnosis group cannot be explained by increased opioid use. Results do not support the second hypothesis that both hypnosis and cognitive behavioral training would reduce chemotherapy or radiation-induced nausea and emesis

"In MT patients, several factors may limit the impact of either cognitive behavioral training or hypnosis on nausea and emesis. First, MT patients receive higher doses of emetogenic agents than are given to most other cancer patients. Second, patients in this study had only two sessions in which to learn relaxation techniques; this may not have provided adequate training. Third, the most severe emetic challenge began immediately with the first dose of chemotherapy rather than having a gradual onset. This did not permit patients to master the techniques with milder symptoms before applying training to intense symptoms. Fourth, for all patients, psychological interventions were provided as adjuncts to medications rather than as substitutes for antiemetics or opioids. Both antiemetics and opioids have substantial cognitive side effects which, in high doses, may impact patients' abilities to implement interventions which are in essence cognitive. This combination of factors may have provided too severe a challenge to a newly learned skill. In contrast to nausea, oral pain developed over a number of days, permitting practice while symptoms were mild and before administration of opioids.

"Results suggest that the imagery component of the hypnosis intervention was central to its efficacy. Not only was the cognitive behavioral intervention without imagery not effective in reducing the symptoms measured, but we found in clinical practice that patients intermittently began to refuse sessions with relaxation alone. Even hypnosis patients, when under the physical stresses of treatment, had shortened attention spans that necessitated briefer inductions, less time spent on relaxation, and more active, engaging imagery.

"... Since, in clinical practice, imagery is frequently a component of cognitive behavioral treatment, these results would not generalize to those settings where imagery is combined with other skill training.

"Several other possible limitations of the cognitive behavioral intervention merit consideration. Our experience indicates that the number of components used in the two training sessions were more than patients could competently learn in a short time. ... A further possibility is that maladaptive cognitions, which are the targets of cognitive restructuring, may be the exception rather than the rule among MT patients who tend to focus, with their families, on positive, hopeful attitudes toward their treatment" (pp. 144- 145).

The authors note that the relatively small sample size may have provided inadequate statistical power to demonstrate effects with some of the outcome variables.

Walker, Leslie G. (1992). Hypnosis with cancer patients. American Journal of Preventative Psychiatry & Neurology, 3, 42-49.

Overviews the uses of hypnosis with cancer, for example to ameliorate side effects of treatment, help patients adjust to having cancer and its symptoms, reduce the distress caused by painful procedures, and to attempt to alter mechanisms of immunity with a view to improving prognosis. Studies in these areas are reviewed.

1991

Burish, Thomas G.; Snyder, Susan L.; Jenkins, Richard A. (1991). Preparing patients for cancer chemotherapy: Effect of coping preparation and relaxation interventions. Journal of Consulting and Clinical Psychology, 59 (4), 518-525.

60 cancer chemotherapy patients were randomly assigned to 1 of 4 treatments: (a) relaxation training with guided relaxation imagery (RT), (b) general coping preparation package (PREP), (c) both RT and PREP, or (d) routine clinic treatment only. All patients were assessed on self-report, nurse observation, family observation, and physiological measures and were followed for 5 sequential chemotherapy treatments. Results indicate that the PREP intervention increased patients' knowledge of the disease and its treatment, reduced anticipatory side effects, reduced negative affect, and improved general coping. RT patients showed some decrease in negative affect and vomiting, but not as great as in past studies. The data suggest that relatively simple, 1-session coping preparation intervention can reduce many different types of distress associated with cancer chemotherapy and may be more effective than often-used behavioral relaxation procedures.

Zeltzer, Lonnie K.; Dolgin, M. J.; LeBaron, Samuel; LeBaron, C. (1991). A randomized, controlled study of behavioral intervention for chemotherapy distress in children with cancer. Pediatrics, 88, 34-42.

Subjects were randomly assigned to hypnosis, nonhypnotic distraction/relaxation, or attention placebo control. Children in the hypnosis group reported the greatest reduction in both anticipatory and postchemotherapy symptoms. Distraction/relaxation kept symptoms from getting worse, but they did not get better, and the control children's symptoms became much worse.

Kaye, J. M.; Schindler, B. A. (1990). Hypnosis on a consultation-liaison service. General Hospital Psychiatry, 12, 379-383.

Studied the use of hypnosis on a consultation-liaison service with a broad spectrum of medically hospitalized patients. Autohypnosis tapes were used for reinforcement. Twenty-nine women and eight men from 24-75 years of age were hypnotized for relief of depression, pain, anxiety, or side effects of chemotherapy. Results were excellent (total to almost total relief of symptoms) in 68%, fair in 22%, and poor in 11%, with no differences among the results with the various conditions. This demonstrates that hypnotherapy is an extremely useful tool in medical management of patients in consultation-liaison psychiatry.

1986

Hendler, Cobie S.; Redd, William H. (1986). Fear of hypnosis: The role of labeling in patients' acceptance of behavioral interventions. Behavior Therapy, 17, 2-13.

One hundred and five outpatient cancer chemotherapy patients were interviewed to assess their attitudes toward hypnosis and relaxation as well as to determine their beliefs in and willingness to try a behavioral procedure. Patients were randomly assigned to groups receiving identical descriptions labeled "hypnosis," "relaxation," or "passive relaxation with guided imagery." The description stressed the behavioral components of hypnosis and relaxation rather than the nonbehavioral techniques often associated with hypnosis such as age regression and posthypnotic suggestion. Patients believed hypnosis to be a powerful process that involved loss of control and altered states of consciousness. When compared with a group of college students, patients held significantly more fearful, conservative views about hypnosis. Patients who received a description of an intervention labeled "hypnosis" were significantly less likely to believe the procedure would effectively control their nausea and vomiting and were significantly less likely to state they would try the procedure than patients in the other two label conditions. This reaction to the label occurred independently of patients' degree of nausea, vomiting, and pain due to their chemotherapy treatments.

1984

Margolis, Clorinda G. (1984). Hypnosis and cancer: An overview of the field. [Unpublished manuscript]

This paper apparently was presented either at American Psychological Association or the Society for Clinical and Experimental Hypnosis. The author has two tables summarizing types of cancer associated with pain, and pain syndromes in patients with cancer

Table 3 is a list of Erickson's procedures for Controlling Pain: --Direct hypnotic suggestion for total abolition of pain --Permissive indirect hypnotic abolition of pain --Amnesia --Hypnotic analgesia --Hypnotic anesthesia --Hypnotic replacement or substitution of sensations --Hypnotic displacement of pain --Hypnotic dissociation

Time and body disorientation --Hypnotic reinterpretation of pain experience --Hypnotic time distortion --Hypnotic suggestions effecting a diminution of pain (from Rossi, Ed., Innovative Hypnotherapy, Vol. IV of the Collected Papers of Milton H. Erickson on Hypnosis, 1980

Table 4 is a list of Sacerdote's Procedures for Controlling Pain: --Teleological approach --Reinterpretation of signals --Associating and conditioning --Dissociation --Simile of electric wiring --Development of amnesia --Positive and negative hallucinations --Induction of dreams --Time and space distortion, and elicitation of mystical states --Relaxation techniques --Glove anesthesia and analgesia --Pain management through control of autonomic functions

(from Barber & Adrian, Eds., Psychological Approaches to the Management of Pain, 1982)

The author describes cases treated by Erickson (one in which he used 12 hours of training, in one session, reported in Rossi's 1980 edited writings of Milton Erickson, Vol. IV) and by Sacerdote.

Author notes that the Hilgards, in Hypnosis in the Relief of Pain (1975), describe the use of hypnosis in treating patients with cancer pain. In all three--Butler (1954), Lea, Ware, and Monroe (1960), and a larger study by Cangello (1961), both success and failure are reported. As the Hilgards point out, about 50% of the patients studied were able to reduce their pain--a percentage the Hilgards remark is rather close to what successful clinicians tend to report.

Morrow, Gary R. (1984). Appropriateness of taped versus live relaxation in the systematic desensitization of anticipatory nausea and vomiting in cancer patients. Journal of Consulting and Clinical Psychology, 52 (6), 1098-1099.

Investigated the suggestion that the relaxation part of systematic desensitization--an effective treatment for the nausea and vomiting experienced by approximately 25% of cancer patients in anticipation of chemotherapeutic treatments-- could be learned from a prerecorded audiotape prior to meeting a psychologist for treatment. 10 cancer patients who had developed anticipatory nausea or vomiting were assigned to either a live-relaxation or a tape-relaxation group. Results show that 4 of 5 Ss assigned to the tape-relaxation group experienced nausea while listening to the prerecorded audiotape, while none of the patients in the live-relaxation group reported nausea when subsequently listening to an audiotape made during the live presentation of relaxation.

Hoffman, Mark L. (1982/83). Hypnotic desensitization for the management of anticipatory emesis in chemotherapy. American Journal of Clinical Hypnosis, 25 (2-3), 173-176.

A hypnotic treatment employing systematic desensitization was used to alleviate anticipatory nausea and vomiting in a middle-aged man undergoing chemotherapy for Hodgkin's Disease. After four treatment sessions, all nausea associated with chemotherapy was eliminated. Results of this treatment are compared with those of another hypnotic treatment recently reported by Redd et al (1982), and reasons for differences are discussed. [Redd, W. H., Andersen, G. V. & Minagawa, R. Y. (1982). Hypnotic control of anticipatory emesis in patients receiving cancer chemotherapy. Journal of Consulting and Clinical Psychology, 50, 14-19.]

LeBaron, Samuel; Zeltzer, Lonnie (1982, October). The effectiveness of behavioral intervention for reducing chemotherapy related nausea and vomiting in children with cancer. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Indianapolis, IN.

-sented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Indianapolis, IN.

Eight children (nine to seventeen years, Mean age 12.1) with cancer received behavioral intervention for chemotherapy related nausea and vomiting. Within three to five days after the administration of each course of chemotherapy, patients rated (1-10 scale; 1 = none, 10 = all the time or maximal amount) their nausea and vomiting and the extent to which chemotherapy bothered them and disrupted their daily routine. After a pre-intervention assessment of 2.5 courses of chemotherapy, patients received intervention (Mean = 2.6 courses). Significant reductions following intervention (Wilcoxon matched- pairs signed ranks test) were found in nausea ( $Z = 2.37, p < .02$ ), vomiting ( $Z = 2.52, p < .01$ ), bother ( $Z = 2.24, p < .02$ ), and disruption of activities ( $Z = 2.38, p < .02$ ). This preliminary study indicates that chemotherapy side effects can be reduced through behavioral intervention.

Lyles, Jeanne Naramore; Burish, Thomas G.; Krozely, Mary G.; Oldham, Robert K. (1982). Efficacy of relaxation training and guided imagery in reducing the aversiveness of cancer chemotherapy. Journal of Consulting and Clinical Psychology, 50, 509-524.

Fifty cancer patients receiving chemotherapy, 25 by push injection and 25 by drip infusion, were assigned to one of three conditions for their chemotherapy treatments: (a) progressive muscle-relaxation training plus guided-relaxation imagery; (b) therapist control, in which a therapist was present to provide support and encouragement but did not provide systematic relaxation training; and (c) no-treatment control. Patients participated in one pretraining, three training, and one follow-up session. Results indicated that during the training sessions, patients who received relaxation training, relative to patients in either of the other two conditions, (a) reported feeling significantly less anxious and nauseated during chemotherapy, (b) showed significantly less physiological arousal (as measured by pulse rate and systolic blood pressure) and reported less anxiety and depression immediately after chemotherapy, and (c) reported significantly less severe and less protracted nausea at home following chemotherapy. The attending nurses' observations during chemotherapy confirmed patient reports. In general, patients in the therapist control condition and the no-treatment control condition did not differ significantly from each other. The differences among conditions generally remained significant during the follow-up session. The data suggest that relaxation training may be an effective procedure for helping cancer patients cope with the adverse effects of their chemotherapy.

Fuchs, K.; Paldi, E.; Abramovici, H.; Peretz, B. A. (1980). Treatment of hyperemesis gravidarum by hypnosis. International Journal of Clinical and Experimental Hypnosis, 28 (4), 313-323

Nausea and vomiting are the most common complaints in the first trimester of pregnancy. Hyperemesis gravidarum presents a unique challenge to the obstetrician trained in medical hypnosis. Between the years 1965-1977, 138 women suffering from extremely severe vomiting in the first trimester of pregnancy were successfully

treated by medical hypnosis. 87 patients were treated in groups and 51 received individual therapy. The results with patients in group hypnotherapy were markedly better than those with patients in individual hypnotherapy. With group hypnotherapy, hospitalization was not necessary; treatment [sic] was given to a number of patients simultaneously and the women felt safer and less lonely. The common motivation of the patients consolidated the psychotherapeutic effect. This made treatment easier and more efficient.

**1979 Clarke, Christopher (1979). Hypnotherapy in the treatment of alcoholism. Australian Journal of Clinical and Experimental Hypnosis, 7 (1), 1-5.**

If an aversive technique is used as a part of a hypnotic or behavior therapy treatment programme for problem drinking, the therapist is faced with the question of which aversive stimulus (or image) to use. This question has been given little in the way of systematic attention because of the widespread belief that there are no grounds for choosing between aversive stimuli which are equally safe, convenient and, of course, noxious. However, recent research in behavioural biology as well as certain clinical results call this assumption into question. Instead this work supports the contrary view: that the quality of the aversive stimulus is a crucial determinant of the effectiveness of aversion therapy. Specifically, this research strongly suggests that an illness or "malaise" experience must occur in conjunction with the alcohol for the conditioning (of an aversion) to be successful. Specific suggestions for the conduct of hypnotic aversion therapy are made in light of this work.

**1976 Cedercrentz, C.; Lahteenmaki, R.; Tulikoura, J. (1976). Hypnotic treatment of headache and vertigo in skull injured patients. International Journal of Clinical and Experimental Hypnosis, 24, 195-201.**

Symptoms of headache and vertigo were treated using direct hypnotic suggestions of symptom relief in 155 consecutive skull injured patients. Posttraumatic headache and vertigo were completely relieved after an average observation period of 1 year 10 months in 50% and 58% of the patients, and partially relieved in 20% and 16% respectively. Most of the relief was achieved after about 4 weekly sessions and, particularly with the headaches, only if treatment began within a few weeks of the injury. Therapeutic outcome was correlated with depth of hypnosis achieved for both headache ( $r = .44$ ,  $p < .0001$ ) and vertigo ( $r = .47$ ,  $p < .0001$ ) symptoms. Patients who could not even achieve light hypnosis obtained no therapeutic improvement, but patients who experienced only light hypnosis were as clinically responsive as those achieving deep hypnosis.

**1953 Kroger, William S. (1953). Hypnotherapy in obstetrics and gynecology. Journal of Clinical and Experimental Hypnosis, 1 (2), 61-70.**

Author's Summary - "A high percentage of gynecologic complains [sic] are due to psychic factors. Therapeutic efforts, therefore, must be directed primarily toward the psychologic component. Until recently, the principal weapon of the dynamically

oriented physician was orthodox psychoanalysis. However, the increased interest for a relatively rapid approach has demonstrated the diagnostic and therapeutic value of hypnoanalysis. This development has been concomitant with the psychoanalyst's [sic] interest in 'brief psychotherapy' and narcosynthesis.

"In many functional gynecologic disorders, hypnoanalysis has supplanted the parent therapy even though this form of treatment utilizes the concepts of dynamic psychiatry.

"The relevant literature on the use of hypnotherapy in functional obstetrical and gynecological disorders has been reviewed.

"Significant areas for research have been pointed out.

"This review emphasizes that hypnosis *per se* is only of value in obtaining symptomatic relief. On the other hand, hypnoanalysis elicits the responsible dynamics behind the symptom, and is effective in reaching all aspects of the personality.

"Hypnoanalysis will be more applicable in obstetrics and gynecology when there is a wider acceptance of its techniques" (p. 68).

## Neuroimaging

2003

Holroyd, Jean (2003). The science of meditation and the state of hypnosis. *American Journal of Clinical Hypnosis*, 46 (2), 109-128.

Two aspects of Buddhist meditation -- concentration and mindfulness -- are discussed in relationship to hypnosis. Mindfulness training facilitates the investigation of subjective responses to hypnosis. Concentration practice leads to altered states similar to those in hypnosis, both phenomenologically and neurologically. The similarities and differences between hypnosis and meditation are used to shed light on perennial questions: (1) Does hypnosis involve an altered state of consciousness? (2) Does a hypnotic induction increase suggestibility? It is concluded that a model for hypnosis should include altered states as well as capacity for imaginative involvement and expectations.

2002

Raz, A.; Shapiro, T. (2002). Hypnosis and neuroscience: A cross talk between clinical and cognitive research. *Archives of General Psychiatry*, 59 (1), 85-90.

Despite its long use in clinical settings, the checkered reputation of hypnosis has dimmed its promise as a research instrument. Whereas cognitive neuroscience has scantily fostered hypnosis as a manipulation, neuroimaging techniques offer new opportunities to use hypnosis and posthypnotic suggestion as probes into brain mechanisms and, reciprocally, provide a means of studying hypnosis itself. We outline how the hypnotic state can serve as a way to tap neurocognitive questions and how cognitive assays can in turn shed new light on the neural bases of hypnosis. This cross talk should enhance research and clinical applications.

Kosslyn, S. M.; Thompson, W. L.; Constantini-Ferrando, M. F.; Alpert, N. M.; Spiegel, D (2000). Hypnotic visual illusion alters color processing in the brain. American Journal of Psychiatry, *157* (8), 1279-1284.

This study was designed to determine whether hypnosis can modulate color perception. Such evidence would provide insight into the nature of hypnosis and its underlying mechanisms. Eight highly hypnotizable Ss (aged 20-35 yrs) were asked to see a color pattern in color, a similar gray-scale pattern in color, the color pattern as gray scale, and the gray-scale pattern as gray scale during positron emission tomography scanning by means of [<sup>18</sup>F]FDG. The classic color area in the fusiform or lingual region of the brain was first identified by analyzing the results when Ss were asked to perceive color as color vs when they were asked to perceive gray scale as gray scale. The results show that when Ss were hypnotized, color areas of the left and right hemispheres were activated when they were asked to perceive color, whether they were actually shown the color or the gray-scale stimulus. These brain regions had decreased activation when Ss were told to see gray scale, whether they were actually shown the color or gray-scale stimuli. These results were obtained only during hypnosis in the left hemisphere, whereas blood flow changes reflected instructions to perceive color vs gray scale in the right hemisphere, whether or not Ss had been hypnotized. 1993

Crawford, Helen J.; Gur, Ruben C.; Skolnick, Brett; Gur, Raquel E.; Benson, Deborah M. (1993). Effects of hypnosis on regional cerebral blood flow during ischemic pain with and without suggested hypnotic analgesia. International Journal of Psychophysiology, *15*, 181-195.

Using <sup>133</sup>Xe regional cerebral blood flow (CBF) imaging, two male groups having high and low hypnotic susceptibility were compared in waking and after hypnotic induction, while at rest and while experiencing ischemic pain to both arms under two conditions: attend to pain and suggested analgesia. Differences between low and highly-hypnotizable persons were observed during all hypnosis conditions: only highly-hypnotizable persons showed a significant increase in overall CBF, suggesting that hypnosis requires cognitive effort. As anticipated, ischemic pain produced CBF increases in the somatosensory region. Of major theoretical interest is a highly-significant bilateral CBF activation of the orbito-frontal cortex in the highly-hypnotizable group only during hypnotic analgesia. During hypnotic analgesia, highly-hypnotizable persons showed CBF increase over the somatosensory cortex, while low-hypnotizable persons showed decreases. Research is supportive of a neuropsychophysiological model of hypnosis (Crawford, 1991; Crawford and Gruzelier, 1992) and suggests that hypnotic analgesia involves the supervisory, attentional control system of the far-frontal cortex in a topographically

specific inhibitory feedback circuit that cooperates in the regulation of thalamocortical activities

1987

Ulrich, P.; Meyer, H. J.; Diehl, B.; Meinig, G. (1987). Cerebral blood flow in autogenic training and hypnosis. Neurosurgery Review, 10, 305-307. (Abstracted in American Journal of Clinical Hypnosis, 1989)

In 12 healthy volunteers with at least an experience of 6 months in autogenic training (AT), the cerebral blood flow (CBF) was measured at rest, in AT, and in hypnosis (H). The results were correlated with individual test profiles. The cortical flow pattern at rest of our AT-trained volunteers did not show the hyperfrontality which is described in the literature. This may be interpreted as an effect of better and habitualized relaxation in long-trained AT practitioners. This flow pattern corresponds to the low grades of neuroticism and aggressivity found in the tests. Furthermore, an activation in central cortical areas and a deactivation in regions which are associated with acoustic and autonomous functions occur. Possible explanations for these phenomena as well as for the relatively low perfusion of the left hemisphere at rest and activation in AT are discussed. The global rise of CBF in Hypnosis may be an activation effect caused by resistance against the hypnotizer: the deeper the trance, the smaller the catalepsy of the right arm and in temporal cortical fields processing acoustic inputs.

1981

Claghorn, James L.; Mathew, Roy J.; Largen, John W.; Meyer, John S. (1981). Directional effects of skin temperature self-regulation on regional cerebral blood flow in normal subjects and migraine patients. American Journal of Psychiatry, 138, 1182-1187.

Vascular headache of the migraine type is associated with vasomotor changes in cerebral arteries. The authors studied whether skin temperature training (biofeedback) reduced the frequency, severity, and duration of these headaches by measuring the regional cerebral blood flow (CBF) in 11 female migraine patients (27-52 years) and 9 female volunteers (22-37 years), using the noninvasive <sup>133</sup>Xe inhalation technique. Half of each group was randomly assigned to a hand-warming or a hand-cooling group. CBF increased in several regions of the left hemisphere to a significant degree only for the significant degree only for the migraineurs who were in the hand-warming group. The pattern of vasomotor regulation apparently differed between migraine and normal Ss. The migraineurs' headache symptoms were affected by both warming and cooling, but warming produced more salutary effects.

2000

Barabasz, Arreed (2000, August). EEG markers of hypnosis: The induction makes a difference. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, D. C..

Rather than attempt to uncover some simplistic unidimensional EEG "signature" of the hypnotic state, this study obtained EEG Event Related Potentials (ERPs) in response to two conditions: suggestion only and an alert hypnotic induction plus the identical suggestion. The suggestion asked the ten participants to hallucinate having earplugs in their ears to attenuate a series of computer generated tone pips. Hypnotizability testing was completely separated in both time (6-9 months prior) and context from this research. Alert hypnosis (Barabasz, 1985; Barabasz & Barabasz, 1996) was used to preclude effects that might be wrought by relaxation. Only the hypnotizable participants showed statistically significant attenuation of their EEG ERPs in response to the hypnotic induction plus suggestion condition in contrast to the identical suggestion alone. An independent post-experimental inquiry revealed that the one highly hypnotizable participant who responded in an equivalent manner to both conditions spontaneously entered hypnosis in an effort to respond to the essence of the instructions. Consistent with previous research (Barabasz, Barabasz, Jensen, Calvin, Trevisan, & Warner, 1999; Barabasz &

Lonsdale, 1983; Spiegel, Cutcomb, Ren, & Pribram, 1985), the data reveal that when responses are time locked to events, robust physiological markers of the hypnotic state emerge that reflect alterations in consciousness corresponding to participants' subjective experiences of perceptual alteration. These effects were not produced by suggestion alone but only by hypnosis in hypnotizable participants. It would appear that hypnotic state induced responses go beyond those wrought by suggestion alone when efforts are made to establish sufficient hypnotic depth. However, it remains important to understand that less demanding effects can also be produced by social influence, context and personal abilities (Kirsch, Council, & Mobayed, 1987; Lynn, Rhue, & Weekes, 1990). Given the leptokertic distribution of hypnotizability in the general population, social influence may account for a number of the more easily produced responses seen particularly in non-clinical university participant research situations where samples are comprised primarily of those with moderate hypnotizability. [Abstract in *Psychological Hypnosis: A Bulletin of Division 30*, Vol. 10, No. 1, Winter-Spring 2001.]

1983; Spiegel, Cutcomb, Ren, & Pribram, 1985), the data reveal that when responses are time locked to events, robust physiological markers of the hypnotic state emerge that reflect alterations in consciousness corresponding to participants' subjective experiences of perceptual alteration. Gruzelier, John (2000). Unwanted effects of hypnosis: A review of the evidence and its implications. *Contemporary Hypnosis*, 17 (4), 161-193.

Reviews the growing evidence of unwanted consequences of hypnosis in experimental, clinical, and entertainment settings. Adverse effects are common, may be physiological or psychological, and are mostly short-lived. The more serious consequences almost exclusively occur in clinical and entertainment applications and have included chronic psychopathology, seizure, stupor, spontaneous dissociative episodes, and the resurrection of memories of previous trauma. Associated phenomena may include physiological events and may be unconsciously mediated. Two cases of 1st episode schizophrenia, one following hypnotherapy and one following stage hypnosis, are described. Evidence of affinities between schizophrenia and hypnosis is revisited in the light of contemporary evidence of the neurophysiological mechanisms of hypnosis and schizophrenia, with implications

for screening vulnerable individuals. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Rossi, Ernest L. (2000). In search of a deep psychobiology of hypnosis: Visionary hypotheses for a new millennium. American Journal of Clinical Hypnosis, 42 (3/4), 178-207.

This search for the deep psychobiological foundations of hypnosis begins with a review of some of the paradoxes of historical hypnosis and the impasse of current theory. It is proposed that further progress requires a deeper investigation of how psychosocial cues can modulate the mechanisms of healing at the CNS, autonomic, neuroendocrine and cellular-genetic levels. The dynamics of hypnotic communication and healing from the cognitive-behavior level to the cellular-genetic are outlined in 4 stages: (1) information transduction between the experiences of consciousness and the limbic-hypothalamic-pituitary system; (2) the psychosomatic network of messenger molecules and their receptors; (3) the immediate early gene protein cascade; and (4) state dependent memory, learning and behavior. Neuroscience research is outlined for its contributions to a mathematical model of how a psychobiological approach to the therapeutic applications of hypnosis and the placebo response could facilitate neurogenesis in the human hippocampus and healing at the cellular-genetic-protein level throughout the body. A series of 10 hypotheses is proposed as a guide for theory and research in therapeutic hypnosis. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1999

Abela, Marcelle Bartolo (1999-2000). The neurophysiology of hypnosis: Hypnosis as a state of selective attention and disattention. [Symposium] Presented at 6th Internet World Congress of Biomedical Sciences - INABIS 2000, Castilla-La Mancha University, Spain.. (<http://www.uclm.es/inabis2000/posters/files/037/index.htm>)

While there is much useful information in this document, there are confusing passages and some with errors of fact. For example, I do not think most researchers in the area of hypnosis would state that \_The two main current theories of hypnosis are those of neo-dissociation and dissociated control,\_ nor would they agree that the Tellegen Absorption Scale is a test of hypnotizability. More significantly, several statements in the Conclusion section do not follow from material presented in preceding sections. For example, the author presents in the body of this paper no discussion of the relationship of ideomotor responses to treatment which might support her recommendation for them being used with low hypnotizable patients. Similarly, no evidence is offered to suggest the writer's conclusion that \_clinical extrapolation of the differences between highs and lows theoretically implicates a greater use of suggestive therapy for the latter group instead of analytical hypnotherapy, because since such therapy normally incorporates more permissive suggestions than in hypnoanalysis, lows would be better able to absorb such suggestions,terminating therapy much faster and more successfully.\_ In fact the

article is devoted primarily to neurophysiological aspects of hypnosis and has little to say about either hypnoanalysis or treatment effects and outcomes. - Editor

**Anderson, Kathryn (1999, November). A test of Barabasz' alert hypnosis on EEG Beta and Theta production for children with ADHD. [Paper] Presented at Annual Meeting of the Society for Clinical and Experimental Hypnosis, New Orleans, LA.**

This study tested the effects of Barabasz's Instant Alert Hypnosis (IAH), also known as Instantaneous Neuronal Activation Procedure (INAP, Barabasz and Barabasz, 1995) used as an adjunct to neurotherapy. The sixteen children who participated in this study met DSM - IV criteria for attention deficit hyperactivity disorder (AD/HD). Trials of neurotherapy alone were compared to neurotherapy combined with alert hypnosis on beta-theta ratios at five electrode sites (Fp1, Fp2, Fz, Cz and Pz). The results showed that EEG beta-theta ratio means were significantly higher (more than twice as large) in the trials of neurotherapy combined with alert hypnosis in contrast to neurotherapy alone. Beta was significantly enhanced while theta was inhibited. The clinical implications of these findings with regard to improved treatment efficacy and reduced time in treatment are discussed. [Abstract taken from SCEH "FOCUS", Winter 2001..]

**Barabasz, A.; Barabasz, M.; Jensen, S.; Calvin, S.; Trevisian, M.; Warner, D. (1999). Cortical event-related potentials show the structure of hypnotic suggestions is crucial. International Journal of Clinical and Experimental Hypnosis, 47 (1), 5-22.**

Electroencephalographic cortical event-related potentials (ERPs) are affected by information processing strategies and are particularly appropriate for the examination of hypnotic alterations in perception. The effects of positive obstructive and negative obliterating instructions on visual and auditory P300 ERPs were tested. Twenty participants, stringently selected for hypnotizability, were requested to perform identical tasks during waking and alert hypnotic conditions. High hypnotizables showed greater ERP amplitudes while experiencing negative hallucinations and lower ERP amplitudes while experiencing positive obstructive hallucinations, in contrast to low hypnotizables and their own waking imagination-only conditions. The data show that when participants are carefully selected for hypnotizability and responses are time locked to events, rather robust physiological markers of hypnosis emerge. These reflect alterations in consciousness that correspond to participants' subjective experiences of perceptual alteration. Accounting for suggestion type reveals remarkable consistency of findings among dozens of researchers.

In their Discussion the authors note that not all of the highly hypnotizable subjects demonstrated the changes predicted, consistent with Hilgard's (1992) observation that individual differences in response remain even among high hypnotizables. Post-experimental inquiry revealed the sources of (non-predicted) response for these two people. "One, showing only a moderate ERP amplitude attenuation in the obstructive condition, noted she pictured a cardboard box in front of the computer

monitor, but 'I pictured a rather small box that didn't block the entire screen!' Another showed an apparently contradictory response, a markedly diminished amplitude in the negative hallucination that called for deafness during the auditory stimuli. This participant reported the perception of complete obliteration of all sounds and, therefore, showed no surprise ERP effect. 'It was kind of scary when he (AB) said 'deaf' the second time. I couldn't hear anything at all. I was glad when he touched my shoulder and it was OK to hear again. I don't think I would do that again ... I mean do the hypnotic suggestion as much!'" (pp. 17-18).

Faymonville, M. E.; Meurisse, M.; Fissette, J. (1999). Hypnosédation: A valuable alternative to traditional anaesthetic techniques. Acta Chirurgica Belgica, 99 (4), 141-146.

Hypnosis has become routine practice in our plastic and endocrine surgery services. Revivication of pleasant life experiences has served as the hypnotic substratum in a series of over 1650 patients since 1992. In retrospective studies, followed by randomised prospective studies, we have confirmed the usefulness of hypnosédation (hypnosis in combination with conscious IV sedation) and local anaesthesia as a valuable alternative to traditional anaesthetic techniques. The credibility of hypnotic techniques and their acceptance by the scientific community will depend on independently-confirmed and reproducible criteria of assessing the hypnotic state. Based on the clinical success of this technique, we were interested in confirming this phenomenon in healthy volunteers. The revivication of pleasant life experiences thus served as the cornerstone of a basic research program developed to objectify the neurophysiological attributes of the hypnotic state. We compared hypnosis to normal alertness with similar thought content. In our experience, the activation profile obtained during the hypnotic state was completely different from simple re-memoration of the same subject matter during normal alertness. This represents an objective and independent criteria by which to assess the hypnotic state.

1998

Danziger, N.; Fournier, E.; Bouhassira, D.; Michaud, D.; De Broucker, T.; Santarcangelo, E.; Carli, G.; Chertock, L.; Willer, J. C. (1998). Different strategies of modulation can be operative during hypnotic analgesia: A neurophysiological study. Pain, 75 (1), 85-92.

Nociceptive electrical stimuli were applied to the sural nerve during hypnotically-suggested analgesia in the left lower limb of 18 highly susceptible subjects. During this procedure, the verbally reported pain threshold, the nociceptive flexion (RIII) reflex and late somatosensory evoked potentials were investigated in parallel with autonomic responses and the spontaneous electroencephalogram (EEG). The hypnotic suggestion of analgesia induced a significant increase in pain threshold in all the selected subjects. All the subjects showed large changes (i.e., by 20% or more) in the amplitudes of their RIII reflexes during hypnotic analgesia by comparison with control conditions. Although the extent of the increase in pain threshold was similar in all the subjects, two distinct patterns of modulation of the

RIII reflex were observed during the hypnotic analgesia: in 11 subjects (subgroup 1), a strong inhibition of the reflex was observed whereas in the other seven subjects (subgroup 2) there was a strong facilitation of the reflex. All the subjects in both subgroups displayed similar decreases in the amplitude of late somatosensory evoked cerebral potentials during the hypnotic analgesia. No modification in the autonomic parameters or the EEG was observed. These data suggest that different strategies of modulation can be operative during effective hypnotic analgesia and that these are subject-dependent. Although all subjects may shift their attention away from the painful stimulus (which could explain the decrease of the late somatosensory evoked potentials), some of them inhibit their motor reaction to the stimulus at the spinal level, while in others, in contrast, this reaction is facilitated.

Jasiukaitis, Paul; Nouriani, Bitá; Hugdahl, Kenneth; Spiegel, David (1997). Relateralizing hypnosis: Or, have we been barking up the wrong hemisphere?. International Journal of Clinical and Experimental Hypnosis, 45 (2), 158-177.

Research and theory over the past couple decades have suggested that the right cerebral hemisphere might be the focus of brain activity during hypnosis. Recent evidence from electrodermal responding, visual event-related potentials, and Stroop interference, however, can make a case for a role of the left hemisphere in some hypnotic phenomena. Although hemispheric activation on hypnotic challenge may depend in large part on the kind of task the challenge might involve, several general aspects of hypnosis might be more appropriately seen as left-rather than right-hemisphere brain functions. Among these are concentrated attentional focus and the role of language in the establishment of hypnotic reality. A left-hemisphere theory of hypnosis is discussed in light of recent findings and theories about a left-hemisphere basis for synthetic or generational capabilities (Corballis, 1991) and a neuro-evolutionary model of a left-hemisphere dopaminergic activation system for the implementation of predetermined motor programs (Tucker & Williamson, 1984). -- Journal Abstract

Dane, Joseph R. (1996). Hypnosis for pain and neuromuscular rehabilitation with multiple sclerosis: Case summary, literature review, and analysis of outcomes. International Journal of Clinical and Experimental Hypnosis, 44 (3), 208-231.

Videotaped treatment sessions in conjunction with 1-month, 1-year, and 8-year follow-up allow a unique level of analysis in a case study of hypnotic treatment for pain and neuromuscular rehabilitation with multiple sclerosis (MS). rehabilitation with multiple sclerosis (MS). Preparatory psychotherapy was necessary to reduce the patient's massive denial before she could actively participate in hypnosis. Subsequent hypnotic imagery and posthypnotic suggestion were accompanied by significantly improved control of pain, sitting balance, and diplopia (double vision), and a return to ambulatory capacity within 2 weeks of beginning

treatment with hypnosis. Evidence regarding efficacy of hypnotic strategies included (a) direct temporal correlations between varying levels of pain relief and ambulatory capacity and the use versus nonuse of hypnotic strategies, (b) the absence of pharmacological explanations, and (c) the ongoing presence of other MS-related symptoms that remained unaltered. In conjunction with existing literature on hypnosis and neuromuscular conditions, results of this case study strongly suggest the need for more detailed and more physiologically based studies of the phenomena involved. - Journal Abstract

1995

Bryant, Richard A.; Somerville, Ernest (1995). Hypnotic induction of an epileptic seizure: A brief communication. International Journal of Clinical and Experimental Hypnosis, 43 (3), 274-283.

This case study investigated the utility of hypnosis to precipitate a seizure in a patient with refractory epilepsy. The patient was twice administered a hypnotic induction and a suggestion to age regress to a day when he was distressed and suffered repeated seizures. The patient did not respond to the first hypnotic suggestion; however, an epileptic seizure was observed in the second hypnotic session. Videorecording and subdural electroencephalograph recording confirmed that he suffered an epileptic seizure. Postexperimental inquiry revealed that the patient used deliberate cognitive strategies to avoid seizure onset in the first session but adopted a more constructive cognitive style in the second session. Findings are discussed in terms of emotions, hypnosis, and cognitive style as mediating factors in the experimental precipitation of epileptic seizures.

DeBenedittis, Giuseppe; Cigada, Mario; Bianchi, Anna; Signorini, Maria Gabriella; Cerutti, Sergio (1994). Autonomic changes during hypnosis: A heart rate variability power spectrum analysis as a marker of sympatho-vagal balance. International Journal of Clinical and Experimental Hypnosis, 42 (2), 140-152.

Spectral analysis of beat-to-beat variability in electrocardiography is a simple, noninvasive method to analyze sympatho-vagal interaction. The electrocardiogram is analyzed by means of an automatic, autoregressive modeling algorithm that provides a quantitative estimate of R-R interval variability by the computation of power spectral density. Two major peaks are recognizable in this spectrum: a low-frequency peak (LF, 0.2 Hz), related to the overall autonomic activity (ortho + parasympathetic) and a high-frequency peak (HF, 0.25 Hz), representative of the vagal activity. The LF/HF ratio is an index of the sympatho-vagal interaction. This technique was applied, using a computer-assisted electrocardiograph, to 10 healthy volunteers (6 high and 4 low hypnotizable subjects as determined by the Stanford Hypnotic Susceptibility Scale, Form C) in randomized awake and neutral hypnosis conditions. Preliminary results indicated that hypnosis affects heart rate variability, shifting the balance of the sympatho-vagal interaction toward an enhanced parasympathetic activity, concomitant with a reduction of the sympathetic tone. A

positive correlation between hypnotic susceptibility and autonomic responsiveness during hypnosis was also found, with high hypnotizable subjects showing a trend toward a greater increase of vagal efferent activity than did low hypnotizables. tone. A positive correlation between hypnotic susceptibility and autonomic responsiveness during hypnosis was also found, with high hypnotizable subjects showing a trend toward a greater increase of vagal efferent activity than did low hypnotizables.

1993

Hall, Howard; Minnes, Luke; Olness, Karen (1993). The psychophysiology of voluntary immunomodulation. International Journal of Neuroscience, 69, 221-234.

In twenty-two studies of intentional efforts of humans to change immune measures, only four monitored psychophysiological parameters. One study reported physiologic alterations associated with immune changes. In this current study we examined changes in pulse rate and peripheral temperature associated with intentional changes in neutrophil adherence. Subjects had blood, pulse and temperature recordings collected before and after either a rest condition (Group A), or a self-regulation exercise (Groups B and C) for two sessions. Group C had four prior training sessions before participating in the experimental sessions. This study found no association between psychophysiological alterations and neutrophil changes. the control group (A) demonstrated no significant neutrophil changes but showed physiologic alterations, whereas, the experimental group (C) that showed increases in neutrophil adherence demonstrated no significant physiologic changes. It was speculated that intentional changes on neutrophil adherence and the pattern of the psychophysiological measures were associated with and reflective of cognitive activity.

Lyskov, E.; Juutilainen, J.; Jousmaki, V.; Hanninen, O.; Medvedev, S.; Partanen, J. (1993). Influence of short-term exposure of magnetic field on the bioelectrical processes of the brain and performance. International Journal of Psychophysiology, 14, 227-231.

The influence of an extremely-low-frequency (ELF) magnetic field on the bioelectrical processes of brain and performance was studied by EEG spectral analysis, auditory-evoked potentials (AEP), reaction time (Roletaking) and target-deletion test (TDT). Fourteen volunteers were exposed for 15 min to an intermittent (1 s on/off) 45- Hz magnetic field at 1000 A/m (1.26 mT). Each person received one real and one sham exposure. Statistically significant increases in spectral power through alpha- and beta- bands, as well as in mean frequency of the EEG spectrum were observed after magnetic field exposure. Field-dependent changes of N100 were also revealed. No changes in the amplitudes or latencies of the earlier peaks were observed. No direct effects on Roletaking, nor on TDT performance were seen. However, practice effects on Roletaking (decrease of Roletaking in the course of the test-sessions) seemed to be interrupted by exposure to the magnetic field.

1992

Spiegel, David; King, R. (1992). Hypnotizability and CSF and HVA levels among psychiatric patients. Biological Psychiatry, 31, 95-98.

The authors found evidence that the ability to experience hypnosis as measured by the Hypnotic Induction Profile is associated with levels of the dopamine metabolite homovanillic acid (HVA) in lumbar cerebrospinal fluid (CSF). Dopaminergic synapses are widely distributed in the frontal cortex, and CSF HVA is correlated with dopamine turnover in the frontal cortex. Thus, dopamine activity, possibly involving the frontal lobes, appears to be involved in hypnotic concentration.

-pamine activity, possibly involving the frontal lobes, appears to be involved in hypnotic concentration.

Weinstein, Edwin J.; Au, Phillip K. (1991). Use of hypnosis before and during angioplasty. American Journal of Clinical Hypnosis, 34, 29-37

In this study, 16 patients matched with 16 controls were hypnotized prior to angioplasty. The hypnotized patients had a 25% increase in the time the cardiologist was able to keep the balloon inflated compared to the controls. Of the hypnotized patients, 13% required additional narcotic pain medication during the procedure as compared to 44% for the controls. Although we found no differences in rhythm, ischemia, blood pressure, or pulse between the two groups, the results of arterial catecholamine levels drawn at the start and at the end of the procedure were unexpected and seemed paradoxical. Norepinephrine levels were significantly higher in the hypnotized group (432 pg/ml, SE 51) than in the control group (281 pg/ml, SE 23) at the start of the procedure and fell more during the procedure than in control patients. Because catecholamines reportedly act as a barometer of neuroanxiety, further studies defining their role are needed.

While sedatives and tranquilizers may reduce anxiety on a coronary care unit, occasionally they result in confusion, agitation, and ataxia (Kornfeld, 1980). Hypnosis can be used in acute medical care settings (Deltito, 1984) and is beneficial in reducing pain, suffering, and anguish (Hilgard & Hilgard, 1975). There is some suggestion that hypnosis may help regulate heart rate and blood pressure (Hilgard & Morgan, 1975).

In this study, patients with even chart numbers were in the control group, while odd-numbered patients were in the hypnosis group. Patients who were deaf or senile were excluded. All patients received their usual medications before angioplasty, and both the hypnosis group and the control group received identical treatment other than the hypnosis intervention. However, only the hypnosis group was interviewed by the first author, on the night before angioplasty, and he was also present during the angiograph itself if necessary to help relax the hypnosis patients.

The hypnosis procedure was a modification of Barber's (1977) Rapid Induction Analgesia, and lasted about 1/2 hour. Patients were given a posthypnotic suggestion that they could achieve the same sense of relaxation the next morning during the angioplasty.

"If the patient had severe angina or had an undue amount of discomfort during the procedure, additional pain medication was given as was felt necessary by the cardiologist.

Two of 16 hypnotized and 7 of 16 control patients received pain medication. The difference is significant at  $p = .05$  (Chi Square)" (p. 34).

"In the hypnotized patients the total catecholamine levels (538 pg/ml, SE 60) and the levels of its major component, norepinephrine (432 pg/ml, SE 51), were significantly elevated above their corresponding control levels (361 pg/ml, SE 31 and 281 pg/ml, SE 23) at the start of the angioplasty procedure ( $p < .01$ ). These were unexpected findings. The epinephrine level in the hypnotized group was also higher than the corresponding level in the control group but did not reach a level of significance.

"At the end of the procedure, catecholamine levels had fallen in both groups, but the drop or [sic] total catecholamines in the hypnotized group of 124 pg/ml (SE 33) was greater than the corresponding drop of 37 pg/ml (SE 25) in the control group. This was significant at  $p < 0.025$ . Why the two groups handled catecholamines differently is not clear" (p. 33).

Generally it is hoped that relaxation will permit the cardiologist to keep a balloon inflated longer, not needing to end the procedure because of pain or a complication. The total time required for the procedure was 79 minutes for hypnotized patients and 86 minutes for controls. The inflation time was 353 seconds for hypnotized and 283 minutes for control patients. These differences (which are in the positive direction) did not achieve significance with statistical testing. However, considering the total procedure time, the balloon was inflated 25% longer in the hypnosis than in the control group ( $p = .10$ ).

In their Discussion, the authors note that the reduction in pain medication required by the hypnosis patients is concordant with less pain medication being required by burn patients who are treated with hypnosis (Schafer, 1975; Wakeman & Kaplan, 1978). They do not have an explanation for finding elevated catecholamines in the hypnotized patients. "Catecholamines reportedly act as a barometer of neuroanxiety (Goldstein, 1981; Zaloga, 1988). Turton, Deegan, and Coulshed had already shown in 1977 that prior to catheterization catecholamine levels were elevated and returned to control levels 3 days later. .... One would expect that if hypnosis does cause relaxation, then those patients who were hypnotized would have a lower arterial catecholamine level than their controls. This was not the case. ... It is known that prolonged stress depletes catecholamine stores (Zaloga, 1988), but it is hard to believe that a brief hospitalized stay would cause a difference in depletion between the two groups. There is no literature dealing with the effect of hypnosis on catecholamine levels" (p. 35).

Spiegel, David; Bierre, Pierre; Rootenberg, John (1989). Hypnotic alteration of somatosensory perception. American Journal of Psychiatry, 146, 749-754.

The effects of hypnotic alterations of perception on amplitude of somatosensory event-related potentials were studied in 10 highly hypnotizable (HH) Subjects and 10 Subjects with low hypnotizability. The HH Subjects showed significant decreases in amplitude of the P100 and P300 waveform components during a hypnotic

hallucination that blocked perception of the stimulus. When hypnosis was used to intensify attention to the stimulus, there was an increase in P100 amplitude. Findings are consistent with observations that HH individuals can reduce or eliminate pain by using purely cognitive methods such as hypnosis. Together with data from the visual system, these results suggest a neurophysiological basis for hypnotic sensory alteration.

Four conditions were presented in random order to each Subject. Normal Attention - subjects were instructed to button-press each time they felt the target stimulus. Passive Attention - subjects were instructed to attend to the stimuli but not button-press. Hypnotic Attention - subjects received a hypnotic induction (eye closure and arm levitation, which provided behavioral confirmation; then instructed to attend carefully to the stimuli, which they were told to experience as 'pleasant and interesting,' and button-press in response to targets. Hypnotic Obstructive Hallucination - hypnotic induction exercise was followed by the hypnotic suggestion of a local anesthetic, such as novocaine, spreading from fingers to hand to forearm on the stimulated limb; then instructed to make the limb cold, tingling, and numb; then told to button-press if they felt any of the target stimuli.

Experimenter was blind to hypnotizability scores.

Results were that the Highs showed significant decreases in P100 (45%) and P300 (38%) amplitudes during a hypnotic hallucination which blocked perception of the stimulus, but an increase (35%) in P100 amplitude when hypnosis was used to intensify attention to the stimulus.

The authors view this as cognitive flexibility akin to the clinical situation in which high hypnotizables reduce or completely eliminate pain. They consider this evidence (along with earlier findings on similar blocking of perception in the visual system) of a neurophysiological basis for hypnotic sensory alteration.

1987

Bongartz, Walter (1987, October). Influence of hypnosis on white blood cell count and urinary level of vanillyl mandelic acid. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Los Angeles.

They hypothesized that hypnosis benefits to immunology are due to alterations in white blood cell counts (WBC). Found that (1) blood samples before and after hypnosis with relaxation scenes led to significant decrease in WBCs compared to watching film of Mesmer or doing mental arithmetic, and (2) Vanillyl Mandelic Acid also was reduced.

After physical exercise, video game, or reading, within 20', the WBCs return to pre-relaxation levels, i.e. they hadn't left the bloodstream. Key to understanding this result: only 50% of WBCs are in circulation, and others adhere to vessel walls; the experience of hypnotic relaxation leads to less sympathetic nervous activation and less epinephrine or hormonal response. WBCs also increased over a day period with mental arithmetic, but remained the same with hypnosis.

This research is only preliminary and exploratory

**1982**

**Sternbach, R.A. (1982). On strategies for identifying neurochemical correlates of hypnotic analgesia: A brief communication. International Journal of Clinical and Experimental Hypnosis, 30 (3), 251-256.**

**A test was made of the general hypothesis that central cholinergic mechanisms underlie hypnotic analgesia. Ss were given the cold pressor pain test under waking and 3 drug conditions. 6 Ss who scored very high on the tailored Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C - T) of E. R. Hilgard, Crawford, Bowers, and Kihlstrom (1979) were given atropine, propantheline, and placebo in double-blind and counterbalanced conditions, to determine if atropine would disrupt hypnotic analgesia. The study was replicated using Ss who scored lower on SHSS:C - T. The results showed only a nonsignificant tendency for atropine to interfere with hypnotic analgesia in the most hypnotizable group of Ss, and for both atropine and propantheline similarly to disrupt hypnotic analgesia for Ss in the less highly hypnotizable group. Alternative strategies are described for identifying the neurotransmitter(s) involved in the trance state.**

**1981**

**Wilson, John F. (1981). Behavioral preparation for surgery: Benefit or harm?. Journal of Behavioral Medicine, 4, 79-102.**

**Elective surgery patients were prepared for surgery with training in muscle relaxation or with information about sensations they would experience. Relaxation reduced hospital stay, pain, and medication for pain and increased strength, energy, and postoperative epinephrine levels. Information reduced hospital stay. Personality variables (denial, fear, Information reduced hospital stay. Personality variables (denial, fear, aggressiveness) were associated with recovery and influenced patients' responses to preparation. Less frightened patients benefitted more from relaxation than did very frightened patients. Nonaggressive patients reacted to information with decreased hospital stay along with increased pain, medication, and epinephrine. Aggressive patients responded to information with decreased hospital stay along with decreased pain, medication, and epinephrine. Patients using denial were not harmed by preparation. A catharsis/moderation model is proposed to explain how information benefits patients. An active coping model is proposed to explain the benefits of relaxation. This study suggests that behavioral preparation benefits even frightened, aggressive, or denying elective surgical patients.**

**1970**

**Sacerdote, Paul (1970). Theory and practice of pain control in malignancy and other protracted or recurring painful illnesses. International Journal of Clinical and Experimental Hypnosis, 18 (3), 160-180.**

Recent neuroanatomical and neurophysiological experimental data suggest absence or presence of pain and changes in pain intensity as expressions of the balance between sensory (peripheral) and central (centrifugal) inputs at synaptic stations. Psychological activities by contributing to the centrifugal input influence conduction, transduction, and perception of pain stimuli. Hypnotically induced analgesia and anesthesia are therefore acceptable as neurophysiological realities. Methods for hypnotic alterations of pain based upon these premises are described utilizing neurophysiological mechanisms, psychodynamic changes, establishment of new behavioral patterns, or changes in time-space concepts and percepts. Case presentations illustrate some of these multiple psychological and physiological approaches to pain control. (Spanish & German summaries) (28 ref.) Hammer, A. G.; Arkins, W. J. (1964). The role of photic stimulation in the induction of hypnotic trance. International Journal of Clinical and Experimental Hypnosis, 12, 81-87.

The relative effectiveness of the ordinary verbal method of trance induction is compared with 2 forms of induction utilizing mechanical photic stimulation, and with methods combining the personal and mechanical features. The criterion of trance adopted was the compulsive carrying out of a difficult suggestion. Results show that mechanical procedures alone are ineffective. On the other hand, the addition of a particular sort of photic driving probably improves trance induction, which suggests that induction is a complex matter involving both social interactions and relatively nonmeaningful impacts on the brain. Subjects were selected with certain predispositions for the hypnotic state and studied in the waking, hypnotic and experimental sleep states by motor conditioned

reflexes modified to a specific function of the frontal system. Excitable, active students of music and literature were found most excitable as subjects, subjects tending to be passive showed no hypnotic responses. Experimental sleep abolished the motor-conditioned reflexes, quite contrary to hypnotic findings. (M.H.E. abstract in AJCH).

1999

Wilson, R. Reid (1999, August). Brief strategic treatment of panic disorder and OCD. [Paper] Presented at the annual meeting of the American Psychological Association, Boston, Massachusetts.

The symptoms, prevalence, and social/economic costs of Panic Disorder, Obsessive-Compulsive Disorder, and other anxiety disorders are reviewed. Cognitive-behavioral therapy (CBT) has demonstrated efficacy for these disorders. Eriksonian and strategic principles of therapy have a number of points of contact with CBT. Taking Panic Disorder and OCD as illustrative models, this paper demonstrates how Ericksonian methods can be fruitfully combined with CBT. Examples include paradoxical intervention, hypnosis and visual rehearsal, reframing, the fractional approach, and pattern disruption.

1997

Van Dyck, R.; Spinhoven, P. (1997). Depersonalization and derealization during panic and hypnosis in low and highly hypnotizable agoraphobics. International Journal of Clinical and Experimental Hypnosis, 45 (1), 41-54.

The primary aim of the present study was to investigate the association between spontaneous experiences of depersonalization or derealization (D-D) during panic states and hypnosis in low and highly hypnotizable phobic individuals. Secondly, the association among level of hypnotizability, capacity for imaginative involvement, and severity of phobic complaints was also assessed. Sixty-four patients with panic disorder with agoraphobia according to the DSM-III-R (American Psychiatric Association, 1987) criteria participated in the study. Proneness to experience D-D during hypnosis was positively related to hypnotizability, but only for agoraphobic

patients who had already experienced these perceptual distortions during panic episodes. Correlations of level of hypnotizability and capacity for imaginative involvement with severity of agoraphobic complaints were not significant. These findings suggest that hypnotizability may be a mediating variable between two different, although phenotypically similar, perceptual distortions experienced during panic states and hypnosis. Implications for both theory and clinical practice are discussed. -- Journal Abstract

1996

Wickramasekera, Ian; Price, Daniel C. (1996, November). Morbid obesity, absorption, neuroticism, and the high risk model of threat perception. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Tampa, FL.

We studied seventy morbidly obese patients, candidates for gastric exclusion surgery. We found that their mean absorption score was significantly lower and that their mean neuroticism score significantly higher than a matched control group. These results are consistent with predictions from the High Risk Model of Threat Perception (Wickramasekera, 1979, 1988). People high in neuroticism are hypothesized to be hypersensitive to threat at a behavioral and biological level, and therefore, at greater risk for stress related psychobiological disorders. People low in absorption are hypothesized to have poor perception of psychosocial sources of threat have a more restricted range of psychological restricted range of psychological methods of coping with threat. Therefore, they may be at greater risk during stress of not recognizing psychosocial sources of threat of unconsciously using substances to self-soothe and of perceiving medical surgical solutions to weight gain as more credible than psychosocial therapy programs. We found that low absorption and high neuroticism as predicted by the HRMTP were significantly more prevalent among the morbidly obese seeking surgical therapy than a matched community control group.

Wickramasekera, Ian (1994, October). On the coincidence of two orthogonal risk factors for psychophysiological regulation and dysregulation: implications for somatization. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

People low or high in hypnotizability are at risk. Our article in the upcoming issue of the Journal of Nervous and Mental Disease will present this information. High hypnotizable people have either somatic symptoms or psychological symptoms; lows show primarily somatic symptoms. We found that 38% of highs and 28% of lows show somatic symptoms. The lows won't usually be found in a Mental Health Center; they are staying in primary care medical services.

Hypnotic ability and insomnia.

Insomnia was defined by EEG in 3 sleep studies (latency to stage 1 onset of EEG), and patients were screened to omit those with pathophysiology. We measured hypnotizability, finding 50% high on Harvard Scale, 40% low, with a small percent in the middle. [Thus the distribution is bi-modal.]

Neuroticism and insomnia (Wickram, Ware & Saxon, 1992). Neuroticism is the "negative affect" variable. Most people high on negative affect are high hypnotizables. Charcot was right [about high hypnotizables being neurotic] but he didn't have a measure of neuroticism. We are measuring negative affect.

**PREDICTIONS.** Low hypnotizables will show only or mainly somatic symptoms and be found in primary medical care or surgical settings. Highs will show a mix of somatic and psychological and somatic symptoms.

Most lows wouldn't sit still for the Harvard Scale, so we used the Absorption scale. We gave the Absorption scale to non-organic chest pain patients. Most had low scores on Absorption, followed by those with moderate scores, and fewest were high on Absorption: 50% low, 36% moderate, 13% high.

Absorption scores in morbidly obese (350# or more) candidates for bypass surgery were: 55% are low on Absorption, 5% are high on Absorption.

People high on hypnotizability and on negative affectivity have greater risk for illness. See results of our research in *American Journal of Clinical Hypnosis*, a recent issue. These people are more psychophysiological reactive, in heart rate, electrodermal reactivity, etc.

Wickramasekera, Ian (1994). Psychophysiological and clinical implications of the coincidence of high hypnotic ability and high neuroticism during threat perception in somatization disorders. *American Journal of Clinical Hypnosis*, 37, 22-33

The electrodermal response to cognitive threat of un hypnotized female patients with somatic symptoms and high on both hypnotic ability and neuroticism (H-H) was found to be significantly higher ( $p < .01$ ) than that of a matched group of female patients moderate on hypnotic ability and low on neuroticism (M-L). On verbal report the H-H and the M-L groups did not differ, but they were significantly different on a measure of self-deception (L scale) or repression. The above findings are consistent with predictions from the High Risk Model of Threat Perception (HRMTP), which states that people in the H-H group are both chronically and acutely more reactive to threat than the people in the M-L group. This finding may have important theoretical, clinical, and financial implications for the diagnosis, therapy, and prevention of somatization disorders seen in primary medical care.

Wickramasekera, Ian (1993, August). Some psychophysiological and clinical implications of the coincidence of hypnotic ability and neuroticism during threat perception. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.

The electrodermal response to cognitive threat (mental arithmetic) of un hypnotized female patients with somatic symptoms, high on hypnotic ability and high on neuroticism (high-high) was found to be significantly higher ( $p < .01$ ) than that of a matched group of female patients moderate on hypnotic ability and low on neuroticism (moderate-low). On verbal report or a subjective units of distress scale (SUDs), the high-high and moderate-low groups did not differ, but they were significantly different on a measure of self-deception or repression. The above

findings are consistent with predictions from the High Risk Model of threat perception. (ABSTRACT from the Bulletin of Division 30, Psychological Hypnosis, Fall, 1993, Vol. 2, No. 3.)

Spiegel, David; Cardena, Etzel (1991). Disintegrated experience: The dissociative disorders revisited. Journal of Abnormal Psychology, 100 (3), 366-378.

Presents proposed changes to the dissociative disorders section of the 4th edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) and reviews the concept of pathological and nonpathological dissociation, including empirical findings on the relations between trauma and dissociative phenomenology and between dissociation and hypnosis. The most important proposals include the creation of 2 new diagnostic entities, brief reactive dissociative disorder and transient dissociative disturbance, and the readoption of the criterion of amnesia for a multiple personality disorder diagnosis. Further work on dissociative processes will provide an important link between clinical and experimental approaches to human cognition, emotion, and personality.

Terr, Lenore C. (1991). Childhood traumas: An outline and overview. American Journal of Psychiatry, 148, 10-20.

Suggests 4 characteristics common to most cases of childhood trauma: visualized or otherwise repeatedly perceived memories of the traumatic event; repetitive behaviors; trauma-specific fears; and changed attitudes about people, life, and the future. Childhood trauma is divided into 2 basic types. Type I trauma includes full, detailed memories, "omens," and misperceptions while Type II trauma includes denial and numbing, self-hypnosis and dissociation, and rage. Characteristics of both types of childhood trauma can exist side by side. Such crossover Type I - Type II traumatic conditions of childhood are characterized by perceptual mourning and depression and childhood disfigurement, disability, and pain. Case examples are provided.

Characteristics of both types of childhood trauma can exist side by side. Such crossover Type I - Type II traumatic conditions of childhood are characterized by perceptual mourning and depression and childhood disfigurement, disability, and pain. Case examples are provided.

Ross, Colin A.; Fast, E.; Anderson, G.; Auty, A.; Todd, J. (1990). Somatic symptoms in multiple sclerosis and MPD. Dissociation, 3, 102-106.

Fifty subjects with multiple sclerosis (MS) were compared to 50 subjects with multiple personality disorder (MPD). MS patients endorsed an average of 3.0 somatic symptoms on structured interview, and MPD subjects an average of 14.5. Somatic symptoms characteristic of neurological illness were trouble walking, paralysis, and muscle weakness, while those characteristic of psychiatric illness were genitourinary and gastrointestinal symptoms.

1989

Spinhoven, Philip; Linssen, A. Corry (1989). Education and self-hypnosis in the management of low back pain: A component analysis. British Journal of Clinical Psychology, 28, 145-153.

Conducted a component analysis of a group program for chronic low back pain patients. 45 patients (aged 31-68 years) participated in the pain control course (PCC), consisting of education about pain and a training in self-hypnosis. A pain diary was used as a measure of pain intensity, up-time, and use of pain medication. Psychoneuroticism and depression were assessed using the Symptom Checklist-90 (SCL- 90) scores. No evidence was found for a differential efficacy of education or self-hypnosis on pain diary and SCL-90 scores. Subjects showed significant changes on all measures except reported pain intensity. It is suggested that the PCC is a noninvasive, inexpensive means of treatment that could be used to teach even more severely disabled low back pain patients to cope more adequately with their pain problem.

Wickramasekera, Ian (1989). Enabling the somatizing patient to exit the somatic closet: A high-risk model. Psychotherapy: Theory, Research and Practice, 26 (4), 530-544.

Problems in establishing a therapeutic alliance make somatizing patients poor candidates for psychotherapy. A logical analysis is presented of the conspiracy of silence between the somatizing patient, the medical doctor, and the health insurance industry regarding the psychosocial factors contributing to somatization. Alternatives are sought to repeated biomedical tests and therapies that are clinically unproductive and iatrogenic. Two psychophysiological pathways are proposed that are promising to reduce the distance between the medical doctors' and the psychologists' procedures. The new profile of illness has produced a paradigm shift with implications for an expansion of the definition of the word "physician".

Pettinati, Helen M. (1988). Hypnosis and memory. New York and London: Guilford Press.

From a review in British Journal of Experimental and Clinical Hypnosis, 7, 175-178, by Vernon H. Gregg]:

Book has 5 sections: 1. method, theory 2. mechanisms of memory enhancement 3. hypnotic and other forms of reversible amnesia 4. clinical uses of hypnosis for increasing accessibility of memories and fantasies 5. Summary

The chapter by Martin Orne et al presents a comprehensive review. Perry, Lawrence, d'Eon and Tallant contribute a lively assessment of age regression procedures in the elicitation of inaccessible memories. They provide a description of procedures, a brief historical review, and discuss problems of confabulation and creation of pseudomemories. Their account is illustrated by clinical and forensic examples and gives an interesting account of belief in reincarnation in terms of source amnesia.

Section 3 has Hollander's chapter on hysteria and memory, which illustrates the concept of reversibility of amnesia with two types of hysterical conditions: one of these types, the dissociative disorders, has the potential for amnesia to be reversed but the other, histrionic personality disorders, is characterized by no reversibility.

In the section on clinical studies of memory enhancement Frankel and Kolb both accept that uncovering repressed memories and fantasies is therapeutically beneficial and that the faithfulness of recovered memories is often not important for therapeutic success. Frankel illustrates the usefulness of hypnosis with several case studies. But he thinks that clinical issues are dealt with too briefly in this book. In her summary chapter Pettinati points to the dearth of systematic research into the effectiveness of hypnosis in clinical settings.

**1987**

Baker, Elgan L.; Nash, Michael R. (1987). Applications of hypnosis in the treatment of anorexia nervosa. American Journal of Clinical Hypnosis, 29, 185-193.

Historic and current reports in the literature involving applications of hypnosis with anorectic patients are reviewed and integrated to explicate core aspects of hypnotic interventions in treating anorexia nervosa. A comprehensive hypnotherapeutic approach is delineated which emphasizes the use of hypnotic strategies to reduce tension, enhance self-control, support increased and realistic body awareness, alter distorted body image, and foster appropriate autonomy and individuation. Preliminary data are also reviewed which support the clinical efficacy of this approach.

**1986**

Wickramasakera, Ian (1986). A model of people at high risk to develop chronic stress-related somatic symptoms: Some predictions. Professional Psychology: Research and Practice, 17, 437-447.

Certain measurable high-risk factors that predispose people to develop functionally based somatic disorders are identified. These risk factors compose a multidimensional model that encompasses variables involved in the predisposition, the precipitation, and the buffering of stress-related symptoms. These high-risk factors are (a) high or low hypnotic ability, (b) habitual catastrophizing cognitions and pessimistic belief systems, (c) autonomic lability or neuroticism, (d) multiple major life changes or multiple minor hassles over a short period of time, and (e) a deficit in support systems or coping skills or both

Spiegel, David; Detrick, Douglas; Frischholz, Edward (1982). Hypnotizability and psychopathology. American Journal of Psychiatry, 139, 431-437.

Compared hypnotic responsivity of 115 chronically ill psychiatric patients (mean age 44.6 years) with that of 83 nonpatient volunteers (mean age 28.5 years). The Hypnotic Induction Profile was administered, and diagnoses were established for patients according to Research Diagnostic Criteria. Results show that all of the diagnosed Ss (those with thought disorder, affective disorder, generalized anxiety, and miscellaneous disorders) were significantly less hypnotizable than the nonpatient comparison group. This effect was unrelated to age or medication differences. Implications of the findings are discussed in relation to a new model of hypnotic responsivity that takes into account the moderating effects of severe psychopathology. 55 refs.

1981

Scignar, C. B. (1981). Rapid treatment of contamination phobia with hand-washing compulsion by flooding with hypnosis. American Journal of Clinical Hypnosis, 23, 252-257.

Two obsessive-compulsive patients with contamination phobias and hand-washing compulsions are presented. Psychoanalytic psychotherapy had resulted in little change. Behavior therapy techniques of thought-stopping, systematic desensitization, progressive muscle relaxation, cognitive restructuring and self-imposed response prevention were first used, resulting in some subjective improvement, but no change in the hand-washing rate. Hypnosis, emphasizing relaxation, positive suggestion and corrective information provided further temporary subjective improvement but little change in compulsive rituals. Hypnosis, combined with the behavioral technique of flooding, produced rapid improvement. The patients maintained improvement at seven years and two years. Flooding under hypnosis may afford obsessive-compulsive patients a rapid and economical therapeutic procedure.

Smyth, L. D. (1981). An experimental hypnotic approach to teaching the psychoanalytic theory of the neuroses: A brief communication. International Journal of Clinical and Experimental Hypnosis, 29 (2), 100-106.

A procedure for training clinical graduate students in the psychoanalytic theory of the neuroses is presented. The procedure makes use of video tapes of experiments in which hypnotically implanted unconscious conflicts were used to drive a wide variety of psychopathology in the laboratory. In the procedure, the graduate students were asked to predict and rate Ss' psychopathology with foreknowledge of certain personality traits of Ss as well as foreknowledge of the nature of the conflicts. The training appeared to be an effective means of teaching them psychoanalytic theory, as well as helpful in enhancing their assessment skills

Throll, D. A. (1981). Transcendental meditation and progressive relaxation: Their psychological effects. Journal of Clinical Psychology, 37 (4), 776-781.

Administered the Eysenck Personality Inventory, the State-Trait-Anxiety Inventory, and two questionnaires on health and drug usage to 39 Ss before they learned Transcendental Meditation (TM) or Progressive Relaxation (PR). All Ss were tested immediately after they had learned either technique and then retested 5, 10, and 15 weeks later. There were no significant differences between groups for any of the psychological variables at pretest. However, at posttest the TM group displayed more significant and comprehensive results (decreases in Neuroticism/Stability, Extroversion/Introversion, and drug use) than did the PR group. Both groups demonstrated significant decreases in State and Trait Anxiety. The more pronounced results for meditators were explained primarily in terms of the greater amount of time that they spent on their technique, plus the differences between the two techniques themselves.

De L. Horne, David J.; Baillie, Jennifer (1979). Imagery differences between anxious and depressed patients. In Burrows, G. D.; Collison, D. R.; Dennerstein, L. (Ed.), Hypnosis 1979 (pp. 55-61). Amsterdam: Elsevier/North-Holland Biomedical Press.

"In conclusion, the topic of this study is as yet a very new area of research. No other studies were found which specifically tested the difference between anxious and depressed people in imagery and hypnotic susceptibility. There were a number of limitations to the present study, which further studies could avoid. Larger samples could be used, and such variables as age, educational level and anxiety should be more carefully controlled. The type of depression, whether agitated or retarded, should be assessed, and level of arousal to the imagined scene measured more accurately, with for example, other physiological measures than the E.M.G. It would

be preferable to test depressed people while they are not on medication. Though the effects of antidepressant drugs on imagery were not actually documented, it would seem very likely that significant effects could exist on the ability to image; these obviously warrant investigation" (p. 61).

Kleinhauz, Moris; Dreyfuss, Daniel A.; Beran, Barbara; Goldberg, Tova; Azikri, David (1979). Some after-effects of stage hypnosis: A case study of psychopathological manifestations. International Journal of Clinical and Experimental Hypnosis, 27, 219-226.

Some deleterious effects of stage hypnosis are described through a case report. A middle-aged respected member of a kibbutz who became the subject of an evening's entertainment by a stage hypnotist suffered a posttraumatic neurosis. The stage hypnotist, unaware of her traumatic childhood during World War II when she and her sister were hidden by Gentiles, requested her to regress to that age. This reactivated a former successfully repressed trauma and acted as a precipitating factor to the development of a traumatic neurosis which was left untreated. She was self-referred for adequate psychiatric treatment 11 years later. This treatment successfully restored her to an adequate level of functioning.

Acosta, Frank X.; Yamamoto, Joe; Wilcox, Stuart A. (1978). Application of electromyographic biofeedback to the relaxation training of schizophrenic, neurotic, and tension headache patients. Journal of Consulting and Clinical Psychology, 46 (2), 383-384.

This study examined the effects of electromyographic (EMG) biofeedback on tension reduction by schizophrenic, neurotic, and tension headache patients. Fourteen patients participated voluntarily in at least 10 weekly EMG biofeedback sessions at a public outpatient clinic. All had complained of chronic tension. Patients showed significant decreases in their muscle tension levels with successive biofeedback training sessions. No significant differences were found between the schizophrenic, neurotic, and tension headache groups. A further contribution was the finding that patients with diverse socioeconomic and educational levels benefitted similarly from EMG biofeedback training.

Lehrer, Paul M. (1978). Psychophysiological effects of progressive relaxation in anxiety neurotic patients and of progressive relaxation and alpha feedback in nonpatients. Journal of Consulting and Clinical Psychology, 46 (3), 389-404.

Gave 10 anxiety neurotic patients 4 sessions of individual instruction in progressive relaxation; 10 patients served as waiting list controls. 10 nonpatients were assigned to each of the same conditions, and an additional 10 nonpatients were given 4 sessions of alpha feedback. Nonpatients showed more psychophysiological habituation over sessions than patients in response to hearing 5 very loud tones and

to a reaction time task. Patients, however, showed greater physiological response to relaxation than did nonpatients. After relaxation, the autonomic responses of the patients resembled those of the nonpatients. The effects of relaxation were more pronounced in measures of physiological reactivity than in measures of physiological activity. Defensive reflexes yielded to orienting reflexes more readily in nonpatients than in patients. There was also a tendency for progressive relaxation to generalize to autonomic functions more than alpha feedback.

Nichols, Michael P.; Bierenbaum, Howard (1978). Success of cathartic therapy as a function of patient variables. Journal of Clinical Psychology, 34 (3), 726-8.

Treated sample of 42 patients with cathartic psychotherapy and evaluated differential effectiveness on types of patients. Patients without mental disorders experienced more emotional catharsis than all others, and those with obsessive compulsive personality disorders improved more than all others as a result of emotive treatment. Contrary to popular notions, neither women nor hysterics experienced more catharsis or improved more in cathartic therapy. Although women and hysterics may cry more easily in daily life, obsessives are apparently more able to maintain focus on unhappy experiences and are therefore able to express more emotion in cathartic therapy. Furthermore, it seems that cathartic treatment is beneficial by disrupting long-standing defenses against emotional experience, rather than by releasing stored-up affects.

Wickramasekera, Ian (1974). Heart rate feedback and the management of cardiac neurosis. Journal of Abnormal Psychology, 83 (5), 578-580.

This article describes the treatment of a chronic case of cardiac neurosis which had failed to respond to several prior medical and psychological interventions. Significant and durable symptomatic response appeared to be correlated with the application of a combination of procedures including heart rate feedback, patient-administered desensitization, and therapist-administered flooding

Schneck, Jerome M. (1966). Hypnoanalytic elucidation of a childhood germ phobia. International Journal of Clinical and Experimental Hypnosis, 14, 305-307.

**A PATIENT IN HYPNOANALYSIS WAS ABLE TO BECOME AWARE OF THE RELATIONSHIP BETWEEN HER CHILDHOOD GERM PHOBIA AND HER EARLIER**

Klemperer, Edith (1965). Past ego states emerging in hypnoanalysis. International Journal of Clinical and Experimental Hypnosis, 13 (3), 132-144.

Patients with anxiety, conversion, or phobic reactions differ from those with obsessive-compulsive reactions in the type of visualization shown in hypnoanalytic regression or revivification. The former produce visualizations showing a well-rounded picture with logical progression of activity and few symbolic distortions.

The latter, however, produce visualizations lacking a logical progression of activity and showing a somewhat disorganized and poorly-rounded picture. Symbolic distortions are frequent, often recurring intermittently. Case studies are presented. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1964

Arluck, Edward Wiltcher (1964). Hypnoanalysis, a case study. New York: Random House.

Details transcripts (90 pages) and comments of a 28 session hypnoanalysis (Jungian) of a World War II soldier with traumatic war neurosis in a military setting shortly after the end of the war, for a conversion reaction with onset just prior to return to the States. Author cautions he found this amount of success in only about 15 of more than 70 individually treated cases. Emphasizes giving suggestions to dream about his condition/problem and utilizing dream interpretation. 53 references

Moss, C. Scott; Thompson, M. M.; Nolte, J. (1962). An additional study in hysteria: The case of Alice M.. International Journal of Clinical and Experimental Hypnosis, 10, 54-74. (Abstracted in Index Medicus, 62, 1425)

Detailed account of the psychotherapy of one female hysteric--a treatment failure--is the stimulant for discussion of the genetics and dynamics of this nosology. Hypnosis revealed the experimental basis for the symptoms and associated adjustment difficulties. The dynamics bear a remarkable resemblance to those advanced by Freud, though issue is taken with several psychoanalytic concepts. The discussion deals largely with the phenomenology of the female hysteric. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Furneau, W. D. (1961). Neuroticism, extroversion, drive, and suggestibility. International Journal of Clinical and Experimental Hypnosis, 9, 195-214. (Abstracted in Psychological Abstracts, 62: 4 II 95F)

In the group studied, the body-sway scores of stable extraverts and neurotic introverts tended to be large, whereas they were smaller for stable introverts and neurotic extraverts. This result was explained in terms of a theoretical model in which the effective drive produced in a S by a test-situation is a function of both his neuroticism and his extraversion. The author believes that the theoretical model generates a number of predictions and suggestions which can serve to guide future experimental work in this field. From Psyc Abstracts 36:04:4II95F. 1955

Ament, Phillip (1955). A psychosomatic approach to the use of anesthesia for a hysterical dental patient: A case history. Journal of Clinical and Experimental Hypnosis, 3, 120-123. (Abstracted in Psychological Abstracts 56: 1280)

Author describes a case highly resistant both to anesthesia and dentistry. Although very responsive to hypnosis, she continued moaning and moving from side to side (later determined to be her way of preventing dental work even though anesthetized). Ultimately a combination of hypnosis and multiple anesthetics was needed, including nembutal, sodium pentothal, nitrous oxide and novocain. In the author's experience, most other patients require only hypnosis or hypnosis plus novocaine

Bowers, Margaretta; Brecher, Sylvia (1955). The emergence of multiple personalities in the course of hypnotic investigation. Journal of Clinical and Experimental Hypnosis, 3 (4), 188-199.

"Summary. This paper is a preliminary report presenting only that portion of the material on one case depicting the actual process in which the multiple personality structure was uncovered. Due to space limitations only the more manifest dynamic material which was involved in the emergence of the personalities (and equally we feel, in their submergence) is reported. For the same reasons only a brief indication of the Rorschach and other psychological material is presented. The paper poses a number of problems which require further study and elaboration.

"Since the patient's history gave no indication of fugue states or periods of amnesia, the possibility of the induction of multiple personalities by the hypnosis itself is considered and a careful noting of what occurred in the hypnotic sessions is made. In the authors' opinion the multiple personality structure preceded the beginning of hypnotic work.

"The significance of an underlying multiple personality structure in a severely obsessive compulsive personality suggests that the obsessive-compulsive defense

binds the underlying multiple personalities so that we have a conscious personality resulting that is conflicted, rigid, and cold as opposed to the hysterical dissociation in which the several personalities take turns in living out their roles.

living out their roles.

"The use of dissociation to repress unacceptable drives and behavior in a repeated effort to develop, through new identifications, a successful adaptation to a changing and conflicted environment, as well as to permit expression of forbidden impulses is indicated. The result of such repeated dissociation was the severe impoverishment of the self.

"The Rorschach finding that one of the personalities was schizophrenic suggests that further study of this material may be of value in the understanding of the development of schizophrenia.

"The question of the emotional and physiological state at the actual moment of change-over from one personality might well lead to further understanding of the process of dissociation which appears to have correlations with the hypnotic state.

"The correlation in this case of extensive age regression studies with the co-existing multiple personality structure should prove a rich field for the study of personality development" (pp. 198-199).

1954

Dittborn, Julio (1954). Dehypnotization and associated words. Journal of Clinical and Experimental Hypnosis, 2 (2), 136-138.

Author tested Freud's hypotheses about signs of emotional conflict gleaned from a word association test. A highly hypnotizable subject who had been accused of theft was tested with the word association test repeatedly. He had been given the suggestion, while in deep hypnosis, that any word provoking emotional conflict would automatically bring him out of hypnosis. That is, "dehypnotization was used as a new method to investigate the conflict-provoking quality of certain stimulus-words in an association word test" (p. 139). Freud's predictions were only partially supported.

Erickson, Milton H. (1954). The development of an acute limited obsessional hysterical state in a normal hypnotic subject. Journal of Clinical and Experimental Hypnosis, 2, 27-41.

The 25 year old female graduate student in psychology had often been used in hypnosis experiments and as a demonstration subject, and had witnessed induction of hypnotic deafness, blindness, and color-blindness though she had not been given those suggestions herself. Scientific curiosity appeared to be the motivation for volunteering to experience hypnotic blindness, but she was skeptical about her ability to experience it. The author gave a series of "exceedingly tedious" suggestions to develop somnambulism (passively responsive and receptive) followed by suggestions leading gradually to development of "blindness" with the intention of concealing it from the hypnotist, with attendant strong and mixed emotions.

The initial attempts failed because the subject ostensibly was deceiving herself into thinking she had developed hypnotic blindness, but the author also was of the opinion that she was seeking to meet unconscious personality needs. The author then covertly changed the goal of the experiment "to develop in the subject an acute hysterical obsessional compulsive mental state which would be accompanied by hypnotic blindness and which would parallel or resemble the obsessive compulsive hysterical mental disturbances encountered in psychiatric practice" (p. 32). The author developed a monologue of suggestions based in part on the utterances of hospitalized obsessive patients and in part on trauma relating to traumatic blindness in a kitten and a friend of the subject. In a slow but directed manner the author built up a double-bind situation which eventually led to the experience of hypnotic blindness as well as heightened emotional reactivity, crying etc. obsessive patients and in part on trauma relating to traumatic blindness in a kitten and a friend of the subject. In a slow but directed manner the author built up a double-bind situation which eventually led to the experience of hypnotic blindness as well as heightened emotional reactivity, crying etc.

Schneck, Jerome M. (1954). An experimental study of hypnotically induced auditory hallucinations. Journal of Clinical and Experimental Hypnosis, 2, 163-170.

"Summary. An experimental study of hypnotically induced auditory hallucinations was incorporated into therapeutic contact with a patient at a time when an exploratory phase of treatment process seemed appropriate. The study was divided roughly into ten parts, nine of which involved attempts to induce hallucinations on an auditory level following an initial control procedure involving 'imagined' conversation. Choice of persons to be hallucinated was made at times by the therapist and at times this was left for spontaneous development by the patient. Some of the episodes involved marked emotional participation by the patient. Others were less intense. 'Imagined' conversations were distinct from hallucinated comments. Her own voice when hallucinated emanated from within herself. Other hallucinated voices had external origins. Some were far away. Her aunt's voice was in the same room. Spatial and temporal elements were divorced from their conventional relationships and distorted in keeping with psychodynamic needs. The patient was able to discuss her experiences and evaluate certain descriptive and dynamic qualities. Certain parts of the total experience served as controls in the evaluation of other parts. The beginning of hallucinatory behavior did not set a pattern for continuous similar activity. Responsive behavior varied from time to time. A hallucinatory episode might be followed by an 'imagined' conversation, although instructions remained the same. Deceased persons were hallucinated on an auditory level. This type of episode with her mother had considerable emotional impact. Her aunt died twenty years ago. Her husband was not hallucinated. Responses involving her daughter showed greater complexity.

"Further studies are in order in connection with the neuropsychological and neurophysiological elements in such hypnotic hallucinatory activity. Such elements as they play a role in visual imagery as described here and in visual hallucinations are also to be examined further. Aside from extensions of the type of investigation

presented here, inroads may be made into an understanding of spontaneous hallucinatory activity among psychotic patients through the utilization of hypnotic exploratory methods. This would have to be preceded by more extensive studies of hypnosis in relation to psychotic patients than have been attempted thus far. The procedure discussed here and many potential ramifications makes possible a wide variety of investigations which can be planned for the future" (pp. 169-170).

#### Nonvolition/automatism

1995

Comey, Gail; Kirsch, Irving (1995, November). Intentional and spontaneous imagery in hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

Students were given one of two versions of the Carleton University Responsiveness to Suggestion Scale (CURSS): a) the original version, which contains instructions to intentionally imagine goal-directed fantasies, and b) a modified version, in which instructions for suggestion-related imagery was deleted. Participants were asked to report their goal-directed fantasies and to indicate whether these occurred spontaneously or were generated intentionally. They were also asked whether they had tried intentionally to generate the suggested experience and to indicate whether they had believed that the suggested states of affairs were real (e.g., whether they thought a hallucinated cat really existed). The deletion of instructions for goal-related imagery significantly increased responsiveness to CURSS suggestions. Spontaneous goal-directed imagery was significantly correlated with behavioral response, but intentional imagery was not. Most successful responders tried to generate suggested experiences intentionally, indicated that they could have resisted challenge suggestions if they really wanted to, and reported believing in the reality of suggested ideomotor and challenge experiences, but not of cognitive suggestions. Voluntary attempts to generate suggested experiences were correlated with subjective responding.

Green, J. P.; Lynn, Steven J. (1995, August). Dissociation, hypnotic amnesia and automatic writing: Is there an association?. [Paper] Presented at the annual meeting of the American Psychological Association, New York.

This study examined whether differences in self-reported dissociative experiences (DES, Bernstein & Putnam, 1986) and past performance on hypnotic amnesia (HGSHS: A, Shor & Orne, 1962) influence the frequency of passing an automatic writing suggestion. Participants (N = 112) were divided into high hypnotizable ('real') and simulating groups. Results from a log linear analysis indicated that automatic writing was independent of both dissociation status and past performance on an ostensibly dissociative hypnotic suggestion (i.e., amnesia). Simulators were more than six times as likely to pass the automatic writing suggestion than reals. Findings were discussed in light of other research regarding the relation between

the DES and hypnotizability. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1995, Vol. 4, No. 3.)

Malinoski, Peter; Martin, Daniel F.; Aronoff, Jodi; Lynn, Steven Jay; Gedeon, Scott (1995, November). Hypnotizability, individual differences, and interpersonal pressure to report early childhood memories. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX. Infantile amnesia is attributed to developmental issues before 24 months. This study indicates non-hypnotic influences can shape early memories that cross the amnesia barrier.

227 Ss completed Harvard Scale and personality measures in Session 1. In Session 2 182 completed a suggestibility scale. In Session 3 they were selected, as if independent of earlier sessions - 143 [may have misheard number] Ss.

Interviewers told the selected Ss that they were experiencing something like psychotherapy, and they were asked to recall their earliest memory (independent of photos, what people had told them, etc.) Then Experimenters probed for earlier memories; that continued until Ss denied any more memories after 2 consecutive probes. Then Ss were asked to close their eyes and get in touch with more memories. Then they were told most Ss can remember more, including sometimes their second birthday party. After 1 minute, Ss were asked about memories of their second birthday. Then they were asked to focus on even earlier memories, implying it was expected and receiving complements for reporting earlier memories. Finally, Ss completed a post-study questionnaire.

Memory report was a verbal description of an event, person, or object. Initial memory mean age was 3.7; it correlated with Openness to Experience Scale and with Fantasy Proneness. Mean age of the last earliest memory report before the close eyes instruction was 3.2 years. After receiving visualization instructions, 59% reported a memory of their second birthday. Compliance correlated .33 with this. Subjective response, nonvoluntariness, and [missed words] also correlated.

Compliance scores correlated .28 with at least one memory at or before age 24 months. Yielding to leading questions correlated also with memory for an event at or before 24 months.

Clarity of memories decreased between conditions of initial memory, earliest query, birthday, and earliest memory. Mean confidence rating on 5 point scale for second birthday memory was 3.3; mean confidence rating for earliest memory was 3.6. Mean accuracy rating was 4.0, and 94% said their memory reports were accurate to at least a moderate degree.

The post study questionnaire, totally anonymous, indicated Ss did not feel much pressure to recall (2.9 on scale of 1-5). Only 9.8% indicated they felt a lot of pressure. Subjects also usually denied that they made up memories to satisfy the experimenter. On average, the reports of memory under visualization conditions occurred two years earlier than their first reported memories.

Woody, Erik Z. (1995, November). Trying, not trying, and trying not to try. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

**In the "classic suggestion effect" the behavior of a hypnotized person following a suggestion is experienced as nonvoluntary. So alterations of experience are important to understand. We can think of it as a misattribution: which cues lead subjects to misattribute their behavior, etc.**

**A different view is to see it as how information is processed (neodissociation theory). There are two views of dissociation to consider: 1. Behavior is voluntary, but that voluntariness is blocked from awareness. (The S is trying but doesn't know it consciously.) This is a barrier model of dissociation. The S lacks information about self agency. Bowers calls it a theory of dissociated experience. 2. Underlying control of behavior is altered (not so governed by executive control) and the subject is correct when they say they are not trying. Bowers called this a theory of dissociated control.**

**A persistent problem is that these two theories of dissociation are incomplete sketches. But cognitive neuroscientists and experimental psychopathologists have recently become interested also, rapidly developing and independently developing the same two theories.**

**Bowers and I stated that the theory presented by Norman (Norman?) and Shallice is similar to dissociative control theory. When a response is habitual, a lower system called contention scheduling can do it; if response is more complex, a higher control supervisory system involving unique information like goals is available, modulating the lower control system. Volition and how it is experienced depends on the nature of the supervisory system. When it is not [or when it is?] modulating or monitoring the contention scheduling process, one experiences will.**

**Thus, hypnosis is in the grey zone where the supervisory system monitors without modulation of contention scheduling--a wide realm. Also, for high hypnotizables hypnosis may weaken the higher level control system associated with the subjective experience of will; this dissociates lower levels of control from higher levels of control. The lower levels cannot be modulated as well at will. This indicates changes of frontal functions.**

**In psychopathology, Chris Frit argues that schizophrenia can be thought of as disorders of volition: 1. Spontaneous self initiated willed actions are generated by a different route to action from unwilled actions. In schizophrenia there is impoverishment of self initiated action. The patient also shows perseverated action. In contrast, when directly instructed the patient can perform complex tasks. This is close to the dissociated control model of hypnosis. Laboratory procedures for studying perseverative acts in schizophrenia can be applied to hypnosis. (However the theory doesn't explain the positive symptoms of schizophrenia.) 2. There is an internal monitor that keeps track of the self initiated aspects of actions (e.g. inner speech), which schizophrenics lack. Likewise delusions of control, due to a failure to track the self initiated aspect of these actions, resemble the dissociated experience aspect of hypnosis.**

**The Classic Suggestion Effect is a mild delusion of control. This is very different from the social psychological view. Nisbett & Wilson say people do not introspect about the sources of their behavior. In their view, believing that alien forces are**

controlling you is due to failure of a mechanism. It is an interesting alternative to social psychological misattribution models to explain the nonvoluntary experience. Functional brain imaging of normal subjects indicates that willed actions involve different areas of brain than nonvoluntary actions. Current thinking is that what differentiates schizophrenics from normals is in how their separate brain regions interact with each other. (This view is consistent with the research of Crawford and others on brain areas involved in hypnosis.) 3. There is a unifying mechanism of meta-representation or second order representations ("mentalizing") which are distinct from normal representations of reality. Consider the example of the suggestion to hallucinate a fly on the Harvard Form A Group Scale. The hypnotist wants me to believe that a fly is buzzing around me. If the second order representation is not there, only the first order representation is there: "a fly is buzzing around me." This is in Frit's theory's term a dementalized experience. The "dementalized experience" is a bit like Sarbin's believed in imagining. Low hypnotizables are plagued with meta-representation ("trying not to try"). Frit's work even suggests some parts of neodissociation theory may be a better representation of schizophrenia than of hypnosis.

1994

Lynn, Steven Jay (1994, October). Toward an integrative theory of hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

This is a re-evaluation of neodissociation and cognitive models of hypnosis, and an attempt to be integrative. This paper focuses more on ideomotor behaviors but we will extend the model to other hypnotic behaviors in the future.

Automaticity of behavior in hypnosis can be accounted for without using a concept of divided consciousness or weakened consciousness. Parapraxes (doing one behavior while intending another) are not instances of decreased control of behavior, but relate to where attention is drawn. This requires a different use of the hierarchy concept from Hilgard's model (which in turn comes from Hull's concept of habit hierarchy).

Here hierarchy is a concept drawn from Miller, Galanter, & Pribram: acts are comprised of molecular units, that are comprised of even more molecular units. Behavior only needs to be processed at an executive level when unusual events occur. But one or more hierarchies may be set into motion at the same time. Dissociation is not an infrequent event. Behavior is controlled by subroutines rather than by an executive control structure; subroutines operate in parallel rather than in a hierarchy. Parapraxes are due to an overlap between two subfunctions.

Parapraxes are different from ideomotor responses, where we pay close attention and involuntariness is reported not just post facto but as part of the experience.

Malinoski, Peter; Aronoff, Jodi; Lynn, Steven J.; Moretsky, Michael (1994, August). Hypnosis and early memories. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

We studied autobiographical memory in the college population, as manifested in the therapy situation, as a way of investigating an individual difference variable. Most people do not have recall before age 3 or 4 (and probably infantile amnesia begins before age 2).

Administered Autobiographical Memory Scale (AMS), and later in context of a hypnosis scale. 247 students were in phase 1, conducted as two separate experiments so that Ss wouldn't link the AMS to measures used in the second study.

First study was presented as a study of personal memories. Asked Ss to distinguish first five birthdays, circumstances around loss of first tooth, first day of high school. Also, they were asked about their earliest memory events, rated according to 3 scales (detail, vividness, accuracy of recall). Authors summed Ss' responses on these 3 ratings for the 8 item scale.

Part II. Administered various scales: Life Experiences, Fantasy Proneness, Wilson & Barber's scale, Imagery Control Scale, Global Psychopathology, 25 item scale of physical and sexual abuse, Brier's list of symptoms of abuse, and DES (Dissociative Experiences Scale). Imbedded were 12 items to test carelessness in responding (e.g. "I have never said Hello to anyone who wore eyeglasses.")

**RESULTS.** Phase 1. Two people indicated they had memories dating to before their first birthday; an additional 5% of Ss gave memories between 12-24 months. This would probably be impossible. Another 14.4% described events between 24-36 months; 37.4% said their earliest memory was at age 3. Mean age for earliest memory was 3.4 years (which agrees with other surveys.) Only 1 subject stated his earliest memory was as late as the tenth year of life.

High intercorrelation was obtained, ranging .79 to .89, between ratings on any of the memory event ratings (as detailed, vivid, or accurate). There was a negative correlation of these ratings with age of recall. Ss who report more detail, vividness, and competence, were also likely to report earlier first memories.

Authors divided Ss into three groups based on age of first memory: 12 with first memory earlier than first year; those whose first memory was between 1-7 years; and those with a later first memory. The earlier memory group were more fantasy prone; and rated their memories as more reliable, vivid. This suggests there are persons who report memories that are covered by infantile amnesia, report them with greater detail, and are more fantasy prone than those who report memory events beginning later in life. This is consistent with Wilson & Barber's finding that fantasy prone people have vivid recall of early childhood events.

than first year; those whose first memory was between 1-7 years; and those with a later first memory. The earlier memory group were more fantasy prone; and rated their memories as more reliable, vivid. This suggests there are persons who report memories that are covered by infantile amnesia, report them with greater detail, and are more fantasy prone than those who report memory events beginning later in life. This is consistent with Wilson & Barber's finding that fantasy prone people have vivid recall of early childhood events.

None of the memory reports correlated with psychopathology or dissociation. Dissociation (DES) was correlated with abuse indicators, however. Compared top and lowest 10% and middle range on DES on their memory scores and found no relationship. There was no support for the idea that report of early life events in

dissociative people is compromised. Failure to recall early memories shouldn't suggest that people are dissociative (which some therapists tend to do).

All three memory measures were associated with Harvard Scale scores. The AMS was administered at the same time as the Harvard. Objective responding on the Harvard correlated with detail, vividness, and accuracy of recall. Also, involuntariness of response correlated with all 3 measures of the AMS. Finally, subjective involvement correlated with all three measures of AMS. At least when hypnosis is measured first, and explicit connection is suggested, there is a connection. Further research is needed to see if the relationship holds when measured in independent contexts. This may explain why High Hypnotizables are more prone to pseudo memories and leading questions. They may come to confuse them with historical reality.

The results suggest caution for early memory reports. They may be vulnerable to confusing fantasy and reality, as well as to biasing effects.

Tellegen, Auke (1994, October). Comments on Symposium "Hypnosis Reconsidered". [Comment/Discussion] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco, , as part of Symposium titled: Hypnosis reconsidered.

I agree that the topography of issues has become more complicated. I would want to look at the distinction between "special process" theories and other views. I still think there is some non-trivial element of difference between the two groups; but it's not one well defined group vs another, with people now distributed across a continuum and to some degree moving around. At the poles of these theoretical positions are real differences (e.g. in favorite hypotheses, research methods). But there has been some closing of the gap between these two poles.

Historically, rapprochement in psychological theories has been the result of hard nosed behaviorism going soft and cognitive in the last 15 years. The behavioral paradigm is the ancestor of the social cognitive view within hypnosis research. You can see the evolution in Ted Barber, and eventually it was carried forward by Spanos. Today all major views of hypnosis have become systems models, requiring flow diagrams. We are comparing more parsimonious (social cognitive) with more surplus meaning positions. Parsimony is a good way to advance knowledge, making a theory more complex only when you have to. The major social psychological positions are widely shared; many are close to common sense. The question is, are they sufficient to the data? The behavioral approach recognizes individual differences but doesn't weight them heavily; it may treat individual differences as a curve fitting issue, or may treat them as training outcome. Associated with the behavioral approach is a tendency not to explore fully individual differences from a naturalistic perspective. The difference in research approaches between the two poles is loosely aligned with Cronbach's correlational vs experimental approaches to psychology.

The role of individual differences in hypnotizability however may be structural, in which case different flow diagrams may be needed, depending on trait levels, on the

eliciting circumstances, etc. Thus we might need different flow diagrams for different levels of hypnotizability.

The role of imagination remains unexplicated across theoretical positions. Everyone since the Franklin committee thinks imagination is important in hypnosis; it is urgent to explore it. Even the most constructivist perspective on perception doesn't equate perception with imagination.

-proaches to psychology.

The role of individual differences in hypnotizability however may be structural, in which case different flow diagrams may be needed, depending on trait levels, on the eliciting circumstances, etc. Thus we might need different flow diagrams for different levels of hypnotizability.

The role of imagination remains unexplicated across theoretical positions. Everyone since the Franklin committee thinks imagination is important in hypnosis; it is urgent to explore it. Even the most constructivist perspective on perception doesn't equate perception with imagination.

We now must turn the flow diagrams into neurobehavioral models, like Helen Crawford is attempting to do.

**COMMENTS FROM THE AUDIENCE:**

**Kenneth Bowers:** The people flowing out from the neodissociation camp are going in different directions. I think that ideas are directly activated, Helen Crawford and John Kihlstrom would think it involves more effort on the part of the hypnotized Subject. Irving Kirsch agrees that at some level the words have to be processed, but doesn't imply great effort. There is some kind of preattentive processing in hypnosis, the kind of processing which allows you to turn when you hear your name, in normal circumstances. Does it still make sense to talk about the field of hypnosis research or theory in terms of the two camps? I fear a return to the situation when the term "two camps" was justified.

**Woody, Erik Z. (1994, October).** Cognitive-processing models of hypnotic dissociation. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Spanos contended that social psychology is an appropriate ground for hypnosis, and his work highlights the value of not taking things at face value (e.g. feelings of nonvolition).

I did this research with Ken Bowers. It addresses the question, does non-volition occupy a small role in hypnosis, or are hypnotic responses performed intentionally despite the hypnotized person's feeling of non-volition.

We did not rely on the research Subject's verbal report. When one exerts intentional effort to suppress a thought, the thought gets stronger. For example, when people try to comply with instruction not to think about white bears, they think about them repeatedly (Waitner's research).

Hypnosis suggestions are for amnesia (inability to remember), not intentional forgetting.

**STUDY ONE.** We used Waitner type instructions vs hypnosis in high and low hypnotizability Ss, to examine the role of intention in response. We used thinking

about one's favorite automobile instead of a white bear as the task stimulus. Subjects were not to think about it for 2 minutes, but to press a button whenever a thought about the automobile surfaced. There was another waking trial with suggestions; then hypnosis and re-testing.

Ss were undergraduates screened on Harvard Scale for hypnotizability and the Waterloo Stanford Group form. High hypnotizables scored 8 or more on both scales, lows scored 4 or less on both.

The variables recorded were total number of button presses, and average length of time per press. Analysis was by a 3 way mixed model ANOVA: high low, induction condition, and suggestion condition (blank mind vs. amnesia)

#### **RESULTS.**

**Mean Number of Button Pushes Over Trials Group Waking Hypnosis**

blank amnesia      mind High 6.9 2.9 1.8 .6 Low 5.2 4.7 4.3 3.7

mind mind High 6.9 2.9 1.8 .6 Low 5.2 4.7 4.3 3.7

**1993**

Miller, Mary E.; Bowers, K. S. (1993). Hypnotic analgesia: Dissociated experience or dissociated control?. Journal of Abnormal Psychology, 102, 29-38.

High-hypnotizable subjects were found superior to low-hypnotizable subjects in degree of pain reduction produced by hypnotic analgesia and by a stress-inoculation (cognitive-therapy) procedure. But, stress inoculation and not hypnotic analgesia impaired performance on a cognitively demanding task that competed with pain reduction for cognitive resources. This outcome implies that hypnotic analgesia occurs with little or no cognitive effort to reduce pain, challenging the social psychological theory of hypnotic response, at least in high-hypnotizable individuals. The findings are also incompatible with the concept of dissociated experience wherein the pain and cognitive efforts to reduce it are separated from consciousness by an amnesia-like barrier. But the results do support the concept of dissociated control, which proposes that suggestions for hypnotic analgesia directly activate pain reduction and thereby avert the need for cognitive strategies to reduce pain.

Spanos, Nicholas P.; Burnley, M. C.; Cross, P. A. (1993). Response expectancies and interpretations as determinants of hypnotic responding. Journal of Personality and Social Psychology, 65, 1237-1242.

Subjects rated the extent to which they expected to respond to each of the suggestions on a hypnotizability scale both before and after the administration of the preliminary hypnotic-induction procedure. After the induction, subjects also rated the extent to which they planned to respond actively and passively to each suggestion. Contrary to strong versions of response-expectancy theory, the extent to which subjects planned to adopt an active interpretation predicted behavioral and subjective indexes of hypnotizability even after controlling for the effects of postinduction expectations. In addition, an active interpretation significantly predicted response to suggestion for which subjects held weak and uncertain

expectations. The relationship between expectation and hypnotizability was found to be fan-shaped rather than linear. Implications are discussed.

Woody, Erik Z. (1993, October). Factors, facets, and fiddle-faddle. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

The classic suggestion effect implies involuntary behavior. A theory by Norman & Tim Shallice (published in a book on cognitive neuropsychology by Shallice) explains the classic suggestion effect in terms of underlying control processes.

There are 2 complementary systems: 1. contention scheduling (routine acts that don't require conscious control, activating schemas through environmental events and other schemas) for well learned habitual tasks. 2. supervisory attentional system - nonroutine actions in centralized processes, accessing unique information, operating only indirectly by modulating lower level control system, biasing their selection of schemas by system #1.

These two systems permit the sense of behavior being automatic or willed. The theory can be used to explain hypnotic nonvolition. For highs, hypnosis may partly disable System #2, dissociating lower levels of control and resulting in genuine changes in behavior because System #1 would be more enabled, triggered directly by co-active schemas and environmental stimuli. This increased dependence on a lower level of control would not rule out a wide range of behavior. It's mainly novel or very complex behaviors that would diminish, plus exercise of will.

The model also illuminates our understanding of behavioral rigidity and the tendency for thought/action to be triggered by [suggestions?]. Spontaneous voluntary behavior would be diminished. (See for example Orne's studies of the effect of apparent power outage during an experiment, in which high hypnotizable Ss did not move or leave the room but sat passively, whereas low hypnotizable simulating Ss simply got up and left.)

Also a weaker "supervisor" would lead to disinhibition of inappropriate or peculiar associations or behavior. In labs one sees few such triggers, although Hilgard observed drug flashbacks. The phenomena of hypnosis sequelae appear like a disinhibition of experiences.

Hypnotic analgesia follows this model too, an automatic and controlled processing of perceptual input.

Amnesia that follows hypnosis can be explained by this theory. Shallice has a model of how memory is affected: memory is a higher control system, enabling the handling of non-routine situations. Confronted by a nonroutine memory problem, the supervisory system formulates a model of what [the information] should look like, pulls out memories, and compares the model. If hypnosis interferes with the supervisor function it should interfere with memory (the description and verification phases) leading to [hypnotic amnesia?]. [With hypnosis one would predict]: 1. Poor access to memories requiring description (not overlearned material). Recall should demonstrate good cued memory but poor free recall. [It has been observed that] hypnotic amnesia selectively impairs free recall rather than recognition recall. 2. Hypnotized Ss should show poorer verification (the ability to

discriminate irrelevant from correct associations). Many studies have shown this, with impoverished verification (e.g. the "discovery" of elaborate previous lives).

A dissociated control theory of hypnosis is thus possible, emphasizing a loss of control of supervisory system processes. It would implicate changes in frontal lobe processing. The essence of hypnosis, according to this approach, is the bypassing of executive control, and the frontal lobe is viewed as a center of executive control.

There are several ways that hypnosis suggests inhibition of frontal lobe functioning: 1. impoverishment of self initiated behavior 2. other-directedness 3. frontal amnesia (unable to distinguish true memories from irrelevant memories; prone to confabulation, especially when probed with false information) 4. poorer in temporal or sequential organization in memory.

How do we proceed to make this theoretical approach useful? We should do more neuropsychological studies, as Helen Crawford does. They emphasize the inhibition of frontal lobe functions.

Testable hypotheses arise: 1. Hypnotizable Ss should show the same kind of problem solving problems as frontal lobe patients. 2. Memory of hypnotized Ss should be like patients with frontal amnesia.

1992 Dixon, Michael; Laurence, Jean-Roch (1992). Two hundred years of hypnosis research: Questions resolved? Questions unanswered!. In Fromm, Erika; Nash, Michael R. (Ed.), Contemporary hypnosis research (pp. 34-66). New York: Guilford Press.

These notes summarize only that part of the chapter concerning nonvoluntary behavior (pp 38-39; 58-61).

The concept of 'nonvolition' has been and continues to be an important issue in hypnosis research. The concept pertains to the "subjective report that the hypnotic suggestion is enacted without the subject's conscious and willful participation" (p. 38). When hypnosis was attributed to a magnetic fluid, in the days of Mesmer, the issue did not arise (because of course a person would not have control over something that happened to them physically). However, when hypnosis came to be considered a psychological phenomenon, the issue of how a behavior could be the result of motivated action and yet not perceived as being under conscious influence became important. In 1819 Faria wrote that the nonvolition paradox is due to the hypnotized subject's tendency to misattribute the source or reason for one's behaviors; he noted that successful suggestions depended upon the subject falsely attributing to the hypnotist the power to influence them. From that point forward, circular reasoning was used to state that one is hypnotized if one experiences their behavior as nonvolitional, and nonvolitional behavior signifies that a person is hypnotized.

"The observation of the seemingly complete automaticity of response in the highly hypnotizable subject led Liebeault in his 1866 book (followed later on by Bernheim and Liegeois) to describe these subjects as 'puppets' in the hands of the hypnotist. This was a quite unfortunate statement, since it would lead to one of the fiercest legal debates surrounding the use of hypnosis in the last 20 years of the 19th century (Laurence & Perry, 1988). ...

"The most prominent author (if not the only one) who attempted to tackle this difficult question was Pierre Janet, who would make the investigation of automatism the basis of his theory of hypnosis, rather than suggestion or suggestibility. This theoretical orientation is best exemplified by his concept of desagrégation psychologique seen in some psychopathologies, or the carrying out of a posthypnotic suggestion in the normal individual (Janet, 1889; see also Ellenberger, 1970; Perry & Laurence, 1984; Prevost, 1973). Nonetheless, until the end of the 19th century, and for a good part of the 20th century, these reports of nonvolition were thought to be the end result of some neurological changes happening during hypnosis--an idea that has not been substantiated by contemporary research." (pp 38-39)

Reports of nonvolition are explained as due to dissociation by Hilgard, or as the results of misattributing the origins of behaviors and experiences by Spanos and by Lynn. Neodissociationists like Hilgard regard misattribution to be a cognitive alteration, mainly an internal triggering mechanism, while social psychologists like Spanos and Lynn regard the misattribution to be the results of situational demands and therefore an external triggering mechanism.

"Regardless of one's preferred metaphor, the issue of nonvolitional reports remains at the core of an integrated view of hypnosis and hypnotizability. The question remains as follows: By which mechanisms does this occur, and how can we predict a priori who will report involuntariness and under what circumstances? Whereas dissociationists have emphasized general cognitive mechanisms and de-emphasized situational factors, social- psychological theorists have emphasized situational variables and de-emphasized individual differences. Given the limitations of both approaches, emphasis will have to be placed not on their continued separation but on their integration, as more and more investigations demonstrate that they clearly interact with each other (see, e.g., Nadon, Laurence, & Perry, 1991)." (p. 60)

"At the height of the confrontation between the two French schools, hypnosis found its way into the legal arena. Following a series of criminal cases in which hypnosis had been allegedly involved, the two schools once again found themselves on opposite sides of the fence. For La Salpêtrière, only those who had a propensity toward criminality (and hystericals were prime candidates) could be the victims of hypnosis. For the Nancy school, in highly responsive individuals suggestions could lead to criminal behavior. Unfortunately for the Nancy school, it soon became evident that the concept of suggestion was not sufficient in explaining the questions raised by the courts, and Bernheim was forced to recognize that in cases where suggestions had played a role, other dispositional and situational factors were probably more important in the genesis of the reprehensible behaviors. His espousing a too extreme position meant that the baby was thrown out with the bathwater. History may indicate that the same fate is now awaiting contemporary theoretical positions that adopt an extreme stance vis-a-vis the phenomenon of hypnosis" (p. 61).

each other (see, e.g., Nadon, Laurence, & Perry, 1991)." (p. 60)

1992

Hargadon, Robin M.; Bowers, Kenneth S. (1992, October). High hypnotizables and hypnotic analgesia: An examination of underlying mechanisms. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

Bowers' dissociated control adaptation of Hilgard's neodissociation theory of hypnosis posits that higher control systems are not used if lower systems are activated.

Imagery may be less important for achieving hypnotic effects. It also may contribute differently than previously thought, an uncorrelated factor. If imaginal involvement and imagery is integral to the production of analgesia using hypnosis, one would get results different than if not integral.

Research: 65 Ss rated as high on two hypnotizability tests participated.

Session 1:

Procedure entailed finger pressure pain: baseline, followed by 2 hypnosis treatment trials. Ss were not informed of the second trial before they did the first.

Standard suggestions: imagery congruent with the suggestion (hand like block of wood, protected by a glove)

Imageless condition: your hand will remain comfortably nonresponsive to the pressure; you will not allow other things to come into your mind.

Outcome Measures

Analogue scale for pain 0-10

Nonvoluntary experience rated 0-4

Session 2:

Administered Tellegen Scale, Woody & Oakman Scale, Marks Vividness of Imagery, Bowers' Effortless Experiencing, and Duality of Experience during age regression.

**RESULTS.**

No difference was found between the standard and imageless conditions in amount of pain reduced. So in high hypnotizables, use of imagery or not doesn't matter for

controlling pain. Some Ss had a clear preference however, for one or the other method (even counter to their own expectations).

Feelings of nonvolition did not differ as a function of imagery use.

Multiple regression showed effects of hypnotizability and effortless experiencing. Ss who have an effortless experiencing of imagery benefit from using it to reduce pain; those who find it more effortful do better without imagery when attempting to reduce pain.

Contrary to last year's results reported by Bowers, high imagery was related to duality of experiencing in age regression.

Dissociated control theory is consistent with the results but not necessarily demonstrated. It is important to discriminate between imagery as a mediator rather than as a co-occurrence. This research suggests, as did Zamansky's work on counter suggestions, that imagery is not as critical for hypnotic response as we previously thought.

Jacoby, Larry L.; Lindsay, D. Stephen; Toth, Jeffrey P. (1992). Unconscious influences revealed: Attention, awareness, and control. American Psychologist, 47, 802-809

Recent findings of dissociations between direct and indirect tests of memory and perception have renewed enthusiasm for the study of unconscious processing. The authors argue that such findings are heir to the same problems of interpretation as are earlier evidence of unconscious influences--namely, one cannot eliminate the possibility that conscious processes contaminated the measure of unconscious processes. To solve this problem, the authors define unconscious influences in terms of lack of conscious control and then describe a process dissociation procedure that yields separate quantitative estimates of the concurrent contributions of unconscious and consciously controlled processing to task performance. This technique allows one to go beyond demonstrating the existence of unconscious processes to examine factors that determine their magnitude

Kunzendorf, Robert; Carrabino, Carlene; Capone, Daniel (1992-93). 'Safe' fantasy: The self-conscious boundary between wishing and willing. Imagination, Cognition and Personality, 12, 177-188.

This experiment tested the hypothesis that a fantasy will impel people to 'act out' only if they fail to distinguish the fantasy from the anticipated reality. In the experiment, one task obtained a baseline measure of how long subjects could resist

eating popcorn, then measured how long subjects could resist popcorn while fantasizing its taste. Another task instructed subjects to merge three circular images with three circular percepts of equal vividness, then presented subjects unexpectedly with only two of the three circular percepts. Some subjects thought that there were three circular percepts during the merger, and for these subjects, the length of resistance to popcorn was significantly shorter during the popcorn fantasy. But for subjects who self-consciously differentiated the two real circles from the three merging images, the normal 'boundary' between wishful fantasy and willful eating was intact.

This research investigated whether people can fantasize without acting out. The authors place the study in the context of theories proposed by Freud and William James. Kunzendorf's source monitoring theory of self-consciousness suggests that "self-consciousness that one is imaging is the phenomenal consequence of neurally monitoring the central source of one's imaged sensations, and self-consciousness that one is perceiving is the subjective quality of neurally monitoring the peripheral source of one's perceived sensations" (p. 178).

The ability to carry out source monitoring varies. Those who have difficulty monitoring whether they are imaging or perceiving may also have trouble distinguishing wishful fantasy from anticipatory imagery, and therefore they might act on it.

This research "identified subjects with poor source monitoring--nondiscerners of reality--and investigated the effect of fantasy on their impulse control" (p. 179).

#### **METHODS.**

Subjects sat in front of a computer monitor for all tests; they completed Eysenck's seventh impulsivity questionnaire for measures of impulsivity, venturesomeness, and empathy, Marks' Vividness of Visual Imagery Questionnaire (VVIQ).

The study used a test in which subjects maintained in mental imagery a red, green, and yellow filled circle that had been on screen, with eyes closed; were instructed to open eyes and merge their 3 imaginary circles with the 3 on the screen (but when they opened eyes only 2 were there), and they were then asked questions about how many circles they saw when they opened their eyes.

Then they were given a taste of popcorn, told to resist eating any more (but could press a key to receive a little if they couldn't resist), and then were told to resist by imagining that they were eating popcorn.

#### **RESULTS.**

Those who discerned the two real circles while imaging a third circle of equal vividness (the Discerners), could resist eating popcorn for 137 sec in the baseline condition and 132 sec in the fantasy condition. Those who could not discern two real circles while imagining a third (Nondiscerners) could resist eating popcorn for 127 sec in the baseline treatment but only 95 sec in the fantasy treatment.

Discerners could identify the missing circle as the red one, whereas nondiscerners could not do so with any certainty; there was no effect of "image vividness".

**"Vivid imagers" whose imagery matched real yellow circles of greater illuminance, exhibited more vivid imagery on the VVIQ as well.**

**In their Discussion, the authors suggest that "fantasy impels people to 'act out' only if they fail to distinguish fantasized sensations from perceived sensations. ... [the theory] is applicable to sexual fantasy and aggressive fantasy as well. This theory--Kunzendorf's 'source monitoring' theory of self-consciousness--implies that fantasies of the sensory consequences of a behavior should not lead to the behavior, so long as the fantasies are self-consciously known to be imaginal and are not expected to be perceptual... But for people who cannot self-consciously distinguish between wishful images of pure fantasy and anticipatory images of perceptual reality, between wishing and willing, fantasies of gastronomical, sexual, or aggressive sensations are implicitly unsafe.**

**"Indeed, as Baars notes, 'the issue of voluntary control is at the very core of human psychopathology' [31, p. 254]. But recently, Baars' and others' theories of volition have emphasized the computer-metaphoric distinction between conscious 'willful' behavior and unconscious 'automatic' action [31, 39-40], and have neglected James' distinction between conscious willing and conscious wishing. Decades ago, when pre-computational theorists like Janet used the term 'automatism' to describe psychopathological behavior, they meant that an abnormally behaving patient was \_consciously 'possessed' by a fantasy\_--a wishful image, a hypnotic suggestion, or a fantasized personality [41]. In reemphasizing the phenomena of wishing, willing, and possession by fantasies, the present article redefines the latter phenomenon as possession by 'unmonitored' fantasies, which are distinguishable from anticipatory images impelling action" (pp. 184-185).**

**Lynn, Steven Jay; Sivec, Harry (1992). The hypnotizable subject as creative problem-solving agent. In Fromm, Erika; Nash, Michael R. (Ed.), Contemporary hypnosis research (pp. 292-333). Guilford Press.**

**These notes are taken only from the section of this chapter that deals with Hypnotic Responding, Imaginative Activity, and Expectancies, and they treat of the concept of nonvoluntary responding (pp 315-316). Other topics covered in the chapter include: Imagination, Fantasy, and Hypnosis Theories; The Hypnotizable Subject as Creative Problem-Solving Agent; Hypnosis and Subjects' Capability for Imaginative Activity; Goal-Directed Fantasy: Patterns of Imaginative Activity during Hypnosis; Hypnosis and Creativity; and a Conclusion.**

**Several studies manipulated expectancies re the relationship between imagination and involuntariness. When Ss were told that "good" hypnotic subjects could (or could not) resist suggestions, "this information affected their ability to resist the hypnotist and tended to affect subjects' report of suggestion-related involuntariness ... [Lynn, Nash, Rhue, Frauman, & Sweeney, 1984]. Furthermore, subjects who successfully resisted suggestions and subjects who failed to do so reported comparable levels of hypnotic depth and imaginative involvement in suggestions.**

**"Spanos, Cobb, and Gorassini (1985) conducted a similar experiment in which they found that hypnotizable subjects who were instructed that they could become deeply involved in suggestions and yet resist them successfully resisted 95% of the**

suggestions and rated themselves as maintaining voluntary control over their behavior. Thus, subjects are able to resist nearly all of the suggestions when resistance is facilitated by situational demands. It is worth noting that subjects in this research who resisted hypnotic suggestions rated themselves as just as deeply involved in the suggestions as Ss who failed to resist suggestions after being informed that deeply hypnotized subjects were incapable of resisting suggestions" (pp. 315-316).

Lynn, Snodgrass, et al. (1987). showed that hypnotizable Ss who were just "imagining" along with suggestions but instructed to resist responding to motoric suggestions acted the way hypnotized Ss did in their earlier countersuggestion research: imagining subjects tended to move in response to suggestion (that "good" Ss responded in certain ways), despite being instructed to resist. In this study, with instructions designed to increase the use of goal directed fantasies (GDFs), low and high hypnotizable subjects reported equivalent GDF absorption and frequency of GDFs. However, highs responded more and reported greater involuntariness than lows, even when their GDFs were equivalent.

"A number of other studies have examined the effects of expectancies on imaginings and hypnotic behavior. Spanos, Weekes, and de Groh (1984) informed subjects that deeply hypnotized individuals could imagine an arm movement in one direction while their unconscious caused the arm to move in the opposite direction. Even though subjects so informed moved in the opposite direction, they imagined suggested effects and described their countersuggestion behavior as involuntary" (p. 317).

Oakman, Jonathan M.; Woody, Erik Z. (1992, October). Automaticity, the Stroop effect, and hypnotic ability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

Builds on the first Dixon study of Stroop effect and hypnotizability, which presented stimuli too fast and also the probabilities of congruent/noncongruent stimuli were varied. Highs had more interference in all conditions, seeming to process with language more. It cast doubt on the use of strategies by highs. Measurement of hypnotizability outside the situation cast doubt on expectancy (social psychology influence) theories.

Automaticity refers to responses that seem effortless, fast, and require little attention. They propose that this characterizes hypnosis. Highly automatic behavior cannot be suppressed. Reading is automatic; color naming is not. The greater the automaticity factor, the more the Stroop effect. Automaticity relates to automatic movement in hypnosis.

Previous research on Stroop used visual tasks, while hypnosis is largely auditory. So we used identification of volume of a word presented over a speaker, plus the regular (visual) Stroop task.

The words "loud" or "soft" were presented as loud or soft in volume. Lows = 4 or lower; highs = 8 or more on Canadian test of hypnotizability, the Waterloo Group Form C.

[In the Visual Stroop?] Reaction Time was greater for incongruent than congruent stimuli for highs (almost statistically significant) but not lows. It is an 8 ms difference for highs.

The Auditory Stroop is very different for both groups; however highs did not show more difference in reaction time than lows.

Auditory and Visual Stroop tasks did not correlate. Waterloo hypnotizability correlated: .28 with Visual Stroop, .11 with Auditory Stroop.

Logan's theory about automaticity seems appropriate: automatization is a shift from using a strategy to relying on memory; inhibition of the automatic response is based on using a strategy instead of relying on memory. Lows may be very able to inhibit automatic processing when necessary; they are the interesting exceptions to the rule, because the Stroop has been a reliable finding in psychological research for years.

**Perry, Campbell (1992). Theorizing about hypnosis in either/or terms. International Journal of Clinical and Experimental Hypnosis, 40, 238-252.**

The present paper addresses 3 issues raised by Coe (1992). First, it maintains that the "altered state" issue of the 1960s remains buried in current dichotomous classifications of hypnosis theories as involving either "special processes" or the social- psychological position. Given the current diversity of the field, it appears imprudent to classify theorizing in either/or terms; additionally, despite a history of using the term "altered state" in a circular way, it is not an inherently circular formulation. It can be used descriptively simply to point to the observation that some individuals in hypnosis report subjective alterations. A second issue broached concerns the metaphorical status of the term "hypnosis"; it is accepted as a misleading metaphor inherited from 19th century investigators such as Braid, Faria, Puysegur, and Liebeault. Provided that it is recognized that this metaphor refers to a "domain" (E. G. Hilgard, 1973) of characteristically elicited behaviors, no problem ensues in retaining this metaphor derived from nocturnal sleep. A subsequent discussion of current conceptualizations of hypnosis indicates considerable agreement among investigators; there is much consensus that hypnosis is an individual differences phenomenon, in which imagination may, in some individuals, become so intense and so vivid, as to take on "reality value," to the extent that a hypnotized person may have difficulty in distinguishing fantasy from reality. The S abilities of imagery/imagination, absorption, dissociation, and automaticity (which may be proved to be an index of dissociation) are proposed as being the main ingredients of the hypnotic experience. Finally, a synergistic approach is proposed as a means of progressing beyond the current impasse of either/or theorizing.

the main ingredients of the hypnotic experience. Finally, a synergistic approach is proposed as a means of progressing beyond the current impasse of either/or theorizing.

**Price, Simani M.; Crawford, Helen J.; Plantier, Mary E.; Jones, Elizabeth P. (1992, October). Sustained attention, selective attention, and automaticity: Relationships to**

**hypnotic responsiveness.** [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

There are four dimensions of attention: 1. focused & sustained attention 2. selective attention 3. divided or dual attention 4. ambient attention (the ability to attend to one thing but have floating attention also)

Ss had Harvard and Group Stanford scales of hypnotizability, to divide them into low, medium, and high groups. They were recruited for a study of attentional correlates with no mention of hypnosis, in order to reduce expectancy effects.

In this study, 57 Ss had two 45 second trials on the Stroop test; the higher scores mean less Stroop-type interference.

We studied the effects of distraction on ability to do mental arithmetic. (There were to ignore a word in the sum column.) Then Ss were tested for implicit memory of the words.

Necker Cube task was administered (to replicate Crawford & Wallace): four trials, 60 sec. each

Absorption Scale

Crawford & Gumbles scale

## **RESULTS.**

There were no differences on most of the tests for high, medium, and low groups. Hypnotizability correlated with extremely focused attentional ability as measured by the DAPI Extremely Focused Attention factor, and the Tellegen Absorption Scale. Moderately Focused Attention loaded on DAPI Moderate Focus. Necker Cube and Implicit Memory (for words) loaded on the Dual Ambient Attention factor.

Somerville, Wayne R.; Jupp, James J. (1992). Experimental evaluation of a brief 'ideodynamic' hypnotherapy applied to phobias. Contemporary Hypnosis, 9, 85-96.

This study used a test-retest design to investigate the effectiveness of a brief 'ideodynamic' hypnotherapy which notionally located and reformulated memories in the treatment of simple phobia disorder. Subjects were 19 phobics randomly assigned to treatment (n = 10) and waiting control groups (n = 9). Rapid, significant, and sustained relief from phobic fear and avoidance was reported by 50% of treatment subjects. A number of symptoms and therapy process variables were correlated with treatment outcome. These included a negative association with hypnotizability and a positive association with hypnotic depth estimates. The ramifications of these and other associations are discussed and it is concluded that the 'ideodynamic approach' investigated may have contributed a therapeutic effect beyond the operation of treatment non-specific factors.

Treatment consisted of: 1. Hypnotic induction. 2. Establishment of ideomotor signals described to clients as a means of communicating with the 'inner unconscious mind'. 3. Beyond the first therapy session, a review of work done in previous sessions. 4. Gaining signaled permission from clients to work on their problem and for the 'inner mind' to review relevant memories. 5. Location of the

'earliest critical event' by the 'inner mind'. 6. Review of the located memory by the 'inner mind'. 7. Establishing age at the occurrence of the 'critical' event. 8. Ideomotor signaling indicating suitability of a visual imagoic processing of the event.

If visual processing was chosen, the dissociated viewing procedure (step 9A) was used next, otherwise the ego-state procedure (step 9B) was employed.

The authors describe each treatment step in detail. Each subject received at least two sessions of therapy, or a maximum of three sessions if signaling indicated the presence of further unresolved memories after two sessions.

They present a case illustrating that the approach is possible with minimally hypnotizable subjects, in the apparent absence of imagoic experience, 'desensitization', catharsis, unpleasant affect, talking through or 'insight'.

"There was a positive correlation between changes in phobic fear and capacity for mental imagery which suggests that this may be one relevant variable in predicting response to memory reformulating therapy.

"There was a negative correlation between changes in fear and hypnotic responsiveness. So, successful therapeutic outcome was obviously not limited to highly hypnotizable subjects. Hypnotizability was assessed in a careful and standardized manner but testing was conducted 10 weeks following therapy. This meant that subjects had a substantial experience in hypnotherapy at assessment. Furthermore, at the time of assessment subjects were aware of the outcome of therapy and of the kinds of memories located during therapy. It has been suggested that an association between level of hypnotizedness achieved during treatment and outcome rather than an association between degree of hypnotizability possible during therapy and outcome, taps an hypnotic effect (Spiegel & Spiegel, 1978).

"All therapy sessions were of equal duration and, as the inductions were standardized, all subjects had an approximately equal opportunity to engage in memory reformulation. However, there were individual differences in the number of memories located and a strong significant association was found between reduced fear and the number of these critical memories that were dealt with. This result suggests that the therapeutic effect may have derived either from factors specific to the therapy cycle or from differing levels of motivation among subjects to undertake the necessary 'work'.

"Maximum discomfort experienced during session two of treatment was negatively correlated with relief from phobic fears. This relationship may again reflect the influence of unresolved problematic memories on subjects who had not achieved relief by that time. It is clearly consistent with relief not being associated with painful abreaction.

"The therapy permitted a pervading privacy through the options of non-imaginative processing of recalled material (which was used by a substantial minority of subjects) and conscious withholding of the content of memories from the therapist (which was employed to a large extent by all subjects). Their reports indicated that this 'privacy' was seen as attractive by both successfully and unsuccessfully treated subjects. Taken with other results mentioned above these process findings suggest that the treatment studied stood up quite well against other

brief but highly stressful exposure treatments for phobia currently in use (e.g. Ost, 1989).

"Further research needs to address the complex question as to what are the necessary and sufficient features of this procedure in producing therapeutic change. Unsolicited comments by subjects about their experience during treatment suggested that some of them were surprised by the 'involuntary' nature of their ideomotor signaling while others said that signaling was under their voluntary control. Some expressed surprise at the nature of the memories that came to them 'suddenly' during therapy. Some memories were of traumatic childhood experiences that were unexpected and considered to have 'nothing to do with my phobia'" (pp 93-94).

Bowers, Kenneth S. (1991). Dissociation in hypnosis and multiple personality disorder. International Journal of Clinical and Experimental Hypnosis, 39, 155-176.

The first part of this paper examines the concept of dissociation in the context of hypnosis. In particular, the neodissociative and social psychological models of hypnosis are compared. It is argued that the social psychological model, in describing hypnotic enactments as purposeful, does not adequately distinguish between behavior that is enacted "on purpose" and behavior that serves or achieves a purpose. 2 recent dissertations (Hughes, 1988; Miller, 1986) from the University of Waterloo are summarized, each of which supports the neodissociative view that hypnotic behavior can be purposeful (in the sense that the suggested state of affairs is achieved) and nonvolitional (in the sense that the suggested state of affairs is not achieved by high level executive initiative and ongoing effort). The second part of the paper employs a neodissociative view of hypnosis to help understand the current epidemic of multiple personality disorder (MPD). In particular, it is argued that many symptoms of MPD are implicitly suggested effects--particularly prone to occur in persons who have a lifelong tendency to use dissociative type defenses. The present author believes that this account is easier to sustain conceptually and empirically than the current view, which states that a secondary (tertiary, etc.) personality accounts for the striking phenomenological discontinuities experienced by MPD patients.

As an example of the fact that behavior that serves a purpose is not always performed on purpose, the author cites not falling out of bed while sleeping, and waking up in response to signals from the bladder to go to the bathroom. Lower levels of control can be dissociated from executive initiative and/or monitoring. "Since the experience of volition is closely tied to executive initiative and effort, suggested behaviors that bypass such initiative and effort are typically experienced as nonvolitional" (p. 157). Dissociated control occurs under waking conditions also, as when one dials a very familiar phone number rather than the one that they intended to dial. In this case, the behavior that is enacted is not what one consciously intended.

Miller's dissertation, also published as Miller & Bowers, 1986, is described on p. 158 ff. Without hypnosis, cold pressor pain (cold water immersion) reduced accuracy of performance on a multiple choice vocabulary test 35%. Both hypnotic analgesia and

cognitive pain management strategies were equally effective in reducing pain of cold pressor test (and both interventions were more effective for high than for low hypnotizable Ss). However, the cognitive strategy group showed an additional drop of 30% in vocabulary performance from pre- to posttreatment cold water immersion (despite successfully reducing their pain). In the hypnosis condition, lows showed only a slight additional decrease (8%) while highs showed a slight (10%) increase in their vocabulary performance from pre- to posttreatment immersion. Thus, the effect of hypnosis in pain control "does not depend on S's utilization of high-level cognitive strategies. Rather, hypnotic analgesia seems to involve the dissociated control of pain--that is, control which is relatively free of the need for high- level, executive initiative and effort. ... Because hypnotic analgesia minimizes the degree of executive initiative and ongoing effort required to reduce pain, however, it seems inappropriate to view such reductions as something achieved on purpose" (p. 161).

Hughes' dissertation is described on p. 162 and ff. Instead of performance decrement on a cognitive task like vocabulary testing, she used increased heart rate as an index of cognitive effort. If heart rate increases when Ss successfully use hypnotic imagery, that would confirm the social psychological view that "suggested effects are achieved by this kind of ongoing allocation of high-level cognitive force or work" (p. 162).

of high-level cognitive force or work" (p. 162).

Highs and lows were hypnotized and administered three trials of neutral and three trials of fearful imagery in counterbalanced order. Each imagery trial lasted 1 minute, after which Ss rated vividness of imagery, effort required, and amount of fear experienced.

Average imagery vividness was higher in highs than lows, for both neutral and fear imagery. For lows the correlation between heart rate increases and ratings of cognitive effort were .54 (neutral imagery) and .49 (fear imagery). For highs, the correlations were -.05 (neutral) and -.52 (fear). Thus, "for low but not high hypnotizable Ss, we find the predicted positive relationship between a cardiac indicator of cognitive effort and the ratings of cognitive effort involved in producing neutral imagery" (p. 163).

"First, for low hypnotizables engaged in fear imagery, ratings of effort are correlated .66 with ratings of fear. In other words, the more low hypnotizable Ss work to produce a fearful image, the more frightening the image is. Second, for high hypnotizables engaged in fear imagery, the correlation between ratings of fear and effort is minus .68-- indicating that the less effort highs report in producing fear imagery, the more frightened they become. Finally, for high hypnotizables, the correlation between ratings of fear and heart rate increase is .59, indicating that the more fear high hypnotizable Ss experience when engaged in fear imagery, the more their heart rate increases (the comparable figure for low hypnotizables is .16)" (p. 164).

The authors discuss why the pattern of correlations is different for people high and low in measured hypnotizability, and summarize the implications of both Miller's and Hughes' research. Both investigations indicate that, at least for high

hypnotizable people, less initiative and effort are required to effect a response to hypnotic suggestion than one would expect. They show how behavior can be both purposeful and nonvolitional (in the sense of not exhibiting conscious intention and strategic efforts). By noting that the sense of nonvolition that accompanies a response to suggestion is an actual alteration in executive control, they provide a model for dissociative psychopathology such as MPD. For although executive control is dissociated, these experiments do not suggest that there is a second executive system or 'personality' that is responsible for the behavior.

Patients diagnosed with MPD have very high measured hypnotizability (Bliss, 1984). In fact, they seem to engage in self hypnosis, withdrawing into a trance or a dissociated state (Bliss, 1984). The authors quote Wilson & Barber (1983) as indicating that highly hypnotized, fantasy-prone normal individuals may become so absorbed in a character being imagined that they lose awareness of their own identity.

The authors offer a neodissociative account of MPD: "People prone to MPD are very high in hypnotic ability and are, therefore, vulnerable to the suggestive impact of ideas, imaginings, and fantasies; what is more, they are high in hypnotic ability because they have learned to use dissociative defenses as a way of dealing with inescapable threat-- such as physical and sexual abuse (Kluft, 1987). ... Fantasied alternatives to reality (including a fantasied alter ego ... ) can become increasingly complex and differentiated. Gradually, these fantasied alternatives begin to activate subsystems of control more or less directly--that is, with minimal involvement of executive level initiative and control. Such 'dissociated control' of behavior does not necessarily eliminate consciousness of it, though one's actions are apt to be experienced as increasingly ego-alien. If and when the activating fantasies and resulting behaviors become sufficiently threatening, however, they can also be repressed into an unconscious (i.e., amnesic) status, thus further separating high-level executive and monitoring functions from the dissociated, ego-alien aspects of oneself. The fully realized result of this process is an individual who is subject to profound discontinuities in his or her sense of self. ... The experience of behaving in an outwardly uncharacteristic manner requires only that subsystems of control are more or less directly activated by ideas and fantasies in a manner that effectively bypasses executive initiative and control" (pp. 168-169).

923, Bowers, 1992 NOTES: Tart allegedly taught ESP skills based on reinforcement, using a machine that projected display and gave feedback immediately, so the subjects could learn to anticipate the picture better. But the picture presented next was time-linked to the S's response (so S could learn it).

1987 Behavioral and Brain Sciences review, with 2 target articles, makes one doubt strength of findings. ESP research doesn't distinguish between description of an observation and its proposed cause.

MPD shares with ESP a tendency to predispose toward a certain explanation. Feeling like one has a separate personality leads to finding evidence for one. But an MPD account is wrong-headed because the diagnosis misconstrues a notion of personality, which is a developmental concept (a pattern of thought, feeling, and behavior). Mischel's (1968) account of human functioning competed with trait theory, so "personality" concept became extraneous.

Defining personality in terms of one's experiences or beliefs about oneself has led to further problems, encouraged by the descriptive approach of DSM III (which depends on patient reports). Drew Weston distinguished between the self and self representation. One can't argue that a computer programmed to describe itself is the same as its descriptions.

Personality can't be reduced to person's beliefs about themselves. A secondary personality cannot be reduced to bizarre experiences a person believes are due to a second personality. Clinicians do not accept as valid the beliefs of a paranoid schizophrenic; or of an anxious neurotic. With multiple personality disorder (MPD) the patient becomes the expert and the clinician the student.

William Smith's 1986 SCEH paper: case study of patient who was convinced her problems were due to unresolved problems from a previous life. He didn't challenge her system but still worked with her successfully, communicating respect without validating her belief.

Advocates of MPDs think the observation that it is associated with high hypnotizability indicates great dissociation; critics think the association indicates great suggestibility. There is a historical parallel: Mesmer probably didn't suggest seizure-like episodes, but implicit suggestions for seizures were probably partially responsible. Mistaken attribution permitted Mesmer to see this as validation of his theory of animal magnetism.

Clinicians are not the only ones to "suggest" MPD syndrome. High profile cases are in the media. We should also remember Orne's 1959 research showing that students who received false information a week earlier in lecture on hypnosis showed the behavior when they were hypnotized.

Janet's disaggregation (dissociation) theory said hysterics and hypnotized people responded to ideas dissociated from the main stream of consciousness. So his contemporaries thought that spontaneous amnesia was a defining feature of hypnosis; yet it is not thought to be so in our era. The idea may have circulated in Janet's time, by popular culture.

MPDs are always highly suggestible so can respond to circulating accounts in the media, and every account that reaches the media can influence these people.

We could abandon the diagnosis of MPD in favor of Spiegel's "disorder of self integration." It is less provocative, does not imply any clinical benefit in the benefits of seeking out more personalities. This might reduce the incidence of this disorder, or likelihood that a suggestible person would develop the disorder iatrogenically.

1991

Brown, Jason W. (1991). Self and process: Brain states and the conscious present. New York: Springer-Verlag.

Author, from the Department of Neurology at New York University Medical School, presents a theory about the genetic unfolding of mental content (mind) through stages, from mental state into consciousness or into behavior. He relates the genesis of mind to brain development but avoids assuming that there is a straightforward correlation between brain development (e.g. myelination) and cognitive development or perception. To some degree, the theory is based on subjective report data and psychological symptoms. The author discusses issues that bear on the phenomena of nonvoluntary responding and dissociation that are reported or described by hypnotized persons.

"The nature of the mental state will determine the relation between self and world, and thus the interpretation given to agency and choice. ... The crossing of the boundary from self to world is a shift from one level in mind to another" (pp. 10-11).

"... if we begin with mind as primary and seek to explain objects from inner states and private experience, the discontinuity between inner and outer evaporates: mind is everywhere, a universe. ... Whereas before we thought to perceive objects, now we understand that we think them" (p. 19).

"The concept of a stratified cognition is central to the notion of a mental state .... This entails an unfolding from depth to surface, not from one surface to the next, a direction crucial to agency and the causal or decisional properties of consciousness" (p. 52). By unfolding from depth to surface, he means from Core, through Subconscious, then Conscious Private Events, and finally Extra-Personal Space.

He goes on to provide a definition of mental states. "A mental state is the minimal state of a mind, an absolute unit from the standpoint of its spatial and temporal structure. ... The state also has to include the prehistory of the organism. ... The concept of a mental state implies a fundamental unit that has gestalt-like properties, in that specific contents-- words, thoughts, percepts--appear in the context of mind as a whole (p. 53).

"The entire multitiered system arborizes like a tree, with levels in each component linked to corresponding levels in other components. For example, an early (e.g., limbic) state in language (e.g., word meaning) is linked to an early stage in action (e.g., drive, proximal motility) and perception (e.g., hallucination, personal memory) .... In sum, a description of the spatial and temporal features of a single unfolding series amounts to a description of the minimal unit of mind, the absolute mental state" (p. 54).

The author's discussion of an individual's physical movement relates to the concept of nonvoluntary movement (or movement without awareness of volition) in hypnosis. "More precisely, levels in the brain state constitute the action structure. As it unfolds, this structure generates the conviction that a self-initiated act has occurred. This structure--the action representation--does not elaborate content in consciousness. ... As with the sensory-perceptual interface, the transition to movement occurs across an abrupt boundary. In some manner, perhaps through a translation of cognitive rhythms in the action to kinetic patterns in the movement, levels in the emerging act discharge into motor (physical) events" (p. 57).

**"The self has the nature of a global image or early representation within which objects-to-be are embedded. ... The self is the accumulation of all the momentary cognitions developing in a brain configured by heredity and experience in a particular way (p. 70).**

**"The deposition of a holistic representation ... creates the deception of a self that stands behind and propagates events. The feeling of the self as an agent is reinforced by the forward thrust of the process and the deeper locus of the self in relation to surface objects. The self appears to be an instigator of acts and images when in fact it is given up in their formation. The self does not cause or initiate, it only anticipates (p. 70).**

**The foregoing notes cover only the first five chapters, less than half the book. Other chapters relevant to hypnosis would be those titled 'The Nature of Voluntary Action,' 'Psychology of Time Awareness,' 'From Will to Compassion,' and 'Mind and Brain.'**

**Dennett, Daniel C. (1991). Consciousness explained. Boston: Little, Brown & Co**

**Material in this book is relevant to discussions about 'nonvoluntary' behavior and (un)conscious experiencing. It combines information from cognitive neuroscience with the philosophy of mind. The author presents a view that consciousness (the 'mind') is the consequence of the brain's activities which give rise to illusions about their own properties. He presents the Multiple Drafts model of consciousness, which reformulates the concept of a 'stream of consciousness.' This provides a basis for consideration of concepts central to cognitive neuroscience and phenomena associated with hypnosis, e.g. experiential states and the nature of the self.**

**The author gives various examples of phenomenology and notes that although these examples are familiar to us, they are totally inaccessible to materialistic science; e.g. the way the sunset looks to someone. He treats people's descriptions of what they experience as a record of speech acts. Thus, observing and interpreting speech acts, inferring from them the speaker's inner states, is like a reader who is interpreting a work of fiction. He gives as examples of how one can scientifically study what does not 'exist' (a) literary theorists who describe fictional entities, (b) anthropologists who study cultural artifacts like gods and witches, and (c) physicists who study a center of gravity.**

In Dennett's theory, multitrack processes of interpretation of sensory inputs and elaboration of those inputs amounts to a kind of 'editorial revision' by the brain. For example in the phi phenomenon a red dot is displayed, followed by a green dot in a different location; the first spot seems to begin moving and then change color in the middle of its illusory passage toward the second location. He points out that awareness of the change in color must occur after seeing the green spot, but one consciously experiences a single spot first red, then red-turning-to-green, finally green. In an example that relates directly to the words used for his theory, he cites contemporary publishing practices, in which several different drafts of an article are in circulation even while the author is revising it. Deciding on some specific moment of brain processing as the moment of consciousness is arbitrary, according to his Multiple Drafts model.

"Visual stimuli evoke trains of events in the cortex that gradually yield discriminations of greater and greater specificity. At different times and different places, various 'decisions' or 'judgments' are made; more literally, parts of the brain are caused to go into states that discriminate different features, e.g., first mere onset of stimulus, then location, then shape, later color (in a different pathway), later still (apparent) motion, and eventually object recognition. These localized discriminative states transmit effects to other places, contributing to further discriminations, and so forth. The natural but naive question to ask is: 'Where does it all come together'? The answer is: Nowhere. Some of these distributed contentful states soon die out, leaving no further traces. Others do leave traces, on subsequent verbal reports of experience and memory, on 'semantic readiness' and other varieties of perceptual set, on emotional state, behavioral proclivities, and so forth. Some of these effects--for instance, influences on subsequent verbal reports--are at least symptomatic of consciousness. But there is no one place in the brain through which all these causal trains must pass in order to deposit their content 'in consciousness'" (pp. 134-135).

The author describes the evolution of the brain, along Darwinian lines, and introduces the idea of culture as a repository and transmission medium for innovations (including innovations of consciousness) as a medium of evolution. Through learning, we humans evolve an American or a Japanese brain. Once we have evolved the 'entrance and exit pathways' for language, they become 'parasitized' by memes (entities that have evolved to thrive in such a niche).

Richard Dawkins coined the term memes to describe the smallest idea elements that replicate themselves reliably (e.g. wheel, alphabet, wearing clothes, right triangle). "The transformation of a human brain by infestations of memes is a major alteration in the competence of that organ" (p. 209).

on 'semantic readiness' and other varieties of perceptual set, on emotional state, behavioral proclivities, and so forth. Some of these effects--for instance, influences on subsequent verbal reports--are at least symptomatic of consciousness. But there is no one place in the brain through which all these causal trains must pass in order to deposit their content 'in consciousness'" (pp. 134-135).

The author describes the evolution of the brain, along Darwinian lines, and introduces the idea of culture as a repository and transmission medium for innovations (including innovations of consciousness) as a medium of evolution. Through learning, we humans evolve an American or a Japanese brain. Once we

have evolved the 'entrance and exit pathways' for language, they become 'parasitized' by memes (entities that have evolved to thrive in such a niche).

Richard Dawkins coined the term memes to describe the smallest idea elements that replicate themselves reliably (e.g. wheel, alphabet, wearing clothes, right triangle). "The transformation of a human brain by infestations of memes is a major alteration in the competence of that organ" (p. 209).

Dennett discusses the similarities and dissimilarities of brains and computers. He suggests that human minds are like serial virtual machines implemented on parallel processing hardware. The stream of consciousness results from our rehearsal of brief experiences, to commit them to memory; language then permits us to describe to ourselves the process of thinking which leads to judgement and action.

The author's discussion of how a verbal expression evolves and becomes manifest is related to how so-called intentional action occurs. [This relates to discussions of nonvoluntary actions in hypnosis.] We assume that because our actions make sense, they are the product of serial reasoning. However, there are multiple channels "in which specialist circuits try, in parallel pandemoniums, to do their various things ... (pp. 253- 254). Bernard Baars has suggested "that consciousness is accomplished by a 'distributed society of specialists that is equipped with a working memory, called a global workspace, whose contents can be broadcast to the system as a whole (p. 42)'" (p. 257). Dennett states that there is no line dividing the events that are definitely in consciousness from those that are outside consciousness. He urges scientists to forgo the concept of the 'inner observer' implied by Cartesian materialism.

Examples of perception that is unaccompanied by consciousness include blindsight (in which the subject does better than chance on visual tests but denies consciousness, and the denials are given credence by neurological evidence of brain damage) and hysterical blindness, which is given less credence because subjects often use the visually provided information in ways blindsight Ss do not. Other behaviors not controlled by conscious thought include blinking when things approach the eye, walking without falling over, regulating our body temperature, adjusting our metabolism, etc. "If I am trying to see a bird that I hear, and stare at the spot but do not distinguish the bird from its background, can I say that it is present in the background of my (visual) consciousness or not?" (p. 336).

The author maintains that if an event doesn't linger and the person is unable to identify and reidentify the effect, it cannot be reported. But such reportability can be improved, as with training the palate of wine tasters. Often, however, we continue disregarding stimuli that impinge on us. There are minor oversights, such as our 'blind spots' or proof reading errors, and major oversights such as a brain-damaged patient's hemi-neglect. In the Multiple Drafts theory, the Observer is replaced by 'coalitions of specialists' that are distributed around in the brain, distributed in both time and space.

Though discrimination or discernment happens, there is no one Discerner doing the work. However, Dennett takes the middle ground on the question of whether a self exists: it is simply a creation like the nest of the Bower bird, or the organized colony of termite ants. "So wonderful is the organization of a termite colony that it seemed to some observers that each termite colony had to have a soul (Marais, 1937). We

now understand that its organization is simply the result of a million semi-independent little agents, each itself an automaton, doing its thing. So wonderful is the organization of a human self that to many observers it has seemed that each human being had a soul, too: a benevolent Dictator ruling from Headquarters" (p. 416). The sense of self is a creation, like a physicist's center of gravity.

Thus, multiple personality disorder is viewed as a self that has gaps; and our sense of self might include different aspects from one year to the other. Hence, "selves are not independently existing soul-pearls, but artifacts of the social processes that create us, and, like other such artifacts, subject to sudden shifts in status. The only 'momentum' that accrues to the trajectory of a self, or a club, is the stability imparted to it by the web of beliefs that constitute it, and when those beliefs lapse, it lapses, either permanently or temporarily" (p. 423).

Finally, the author has an extensive discussion of the concepts of 'qualia' and of 'epiphenomena' and seems to have little use for either term in trying to understand Mind.

-ever, Dennett takes the middle ground on the question of whether a self exists: it is simply a creation like the nest of the Bower bird, or the organized colony of termite ants. "So wonderful is the organization of a termite colony that it seemed to some observers that each termite colony had to have a soul (Marais, 1937). We now understand that its organization is simply the result of a million semi-independent little agents, each itself an automaton, doing its thing. So wonderful is the organization of a human self that to many observers it has seemed that each human being had a soul, too: a benevolent Dictator ruling from Headquarters" (p. 416). The sense of self is a creation, like a physicist's center of gravity.

Thus, multiple personality disorder is viewed as a self that has gaps; and our sense of self might include different aspects from one year to the other. Hence, "selves are not independently existing soul-pearls, but artifacts of the social processes that create us, and, like other such artifacts, subject to sudden shifts in status. The only 'momentum' that accrues to the trajectory of a self, or a club, is the stability imparted to it by the web of beliefs that constitute it, and when those beliefs lapse, it lapses, either permanently or temporarily" (p. 423).

Finally, the author has an extensive discussion of the concepts of 'qualia' and of 'epiphenomena' and seems to have little use for either term in trying to understand Mind.

Gibson, H. B. (1991). Can hypnosis compel people to commit harmful, immoral and criminal acts?: A review of the literature. Contemporary Hypnosis, 8, 129-140.

The literature relating to whether hypnosis can be used to compel people to perform acts that are dangerous, immoral or criminal is reviewed, some evidence over the past 200 years being discussed. Relevant real-life instances are cited as well as the laboratory studies of the twentieth century. Detailed criticisms of the latter are made, and it is shown that although no really conclusive findings have emerged, such research has strongly implied that hypnosis does not increase compliance. Four past criminal trials concerned with alleged rape and sexual assault are cited. It is concluded that whilst hypnosis may be one among a number of techniques used in

sexual seduction, it is not reasonable to claim that rape has ever been effected by means of hypnosis alone.

Lynn, Steven Jay; Weekes, J. R.; Neufeld, U.; Ziuney, O.; Brentar, J.; Weiss, F. (1991). Interpersonal climate and hypnotizability level: Effects of hypnotic performance, rapport, and archaic involvement. Journal of Personality and Social Psychology, 60, 737-743.

Designed to extend research by McConkey and Sheehan, they tested 24 hypnotizable and 21 unhypnotizable Ss in high interpersonal/high rapport (including education about misconceptions about hypnosis, eye contact, and friendly self-disclosure) and low interpersonal/low rapport testing contexts. Overall, hypnotizable Ss were more responsive to hypnosis, rated the hypnotist more positively, and experienced greater involuntariness and archaic involvement than unhypnotizable subjects. However, results provide support for the hypothesis that low hypnotizable Ss are particularly sensitive to variations of the hypnotist's interpersonal behavior. Only low hypnotizable Ss' objective and subjective hypnotic performance on the SHSS, Form C, was enhanced by hypnotist behavior designed to optimize rapport. Hypnotizable Ss' behavior was stable across testing contexts.

Madrid, Antonio D.; Barnes, Susan v.d.H. (1991). A hypnotic protocol for eliciting physical changes through suggestions of biochemical responses. American Journal of Clinical Hypnosis, 122-128.

We employed brief hypnotherapy to effect physical changes in patients suffering from medical disorders including allergies, rectal bleeding, systemic lupus, hyperemesis, headache, asthma, and chronic pain. We present, in language appropriate to the individual patient, considerations and suggestions to effect the release of healing biochemicals. Ideomotor signals indicated the patient's awareness of the healing. We hypothesize that the technique triggered novel state-dependent memory, learning, and behavior.

They hypothesize that the technique they use triggers novel state-dependent memory, learning, and behavior (See for example Rossi, 1987, and Rossi & Cheek, 1988).

Hypnotic Protocol: "1. Tell the patient that he can heal himself by allowing his body to supply its own biochemicals needed to make him well. If a specific biochemical is known, such as cortisone or endorphins, name it. "2. Hypnotize the patient. Resistant or hard to hypnotize patients need not be deeply hypnotized because the patients, using this protocol, will automatically go into trance while accomplishing the next task of accessing and using ideomotor signals (Erickson, 1980; Rossi & Cheek, 1988). "3. Tell the patient that his index finger will automatically and involuntarily twitch and float when his body releases the biochemicals he needs. This ideomotor response (Rossi & Cheek, 1988) is the sole physical response required of the patient. Rossi hypothesizes that the ideomotor response correlates

with biochemical changes (Rossi & Cheek, 1988). "4. Next, ask the patient to consider some things (as described below). Present the considerations one after another until one of them triggers the ideomotor response. "5. In some instances, ask the patient to practice on his own. Many patients who have dramatic emotional reactions during or at the completion of the task may not need to practice on their own" (p. 123).

They present several 'considerations' to the patient, one after the other, tailored to the patient's specific case, until his finger twitches or floats, indicating a biochemical response. For example, the following 'considerations' have been used: "1. Psychodynamic: 'Consider that you are not blamed for anything; that you are in fact perfect just the way you are; that you are loved by those you care about.' 'Consider that you can forgive whoever needs forgiving for hurting you.' 'Consider that there are no longer any threats; everything is better; everything is as it used to be.' "2. Autosuggestion: 'Tell your body to heal. It knows what to do; so ask it to do it.' 'Tell your adrenal glands to produce the steroids that your body needs.' 'Allow a glowing light to permeate that injured back, filling it with healing energy.' "3. Incompatible responses: 'Cover yourself with a cool breeze, cooling the injured leg.' 'Imagine your back getting slack and limp and relaxed.' 'Imagine your stomach lining becoming smooth and moving with easy, ocean-like waves.' "4. Emotion calling: 'Consider yourself feeling very happy with everything, for no reason at all.' 'Consider yourself getting angry at someone--your mother, your wife (husband), your boss, your lawyer.' "5. Bargaining: 'Tell yourself that you will heal if you agree to stay away from that job.' 'Tell yourself you will heal by allowing your right arm to begin to hurt when you are over- exerting yourself.' 'Tell yourself that you will heal in exchange for something else, not so serious, to replace this disease and to serve the same function'" (pp. 123-124).

are over- exerting yourself.' 'Tell yourself that you will heal in exchange for something else, not so serious, to replace this disease and to serve the same function'" (pp. 123-124).

They present seven cases involving, respectively, allergies, rectal bleeding, systemic lupus, hyperemesis of pregnancy, adult onset asthma, chronic pain, and cluster headaches. Two cases were particularly interesting because they represented patients who did not respond initially.

Their procedure involves reframing the state or emotion originally associated with the onset of disease using considerations, and then giving a suggestion that it is within the power of the person, rather than factors outside, to heal the body. First they instruct the patient that the body can heal itself; then they give the list of suggestions for the patient to consider, persisting with different considerations until they get an ideomotor response. Incorporation of the patient's psychodynamic issues appears to be very important.

The authors regard it as unimportant if the patient cannot be hypnotized; "As Cheek (Cheek & LeCron, 1968; Rossi & Cheek, 1988) points out, the patient's inability to be hypnotized may be synonymous with his disease. It is actually beneficial if the patient cannot achieve ideomotor responses at first because both he

and the therapist then trust the validity of the response when it does occur after the appropriate consideration" (p. 127).

Pekala, Ronald J. (1991). Hypnotic types: Evidence from a cluster analysis of phenomenal experience. Contemporary Hypnosis, 8, 95-104.

The phenomenological experiences of very-low and very-high, and low, medium and high susceptible individuals were cluster analyzed, attempting to determine if individuals of differing levels of hypnotic susceptibility report experiencing different types of phenomenological experience during hypnosis. Phenomenological experience was assessed by means of a self-report questionnaire called the Phenomenology of Consciousness Inventory (PCI); it allows for quantification of 12 dimensions of phenomenological experience. K-means cluster analysis yielded two relatively distinct clusters of individuals for both low/very-low and high/very-high susceptible individuals. These results suggest at least two types of very-low/low and very-high/high susceptible individuals as determined by their reported experiences during hypnosis.

The author notes that Sheehan and McConkey (1982) found three types of highs: concentrative, independent, and constructive. Spanos, Lush & Gwynn, 1989, found two groups of lows--one capable of learning hypnotic skills and the other less so.

In this study the author did two cluster analyses: (1) Harvard lows (0-1) and highs (11-12), and (2) all subjects divided into lows, mediums and highs, with cluster analyses performed separately for these three groups.

In the first analysis, there were two groups of very low hypnotizable subjects distinguished on the basis of altered state of awareness and rationality; and two very high groups, distinguished on the basis of imagery and positive affect.

One group of very lows reported "little alteration in altered state and altered experience and almost complete volitional control, self-awareness, rationality and memory" (p. 98)

and were called 'classic very lows' because they were like refractory subjects in their self reports. The other group of very lows reported "moderate alterations in altered state and altered experience, and major decrements in volitional control, self-awareness, rationality and memory" (p. 98) and were called 'pseudo very lows' because their reports were a little like medium or high hypnotizables.

One group of very high hypnotizables had "great alterations in state of consciousness and moderate altered experiences; a loss of control, self awareness, rationality and memory; and little vivid imagery" (p. 98) and were called 'classic very highs' because their reported experience was like that of somnambules. The other type of highs were called 'fantasy very highs' because they had "moderate alteration in consciousness and experience, a great deal of vivid imagery, moderate positive affect, and only mild-to-moderate losses in rationality and memory" (p. 100).

When low, medium, and high susceptible subjects' PCIs had separate cluster analyses, the lows had three clusters: classic, dialoging, and pseudo lows. The dialoging group was between the other two in their experiencing yet reported a

great deal of internal dialogue. Among the highs, the same two clusters appeared as for the very highs.

Among the mediums there were two groups: high mediums who reported a significant drop in volitional control, self-awareness, rationality, memory, and internal dialogue, and an alteration in state of awareness; and low mediums who had milder changes.

Comparing results to Sheehan and McConkey (1982), the classic highs may correspond to their concentrative type and the fantasy highs to their independent type, because the latter generated imagery without a request to do so.

Regarding the pseudo-lows, "it is intriguing that there appear to be some individuals who make little response on the behaviorally oriented Harvard Scale, and yet report some phenomenological alterations. Are they individuals for whom hypnosis may be somewhat more effective even though they are not that hypnotizable (as measured by the 'direct' Harvard Scale) or could they be Spanos's (Spanos et al., 1989) 'trainable' low susceptibles?" (p. 102).

Wagstaff, Graham F. (1991). Hypnosis and harmful and antisocial acts: Some theoretical and empirical issues. Contemporary Hypnosis, 8, 141-146.

The author analyses paper in same issue of this journal: Gibson, H. B. (1991). Can hypnosis compel people to commit harmful, immoral and criminal acts?: A review of the literature. He presents a critique from the point of view of "state" theorists, and concludes: "Where does this leave us? The area seems to be a potential minefield for any unsuspecting dissociationist. Personally, I think that both parsimony, and what empirical evidence there is, point to a non-state approach to this issue. However, despite the inevitable uncertainties and differences of opinion, there is perhaps a very obvious and important lesson to be gained by all from studies in this area. It has been fashionable to write off experimental studies on this topic on the grounds that subjects in these studies generally perceive the situation as 'safe'; this is not only the case in hypnosis research but also in general social-psychological work on obedience (see, for example, Orne & Holland, 1968; Mixon, 1974). Some have questioned this assumption that subjects only obey the experimenter when they perceive the situation to be safe (see Barber, 1969; Milgram, 1974), but what often goes unnoticed is the significance of this assumption in itself. If labeling a situation as 'hypnosis', or even just an 'experiment', can make subjects think that any apparently harmful act they are requested to perform is safe, think of the implications; here, in itself, is a potentially powerful, even lethal, mechanism by which people in hypnotic contexts may be induced to perform harmful and antisocial acts. They perform them because, given the context, they think it is safe to do so! In the study of Orne and Evans the venomous snake the subjects were instructed to grasp was placed behind an 'invisible' glass screen, and the acid they were instructed to throw at the experimenter had been, allegedly unknown to them, replaced by a harmless liquid; one wonders, however, if writers would be so dismissive if the liquid that Orne and Evans' subjects threw at the experimenter had actually burned him, or the snake that they picked up had actually killed them" (pp. 144-45).

induced to perform harmful and antisocial acts. They perform them because, given the context, they think it is safe to do so! In the study of Orne and Evans the venomous snake the subjects were instructed to grasp was placed behind an 'invisible' glass screen, and the acid they were instructed to throw at the experimenter had been, allegedly unknown to them, replaced by a harmless liquid; one wonders, however, if writers would be so dismissive if the liquid that Orne and Evans' subjects threw at the experimenter had actually burned him, or the snake that they picked up had actually killed them" (pp. 144-45).

1990

Bartis, Scott P.; Zamansky, Harold S. (1990). Cognitive strategies in hypnosis: Toward resolving the hypnotic conflict. International Journal of Clinical and Experimental Hypnosis, 38, 168-182.

Two experiments were carried out to assess the relative contributions of dissociation and absorption as cognitive strategies employed by high and low hypnotizability Ss in responding successfully to hypnotic suggestions. Of special interest was the manner in which Ss deal with conflicting information typically inherent in hypnotic suggestions. In the first experiment, Ss rated their attentional focus and the involuntariness of their experience after responding to a number of hypnotic suggestions administered in the usual manner. In the second experiment, the level of conflict was varied by instructing some Ss to imagine a circumstance that was congruent and other Ss to imagine a circumstance that was incongruent with the suggested behavioral response. The results of the 2 experiments were consistent in suggesting that, depending upon the nature of the hypnotic suggestion, high hypnotizability Ss are able to employ dissociation or absorption in order to respond successfully. Low hypnotizability Ss, on the other hand, seem to be relatively ineffective dissociators. When the structure of the hypnotic suggestion precludes the use of absorption, the performance of low hypnotizables deteriorates.

Coe, William C. (1990). Are the Conclusions Valid? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 237-239.

The authors confounded variables, e.g. hypnotic susceptibility and monetary incentive (in Study IV), and Study IV was different from the other 3 studies, so that any differences/similarities between these studies can't be attributed to susceptibility level, degree of incentive, or interaction between them.

A simulator design would clarify why 50% of Ss in Study IV did not resist and lost \$100; also, postexperimental interviews focusing on Ss' reasons for resisting or not resisting would be helpful. Did nonresisters actually believe that they would receive \$100 for resisting?

The Subject population was not homogeneous in occupation, and students are financially poorer than others--which would affect incentive strength. Were those who resisted the ones who could use the money the most?

Small sample sizes obviating statistical tests is a problem. Coe nevertheless evaluates 4 variables in terms of the 'power' of their effects on hypnosis: 1. Susceptibility level. Studies I, II, and III all show correlations between hypnotizability and compliance with resistance, suggesting that high hypnotizables are not as susceptible to resistance manipulation; however across studies, highs in one study seem to comply at the same rate as lows in another study, and as many as 50% of high hypnotizables in the strong incentive (\$100) study were able to resist suggestions. 2. View of the Hypnotist. Coe states that -gestions. 2. View of the Hypnotist. Coe states that one can't evaluate the question with the data given. One would need an experimental condition that would also create a negative view of the hypnotist, as all samples tended to view the hypnotist positively. 3. View of Resistance Instructor. Again, one would need a research design that separates the effects of hypnotic susceptibility from effects of Ss' views of the resistance instructor. "Nevertheless, Study IV suggests that for high susceptibles the view of the resistance instructor has little effect. Three resisters viewed him as positive, whereas the other three viewed him as negative; further, nearly all of the nonresisters viewed him as neutral" (p. 238). 4. Degree of Incentive. This too was confounded with susceptibility level, as "the higher value was only offered to the very high susceptibles in study IV. Half of them took it, half did not" (pp. 238-239). Coe also remarks that "the expectational effects on subjects of being in an experiment have not been addressed adequately. It is possible that the experimental paradigm as currently presented is incapable of providing an unambiguous answer to the question of coercion. In naturalistic settings subjects may react quite differently than they do when they know they are participating in an experiment" (p. 239).

Dixon, Mike; Brunet, Alain; Laurence, Jean-Roch (1990). Hypnotizability and automaticity: Toward a parallel distributed processing model of hypnotic responding. Journal of Abnormal Psychology, 99, 336-343.

Tested a hypothesis from parallel distributed processing theory that highly hypnotizable Subjects have greater connection strengths along verbal pathways and would show greater Stroop effects than low hypnotizability Subjects. Using the paradigm from J. Cheesman and P. M. Merikle (see PA, Vol 76:3722) which varied cue visibility and probability, automatic and strategic effects on Stroop performance were assessed. Compared with 9 low and 9 moderately hypnotizable Subjects, 9 highly hypnotizable ones showed significantly greater Stroop effects for both visible- and degraded-word trials. No strategic differences emerged for the 3 hypnotizability groups. These findings support the contention that highly hypnotizable persons have stronger verbal connection strengths than their moderately and low susceptible counterparts, and they may account for highly hypnotizable persons' propensity to disregard personal attributions and label their responses in hypnosis as being involuntary.

Holroyd, Jean (1990). How hypnosis may potentiate psychotherapy. In Fass, Margot L.; Brown, Daniel (Ed.), Creative mastery in hypnosis and hypnoanalysis (pp. 125-130). Hillsdale, NJ: Lawrence Erlbaum Associates

This chapter is a reprint of an article published in the *American Journal of Clinical Hypnosis* in 1987. It provides a conceptual framework for understanding psychotherapy processes in the context of a hypnotic state. Based on empirical and theoretical considerations, the author identified nine changes occurring with hypnosis: changes in attention and awareness, imagery, dissociation, reality orientation, suggestibility, mind-body interactions, initiative or volition, availability of affect, and relationship. "This chapter proposes that hypnotherapy exploits hypnotic phenomena-- takes advantage of them--in the service of standard therapy endeavors" (p. 125).

Levitt, Eugene E.; Baker, Elgan L., Jr.; Fish, Ronald C. (1990). Some conditions of compliance and resistance among hypnotic subjects. *American Journal of Clinical Hypnosis*, 32 (4), 225-236.

Five experimental approaches to the resolution of the century-old Bernheim/Janet dispute and the issue of involuntariness or coercion (the classical suggestion effect) are presented. Four experiments are reported that follow one of the approaches: attempts to induce hypnotic subjects to resist suggestions made in trance. The design is one in which a "resistance instructor" proposes a reward for the resisting subject. Tentative inferences from the results are that the classical suggestion effect is found with a small number of subjects; for a larger number of subjects there is no classical suggestion effect, and for many subjects the outcome is equivocal. Relational factors in the hypnotic dyad influence responsiveness in the subject, the effect being least for those whose susceptibility is high.

Study I. Used a \$5 bribe, two suggestions, and Ss resisted average of 1.2 suggestions. 9 Ss resisted both, 5 resisted neither, and 6 (30% of Ss) resisted one test suggestion. Resistance appeared to be related to impression of the resistance instructor, suggesting that "neither the monetary bribe nor hypnotic responsiveness was as important to the resistance/compliance dimension as relational factors" (p. 228).

Study II. Used only one suggestion, obtained quantitative ratings of the two instructors, and offered \$10 to resist one suggestion. 19/40 Ss (48%) resisted. The authors wondered whether the difference in impressions of hypnotist and resistance instructor might be due to very limited contact with the latter.

Study III. Ss were greeted by the resistance instructor, who accompanied Ss to the experimental room, discussed the information under 'Establishing Rapport Prior to the Initial Induction' in the SHSS:A and a condensed version of the introduction to the Eye Closure item (10 minutes). Then he left, the hypnotist entered and administered the same 9-item SHSS:A that had been employed in Studies I and II. The resistance instructor then entered and offered \$10 if the S could successfully resist the hypnotist's suggestion on the second try [of an item just passed successfully]. The hypnotist re-entered, repeated SHSS:A instructions for the

selected item, brought S out of hypnosis, and then a different experimenter did a structured interview--to give impressions of the hypnotist and the resistance instructor on an Adjective Rating Form (ARF), to estimate depth of their trance on 0-8 scale before and after contact by the resistance instructor. Then S was paid if he/she had resisted. The resisters obtained a mean on the SHSS:A of 4.8 compared to 7.9 for the nonresisters, significant t-test for the difference (p<.01).

**Table 1 A Comparison of Interview Ratings of Hypnotists and Resistance Instructors in Two Studies**

**Hypnotist\* Resistance Instructors\*\* Study N Pos Neutral Neg Pos Neutral Neg II 39 69% 31% 0% 5% 72% 23% III 30 63% 20% 17% 43% 27% 30%**

**Chi square (2) = 7.71, p <.05 \*\* Chi square (2) = 24.3, p <.001 [N.B. Figures were rounded to nearest whole number by JH.]**

**The correlation between hypnotizability on the SHSS and Resistance may be found in Table 2, along with the percentage of nonresisters in each of the four studies.**

**Table 2**

**Correlation SHSS Percent Study N R-NR/SHSS Mean Nonresisters I 20 -.37\* 7.1 40 II 40 -.44 6.2 52 III 30 -.54 5.8 33 IV 12 -- 8.8 50**

**6.2 52 III 30 -.54 5.8 33 IV 12 -- 8.8 50**

**\* Not significant**

**In Table 1 it may be seen that perceptions of the hypnotist and the resistance instructor changed from Study II to Study III. "In summary, the manipulation of time spent in the second experiment increased the proportion of resisters and dramatically improved the impression of the resistance instructor. Nevertheless, the evidence suggests that the hypnotist continued to be perceived positively and, according to our best measure, was still perceived more positively than the resistance instructor" (p. 232).**

**Because they suspected that the impressions of the experimenters might be confounded by hypnotic susceptibility, and \$10 might not be enough reward for behavior shaping, the experimenters designed Study IV. Study IV used 12 high hypnotizables (scoring 11 or 12 on Harvard Scale; with a group mean of 8.8 on a 9-item version of the SHSS:A). The same procedure as in Study II was carried out, except that four experimenters other than the authors were the hypnotists and resistance instructors; each experimenter worked with three subjects. The incentive was \$100 to resist.**

**The results of this procedure were that six Subjects resisted and six complied; each group scored 8.8 on the SHSS:A 9-item scale; resisters had 5.7 mean and nonresisters 5.1 mean depth (nonsignificant).**

**Resisters and compliers were exactly alike in their perceptions of the hypnotist, but appeared different in perception of the resistance instructor (and the N was too small to test statistically).**

**\*Lower score is more favorable.**

**Summary of the Four Studies:**

**The data in Tables 2-5 reflect a critical finding. "There was a sharp drop in the number of Ss who did not resist, or it may be clearer to put it as a sharp increase in the number of resisters. The change is nearly 40%.**

**"However, when only responsive subjects were used as in Study IV, the percentage of nonresisters is much the same as it was in Study II" (p. 233). The authors conclude that "relational factors are more important in hypnotic behavior among less responsive subjects" (p. 233).**

**"The data contrasting resisters and nonresisters are somewhat confusing. There were more positive and negative impressions among subjects who resisted and more neutral impressions and no negative impressions among the nonresisters," (pp. 233-234) though the number of cases involved is quite small. Using the ratings, the nonresisters had a more favorable impression of the hypnotist than did the resisters, which is in accord with the interviewers' ratings.**

**"A striking finding is that nonresister Ss in Study IV had a less favorable impression of both hypnotist and resistance instructor ... a clear reversal from Study III for the hypnotist, not quite so clear for the resistance instructor" (p.234).**

**so clear for the resistance instructor" (p.234).**

**Levitt, Baker, & Fish draw the following inferences: "1. Hypnotic influence is truly coercive for a very small number of what Register & Kihlstrom (1986) have called the 'hypnotic virtuoso,' the most responsive individuals; for them, the classical suggestion effect is a reality; 2. Hypnotic influence, though perhaps not truly coercive, is manifestly strong for a somewhat larger group of highly responsive individuals; the classical suggestion effect may exist for them; 3. For many individuals who behave in accordance with hypnotic suggestions, the classical suggestion effect does not exist; 4. Relational factors in the hypnotic dyad influence hypnotic responsiveness. The influence is strongest among individuals of low-to-moderate hypnotic responsiveness; 5. The more positive the impression of the hypnotist, the greater will be his influence on the hypnotized individual; 6. A subject's impression of a hypnotist will tend to be favorable even though the sole interaction between the two is the induction of the trance; 7. Preliminary efforts to build rapport with the subject will tend to improve the already positive impression created by the hypnotist" (pp. 234-235).**

**Levitt, Eugene E.; Baker, Elgan L., Jr.; Fish, Ronald C. (1990). Some conditions of compliance and resistance among hypnotic subjects: A rejoinder to invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 246-249.**

"We cannot see how Lynn can allege that in three of the studies there was no relationship between resistance-nonresistance and perception of the hypnotist. The appropriate correlation coefficients are reported in Studies II and III.

"Coe's point about the confounding of incentive and susceptibility might be valid if we had no prior knowledge of the relationship between resistance and susceptibility. But we already knew that the most susceptible Ss were likely to be the nonresisters. In Study IV, we abandoned susceptibility as an independent variable and made it a sample descriptor. ... [However] we resonate to Coe's suggestion of simulators" (p. 247).

"In our first three studies, we reported no relationship between occupation and resistance, an admittedly crude but unobtrusive approach to the question of whether the most financially needy subjects were the resisters. We usually compared the students in the sample with the employed subjects. We did not report this lack of relationship in Study IV in which only three subjects were students. Two resisted, one did not.

We must accept responsibility for provoking Coe's question about the credibility of the financial incentive in Study IV, by poor reporting. In a postexperimental inquiry, one subject (a resister) was mildly suspicious of the offer. All other Ss found the resistance instructor credible" (pp. 247-248).

"Our own more recent research suggests that offering undergraduate students additional points toward the final class grade can yield more resisters than the money incentive in Study IV (Levitt, Baker, Hacker, Klion, Krause, Lytle, & Vanderwater- Piercy, 1990 in press)" (p. 248).

"We have suggested that the hypnotic phenomenon is apparently experienced differently among subjects, and the critical factors are thus also likely to vary from subject to subject. We would be quite willing to accept Bernheim's estimate that 17% are incapable of resisting hypnotic suggestions, as cited by Weitzenhoffer.

We agree with Spiegel that the issue of the coercive potential of hypnosis is 'not really settled by mean differences across groups.' Measures of central tendency are apt to obscure the minority of Ss who may experience coercion in experiments with designs different from ours" (p. 248).

[The study referred to above is Levitt, E. E., Baker, E. L., Hacker, T., Klion, R., Krause, A. A., Lytle, R., & Vanderwater-Piercy, J. (1990 in press). Compliance and resistance in the hypnotic state: the effect of a social or an academic countermotivation. In R. van Dyck, P. Spinhoven, . J. W. van der Does, Y. R. van Rood, & W. De Moor (Eds.), *Hypnosis: Current theory, research, and practice.* Amsterdam: Free University Press.]

Lynn, Steven Jay (1990). Is hypnotic influence coercive? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. *American Journal of Clinical Hypnosis*, 32 (4), 239-241.

Unlike Levitt, Baker, & Fish (1990), Lynn, Rhue, & Weekes (Psychological Review, 1990 in press) concluded that nonvoluntary behaviors in hypnosis are similar to

other spontaneous social behaviors (like conversational response to social stimuli). "Hypnotized subjects, like nonhypnotized subjects, act in terms of their aims, according to their point of view, and in relation to their interpretation of appropriate behavior and feelings" (p. 239).

"Research shows that hypnotizable subjects resist and even oppose suggestions as a function of their expectancies and perceptions about appropriate hypnotic behavior (Lynn, Nash, Rhue, Frauman, & Sweeney, 1984; Lynn, Snodgrass, Rhue, & Hardaway, 1987; Lynn, Weekes, Snodgrass, Abrams, Weiss, & Rhue, 1986; Spanos, Cobb, & Gorassini, 1985). In one study (Spanos et al., 1985), when subjects were informed that deeply hypnotized subjects were capable of becoming involved in suggestions and simultaneously resisting them, subjects resisted 95% of the suggestions. When subjects were told that deeply hypnotized subjects were incapable of resisting suggestions, they passed the majority of suggestions. Thus, knowledge about what constitutes appropriate hypnotic role behavior is a reliable determinant of resistance, apparently more reliable than the monetary lures used by Levitt et al." (P. 240).

These studies by Levitt et al. only used behavioral measures of resistance and hypnotizability, and Ss' perceptions of the resistance instructor and hypnotist. "The ratings of global perceptions are, however, no substitute for measures of subjects' perception of the \_relationship\_. ... The failure to measure important variables relevant to the central dimensions of concern--coercion, compliance, involuntariness, and relational factors--precludes meaningful interpretation of the nonresisters' motivation and behavior" (p. 240).

As Orne (1959) has suggested, we should not attribute behavior in the hypnosis context to something unique to hypnosis (such as coercive influence), because other kinds of social context also constrain behavior, e.g. psychotherapy and psychology experiments, with coercive features. Therefore, it seems important in the future to compare the responses of hypnotized subjects with those of subjects in waking-imagination and hypnosis-simulating conditions. In addition to looking at their behavior, it is important to examine their own perceptions of their actions, given the complexity of the social situation entailed in hypnosis.

"Finally, there are statistical grounds to be wary of the authors' conclusions. They assert that 'relational factors in the hypnotic dyad influence hypnotic responsiveness,' yet in three of the studies (I, II, and IV), subjects' ratings of the hypnotist failed to discriminate whether they resisted or responded to the suggestion" (p. 241). Even where Study III was compared with Study II, the difference in the percentage of Ss who resisted failed to reach statistical significance. "In fact, across all studies, differences in overall resistance rates were not documented by statistical tests--despite procedural variations and differing monetary incentives. So contrary to authors' assertion, relational factors \_in the hypnotic dyad\_ generally had little bearing on resistance behavior. If anything, ratings of the resistance instructor had greater weight" (p. 241).

Pekala, Ronald J.; Forbes, Elizabeth J. (1990, Spring). Subjective effects of several stress management strategies: With reference to attention. Behavioural Medicine, 39-43.

This study assessed variations in reported attentional experience associated with several stress management techniques (hypnosis, progressive relaxation, deep abdominal breathing) and baseline (eyes closed) as a function of hypnotic susceptibility. Three hundred nursing students experienced the stress management conditions and afterward completed a self-report inventory, the Dimensions of Attention Questionnaire (DAQ), in reference to each condition. The DAQ quantifies 12 aspects of attentional experience in a reliable and valid manner. The results demonstrated that progressive relaxation, hypnosis, and deep abdominal breathing are characterized by differences in reported attentional experience that are further moderated by an individual's hypnotic susceptibility. The clinical implications of these results are discussed.

"Significant main effects were found for conditions for perspicacity, absorption, and control, with progressive relaxation associated with increased perspicacity and absorption, but with decreased control vis-a-vis hypnosis.

"Significant main effects for groups were found for perspicacity, locus, direction of attention, absorption, control, and vigilance. ... [Post-hoc comparisons] revealed that high susceptibles (vis-a-vis low susceptibles) reported increased perspicacity, absorption, a more inward-focused attention, more feelings of being out of their bodies, and decreased control and vigilance. High-mediums were also different from lows (in the same direction) for all of the above comparisons except for direction of attention. Low-mediums, along with lows, were different from highs for absorption and control.

"Significant interactions between conditions and groups were found for absorption, control, and vigilance. Whereas low susceptibles reported significantly increased absorption but significantly decreased control and vigilance during progressive relaxation than during hypnosis, high susceptibles reported no significant differences between relaxation and hypnosis for absorption, control, or vigilance" (p. 41).

The authors describe the differences found for deep abdominal breathing on p. 41.

"The interaction effects suggest that the experience of hypnosis and progressive relaxation are moderated by a person's hypnotic susceptibility--low susceptibles experience significantly greater absorption, but decreased control and vigilance during progressive relaxation than during hypnosis, although there are no such differences for high susceptibles. This suggests that progressive relaxation may be a 'better' procedure than hypnosis to use with low susceptibles, at least if one wants to increase absorption and decrease vigilance and control" (p. 42).

The authors also note that "deep abdominal breathing is associated with increased 'calmness of mind,' in reference to a baseline condition, as demonstrated by increased attentional detachment and equanimity, and decreased vigilance and density (the 'amount' of thoughts going through one's mind)" (p. 42).

Perry, Campbell (1990). Coercion by hypnosis? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 242-243.

"A postexperimental inquiry (following Orne, 1959) might have informed the reader of the degree to which operationalization of the coercion in terms of disobedience was successful. Without this additional step, it is difficult to determine whether what was found in the laboratory by these investigators applies to what has been reported in clinical and field settings for almost 200 years" (p. 242).

"In particular, elsewhere, the authors equate coercion with involuntariness and appear to view involition as a euphemism for coercion. While I agree that perceiving involition of one's own behavior may contribute to the commission of unconsenting acts in hypnosis, the two are easily distinguished at the conceptual level. Laboratory subjects ordinarily report much behavior in hypnosis that is experienced involuntarily, without the issue of it being coerced ever being broached" (p. 242).

Author describes cases in which patients claimed they participated in sex with hypnotist against their wills because they were hypnotized. "What may be happening in both of these reports is that the hypnotized subjects found themselves responding involuntarily; from this, they appear to have adduced that they could not resist the hypnotist's suggestion. That is, they were coerced not by hypnosis but by their belief, which was a direct function of the experience of involuntariness, that they could not resist" (p. 243). "In short, if a hypnotized person equates involuntary behavior with powerlessness, "coercion" may occur in this limited sense. Conceptually, this appears to be a far cry from equating involition with coercion" (p. 243).

Spiegel, David (1990). Theoretical and empirical resistance to hypnotic compliance. Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 243-245.

Does hypnosis bypass the will, facilitate coercion? The hardest thing for trauma victims to do is to admit helplessness. Furthermore, it is interesting that these same dissociative phenomena seem to be elicited by traumatic experience, the stark imposition of involuntariness (Stutman & Bliss, 1985; Spiegel, Hunt, & Dondershine, 1988). What, then, are we to make of experiments that purport to show that hypnotizable and hypnotized individuals comply with hypnotic instructions irrationally? At some level this challenges our comfortable belief that we always act in our enlightened self-interest, unaffected by unwanted influence. If that can happen even once, our pride of self-ownership is reduced.

Taken as a whole, the studies show that high hypnotizables comply with hypnotic instructions, even in the face of resistance instructions, whereas low hypnotizables are less likely to, especially when conditions foster a relatively less negative view of the resistance instructor. As the authors note, subjects always viewed the hypnotist more positively than the resistance instructor, which in itself suggests the

nonrational influence intrinsic to hypnosis. Free will is not abrogated, it is simply not exercised. The Ss are fundamentally choosing whether or not to comply. Half of the highs in Study IV resisted the hypnotic instruction. However, hypnotized individuals tend to narrow the focus of attention, thereby reducing their ability to consider alternatives such as the resistance instruction.

William James (1890) believed that all ideas were invitations to action. Why, then, do we not act on every idea we have, he pondered on a snowy morning while lying in bed. He observed that he would try to get himself to arise by picturing himself doing so. "Why, then, am I still in bed?" He realized that he was editing the primary idea, reflecting on how cold it was, how long it would take to light a fire, and how much time he had until his classes. In a state characterized by a narrowing of the focus of attention, we are less likely to edit the primary idea, and therefore more likely to act. In the experiments presented, the resistance instructor attempts to act as an external editor on the primary hypnotic instruction. Those capable of focusing attention sufficiently disattend to the editing and comply. These studies show that, thankfully, hypnosis is less than automatic submission to instruction but, interestingly, more than simple conscious response to new information.

**Weekes, John R.; Lynn, Steven Jay (1990). Hypnotic suggestion type, and subjective experience - the order-effects hypothesis revisited: A brief communication. International Journal of Clinical and Experimental Hypnosis, 38, 95-100**

In a replication and extension of Field, Evans, and Orne's (1965) research, no support was found for the hypothesis that suggestion order is related to hypnotic responding. Confirming earlier findings, subjects were no more responsive to suggestions ordered from easy-to-difficult than they were to suggestions ordered from difficult-to- easy. Measures of subjective involvement in suggestions, involuntariness, and archaic involvement with the hypnotist were no more sensitive to order effects, nor were order effects more apparent with subjects who received direct versus indirect suggestions. Confirming earlier research, direct suggestions did facilitate suggestion-related involuntariness and response to the hypnotic amnesia item after cancellation, whereas indirect suggestions enhanced fears of negative appraisal by the hypnotist. Thus, authoritative suggestions enhance responding to a cognitive-delusional item relative to more permissive suggestions. Finally, female subjects were more involved in suggestions than were males, particularly in response to more difficult tests items.

**Weitzenhoffer, Andre M. (1990). Are induced automatisms necessarily coercive? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 245-246.**

"For the sake of maintaining historical accuracy, I would like first to remark that the ability of hypnotized Ss to resist suggestions was probably never a central issue in the Nancy-Salpetriere controversy. The main quarrel was about other fundamental matters (Crocq, 1900; Barrucand, 1967). It also needs to be said that

Pierre Janet should not be seen as representing the Salpetriere in the above controversy. Very little of his extensive writings reflect the ideas of Charcot with whom he was associated for only 4 years (1889- 1893) (Barrucand, 1967; Ellenberger, 1970). Lastly, let it be noted that the association of automatism with hypnotic behavior antedates Bernheim. Despine wrote about it at length as early as 1868, and Charcot (1882) clearly stated before Bernheim that automatic responses to suggestions were characteristic of induced somnambulism. This was at least one view they shared.

Referring to the material quoted from my 1978 paper, the authors assert Bernheim's definition of automatism implies a subject responding to a suggestion *qua* suggestion is "unable to resist" it. But all the definition says is that the will does not directly enter into the production of automatisms. It does not say the will cannot effectively intrude at some point or other. This definition, quoted out of context, was part of a more extensive discussion of *what the nature* of an automatism was for Bernheim. The discussion also went into details regarding *the conditions* under which Bernheim understood automatisms can occur and hold sway. In this greater context, Bernheim (1888a, 1888b) viewed the occurrence of automatisms as normally subject to control by the ego processes responsible for volitional activities. He saw the degree to which a person's behavior can be controlled by automatisms initiated by suggestions to be a function of the extent to which certain ego processes become inactive, ineffective, or cooperatively permit the automatisms to occur. Bernheim recognized that both cognitive and relational factors played an important part in the latter case. Bernheim (1888a, 1888b) also stated that data he had collected showed subjects *could* resist suggestions to varying degrees, with only 17%, who made up the class of somnambules, being *totally incapable* of resisting" (pp. 245-246).

"Stating the matter more concretely, I doubt many people would speak of an individual having been 'coerced' into producing a knee-jerk reflex under appropriate stimulation. Should the situation be any different in the case of other reflexes and, more particularly, the reflex ideodynamic action presumed to underlay suggested acts (Weitzenhoffer 1978, 1989)? I do not think so. It seems to me that what the authors have really and directly examined in their article is the extent to which the classical suggestion effect can be countered by conscious, voluntary control" (p. 246).

1989

Baker, Elgan L.; Levitt, Eugene E. (1989). The hypnotic relationship: An investigation of compliance and resistance. International Journal of Clinical and Experimental Hypnosis, 37, 145-153.

The purpose of this investigation was to assess the ability of hypnotic Ss to voluntarily resist a neutral suggestion when a monetary reward was offered for resistance. 19 of 40 Ss (47.5%) successfully resisted after money was offered by the "resistance instructor." The correlation between resistance/compliance and

hypnotizability was  $-.44$  (high hypnotizables were more likely to comply). Ss' impressions of the hypnotist tended to be positive; impressions of the resistance instructor tended to be neutral. There was a tendency for nonresistors to have a more positive view of the hypnotist but it is not as marked as was found in an earlier study (Levitt & Baker, 1983).

Twelve (75%) of the high hypnotizables did not resist; two (16.7%) of the low hypnotizable Ss did not resist.

In their discussion, they state that "these data support the conclusion that hypnotizability or talent accounts for a significant portion of the variance in determining compliance with suggestions during trance. ... [Further], this research may be conceptualized as examining the contributions of a trait variable (hypnotizability) as compared with a variety of situational or state variables (motivation, social perception, environmental contingencies) in determining compliance and suggestibility. Inherent in this model of research is the assumption that many observed hypnotic phenomena (such as suggestibility) are interactive in nature, representing the outcome of the interplay between trait and state variables and between historically determined and contemporary forces. Such a perspective is consistent with the emerging view of trance behavior and experience and validly parallels the phenomenology of experimental and clinical hypnosis which describe both consistency and variability in hypnotic responsiveness for a specific subject or patient across varying conditions and time" (p. 151).

-temporary forces. Such a perspective is consistent with the emerging view of trance behavior and experience and validly parallels the phenomenology of experimental and clinical hypnosis which describe both consistency and variability in hypnotic responsiveness for a specific subject or patient across varying conditions and time" (p. 151).

"This study also serves to clarify the important role of positive social perception and a positive sense of alliance with the hypnotist as a correlate of compliance with suggestion. It is clear that Ss who complied despite inducements to resist reported a more positive perception of the hypnotist and a more gratifying sense of relatedness with him than did their counterparts who resisted in response to financial inducement. These data do not indicate whether the positive perceptions contributed to compliance, as transference theories of trance involvement would predict, or whether they were consolidated after the fact due to other variables such as management of potential cognitive dissonance. It does seem reasonable to conclude, however, that the relationship is influential in the process of suggestibility and compliance" (p. 151).

Lynn, Steven J.; Rhue, Judith W.; Weekes, John R. (1989). Hypnosis and experienced nonvolition: A social-cognitive integrative model. In Spanos, N.P.; Chaves, J.F. (Ed.), Hypnosis: The cognitive-behavioral perspective (pp. 78-109). Buffalo, NY: Prometheus.

The authors present a model to account for the subjective experience of nonvolition. The model rests on four observations: (1) nonvoluntary responses "have all of the

properties of behavior that is typically defined as voluntary" (p. 108); (2) "hypnotizable subjects can resist suggestions when resistance is defined as consistent with the role of a 'good' hypnotized subject" (p. 108); (3) "Hypnotic behaviors are neither reflexive/automatic ... nor manifestations of innate stimulus-response connections" (p. 108); (4) "Hypnotic performances consume attentional resources ... in a manner comparable to nonhypnotic performances" (p. 108). They continue, "At the same time, many of the cognitive operations and affective reactions that accompany hypnotic responding are not readily accessible to consciousness" (pp. 108-109).

Meyer, H. K.; Diehl, B. J.; Ulrich, P. T.; Meinig, G. (1989). Changes in regional cortical blood flow in hypnosis. Zeitschrift für Psychosomatische Medizin und Psychoanalyse, 35, 48-58.

Regional cerebral blood flow (rCBF) was measured by means of the 133-Xenon inhalation method in 12 healthy male volunteers who had several months of experience in doing self-hypnosis (autogenic training). During hypnotically suggested right arm levitation, as compared to resting conditions, they found an increase in cortical blood flow and an activation of temporal areas; the latter finding was considered to reflect acoustical attention. In addition, a so-far-unexplained deactivation of inferior temporal areas was observed during successful self hypnosis and hypnosis. While there was a global absolute increase of cortical blood flow bilaterally, they could not observe a relative increase of the right as compared to the left hemisphere during hypnosis. Several subjects successfully performed the levitation of the right arm, despite a relative left hemispheric activation, provided the absolute right hemispheric activation remained dominant.

Pekala, Ronald J.; Bieber, Stephen L. (1989-90). Operationalizing pattern approaches to consciousness: An analysis of phenomenological patterns of consciousness among individuals of differing susceptibility. Imagination, Cognition and Personality, 9 (4), 303-320.

Pattern differences in subjective experience, as assessed by a self-report inventory, the Phenomenology of Consciousness Inventory (PCI), were compared across low, low-medium, high-medium, and high hypnotically susceptible individuals during hypnosis and eyes-closed. A hierarchical factor analytic approach was utilized that allowed for the determination of pattern differences among PCI dimensions as a function of hypnotic susceptibility. The factor analyses found that the four susceptibility (sic) groups were 'pattern equivalent' during eyes-closed, partially pattern dissimilar during hypnosis, and partially pattern dissimilar when comparing hypnosis against eyes-closed. The nature of these results support previous analyses (1) which compared pattern structure differences as a function of correlational matrices. The results suggest the complementarity of Bieber's (2) and Pekala's (3) approaches for assessing pattern differences in consciousness and are congruent with the theorizing of Tart (4), Izard (5), and the PDP researchers on the importance of pattern structure changes in understanding states of consciousness.

**Pekala, Ronald J.; Kumar, V. K. (1989). Phenomenological patterns of consciousness during hypnosis: Relevance to cognition and individual differences. Australian Journal of Clinical and Experimental Hypnosis, 17 (1), 1-20.**

Relationships among phenomenological subsystems of consciousness associated with a baseline condition and an hypnotic induction condition were compared across individuals of differing hypnotic susceptibility. Phenomenological experience on 12 subsystems of consciousness was quantified by means of the Phenomenology of Consciousness Inventory (PCI) and the relationships between dimensions were statistically assessed. The results replicated previous findings and suggested that hypnosis has differential effects upon the reported organization of phenomenological structures of consciousness across subjects of differing susceptibility. The data from the previous and present studies were pooled and the combined data were reanalyzed. The results provided further support for the differential pattern structure across low and high susceptibles during hypnosis. Furthermore, differences in pattern structure were augmented when comparing very low versus very high susceptible individuals.

**Ronnestad, Michael Helge (1989). Hypnosis and autonomy: A moderator analysis. International Journal of Clinical and Experimental Hypnosis, 37, 154-168.**

The study focused on autonomy as a moderator variable in the prediction of subjectively reported hypnotic depth. Ss in the experimental part of the study were 56 undergraduate psychology and education majors classified as either high or low in autonomy. Ss who were equated on capacity for absorption were individually administered 1 of 3 hypnotic inductions: an authoritarian induction, a permissive hetero- induction, or a self-hypnosis induction. The study had a double-blind design. The data suggest that situational manipulation has greater impact on low than on high autonomy Ss. Individual-difference variables such as absorption, have greater impact on hypnotic depth for high than for low autonomy Ss. The data indicate that the hypnotic behavior of high autonomy Ss is more likely to be self-congruent and less likely to be demand-congruent. A factor-analytic inquiry of absorption confirmed the importance of affective/regressive capacity for hypnotic functioning for high autonomy Ss. The study supported the alternate-path perspective of hypnosis.

There is very little research on autonomy and hypnosis. The authors cite studies showing only a modest relationship between hypnotizability and locus of control.

In this study, 176 students were assigned to the high autonomy group if they were in the upper 1/3 of two of 3 autonomy scales (Rotter's Locus of Control Scale, the Inner- Directedness Subscale of the Shostrom Personal Orientation Inventory, and the Autonomy subscale of Jackson's Personality Research Form) and not in the lower 1/3 of the third scale. Ss were designated as low autonomy if the obverse obtained. This procedure yielded 27 high and 29 low autonomy Ss.

Ss were hypnotized with one of three inductions: authoritarian with many motor items (Barber Suggestibility Scale), permissive with mostly imagery (Barber & Wilson's Creative Imagination Scale), or guided self-hypnosis with mostly imagery

(taken from Fromm et al, 1981). After hypnosis, Ss rated their own hypnotic depth on a 1-10 scale, and their perception of E or the procedure as authoritarian and directive. Ss' attitude, expectations, motivation, and experienced effortlessness were measured. E rated Ss for pre-hypnosis rapport and post-hypnosis rapport.

The results indicated that there was no difference in hypnotizability level between high and low autonomy Ss. The correlation between effortlessness of experience and hypnotic depth was high for low autonomy Ss (.51) but not significant for high autonomy Ss (.12). In general the two groups were very similar in terms of mean scores on most variables. The differences appeared in the correlations between self-reported hypnotic depth and the other variables. For low autonomy Ss correlations were not significant between depth and pre-hypnotic variables (rapport-pre, absorption, expectation) but for highs the same correlations were significant (rapport-pre .47, absorption .54, expectation .48).

But for post-hypnosis variables, low autonomy Ss had significant correlations between depth and the two variables measured from post-hypnosis interviews (perceived authoritarian/directiveness .40, effortlessness .51) and the highs did not have significant correlations. The multiple correlation between these variables and depth was  $R = .28$  for low autonomy Ss (with no contribution from rapport-pre) and  $R = .72$  for high autonomy Ss, with absorption contributing most. The more they perceived the induction as authoritarian or directive, the greater depth reported by low autonomy Ss. Although low and high absorption Ss did not differ on the Absorption Scale, absorption predicted hypnotic depth better for the highs.

The author divided the Absorption Scale into four rational factors: Affective/Regressive, Perceptual/Cognitive, Dissociative, and Mystical. Low and high autonomy Ss scored at approximately the same level on these categories, but correlations between these categories and depth for low and high autonomy Ss were somewhat different. (See Table.)

#### Correlations between Categories of Absorption and Hypnotic Depth for Low and High Autonomy Ss

Absorption	Low Autonomy	High Autonomy	All Ss	Category	r	r	r
Affective/Regressive	.14	.56**	.33**	Perceptual/Cognitive	.25	.33*	.29*
Dissociative	.32*	.57**	.47**	"Mystical"	.07	.16	.11

In their discussion, the authors note that one might assume that high autonomy Ss would be less affected by variations in hypnosis procedures than low autonomy Ss. The differences found in depth scores for these two groups were supportive of this expectation. "Fluctuations in subjectively reported depth scores for low autonomy Ss only, clearly suggest autonomy to be a moderator variable" (p. 163).

Moreover, the results indicate "that high autonomy Ss in comparison to low autonomy Ss are more likely to express their inner dispositions, such as absorption and expectation, in the hypnotic setting. High autonomy Ss may be more reflective of and attuned to individual predisposing characteristics and less influenced by situational demands. ... the hypnotic behavior of high autonomy Ss is more likely to be self- congruent and less likely to be demand-congruent. Low autonomy Ss, however, are more likely to be demand congruent and less likely to be self-congruent. The latter finding was suggested both by the significant F ratio for low autonomy Ss across treatments, and also by the stronger relationship found for this

group between depth and how authoritarian/directive they perceived the procedure to be" (p. 163).

[Paradoxically, among low autonomy Ss an authoritarian approach yields less depth but greater suggestibility (higher hypnotizability scores).] "The tendency for low autonomy Ss to have a higher behavioral score on the authoritarian procedure is consistent with Tellegen's (1979) assumption that there are two pervasive dimensions in current hypnotizability measures--a compliance dimension and a true hypnotic responsiveness dimension. According to Tellegen, motor items may be more saturated with compliance, while cognitive items may be more saturated with true hypnotic responsiveness. The BSS has a motor emphasis, and the higher behavioral scores for the low autonomy group of Ss may be interpreted as an expression of compliance.

"In addition to the inner-directedness and self-congruence hypothesis of why autonomy may be a moderator variable, another possible explanation is related to accuracy of self-perception. The intercorrelational and multiple regression data showed repeatedly that a stronger relationship existed between prehypnotic variables and hypnotic depth for high autonomy than for low autonomy Ss. The relational capacity, as tapped by the rapport-pre variable, absorption, which may be conceptualized as a personality trait; and expectation, a cognitive variable, were all related to depth for high autonomy Ss. For low autonomy Ss, none of these variables were individually related to depth. Differences in Ss' accuracy of self-reporting may explain this. According to ego-psychology theory, highly individuated Ss, with clear self-other differentiation and congruence in self-perception, are better able to make accurate statements about themselves. The self-assessments of Ss with low differentiation capability may be less accurate and possibly more affected by demand characteristics and response set. In other words, their self-assessments have more error. The generally lower correlations for the low autonomy Ss may reflect this" (p. 164).

"A report of subjectively reported hypnotic depth following CIS and the self-hypnosis scales may reflect clarity of imagery, while a report of depth following BSS may reflect experiences of kinesthetic/bodily changes" (p. 165).

predisposing characteristics and less influenced by situational demands. ... the hypnotic behavior of high autonomy Ss is more likely to be self-congruent and less likely to be demand-congruent. Low autonomy Ss, however, are more likely to be demand congruent and less likely to be self-congruent. The latter finding was suggested both by the significant F ratio for low autonomy Ss across treatments, and also by the stronger relationship found for this group between depth and how authoritarian/directive they perceived the procedure to be" (p. 163).

[Paradoxically, among low autonomy Ss an authoritarian approach yields less depth but greater suggestibility (higher hypnotizability scores).] "The tendency for low autonomy Ss to have a higher behavioral score on the authoritarian procedure is consistent with Tellegen's (1979) assumption that there are two pervasive dimensions in current hypnotizability measures--a compliance dimension and a true hypnotic responsiveness dimension. According to Tellegen, motor items may be more saturated with compliance, while cognitive items may be more saturated with true hypnotic responsiveness. The BSS has a motor emphasis, and the higher

behavioral scores for the low autonomy group of Ss may be interpreted as an expression of compliance.

"In addition to the inner-directedness and self-congruence hypothesis of why autonomy may be a moderator variable, another possible explanation is related to accuracy of self-perception. The intercorrelational and multiple regression data showed repeatedly that a stronger relationship existed between prehypnotic variables and hypnotic depth for high autonomy than for low autonomy Ss. The relational capacity, as tapped by the rapport-pre variable, absorption, which may be conceptualized as a personality trait; and expectation, a cognitive variable, were all related to depth for high autonomy Ss. For low autonomy Ss, none of these variables were individually related to depth. Differences in Ss' accuracy of self-reporting may explain this. According to ego-psychology theory, highly individuated Ss, with clear self-other differentiation and congruence in self-perception, are better able to make accurate statements about themselves. The self-assessments of Ss with low differentiation capability may be less accurate and possibly more affected by demand characteristics and response set. In other words, their self-assessments have more error. The generally lower correlations for the low autonomy Ss may reflect this" (p. 164).

"A report of subjectively reported hypnotic depth following CIS and the self-hypnosis scales may reflect clarity of imagery, while a report of depth following BSS may reflect experiences of kinesthetic/bodily changes" (p. 165).

Schuyler, Bradley A.; Coe, William C. (1989). More on volitional experiences and breaching posthypnotic amnesia. International Journal of Clinical and Experimental Hypnosis, 37, 320-331.

Highly responsive hypnotic subjects, who were classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia, were compared with each other on four physiological measures (heart rate, electrodermal response, respiration rate, muscle tension) during posthypnotic recall. Two contextual conditions were employed: One was meant to create pressure to breach posthypnotic amnesia (lie detector instructions); the other, a relax condition, served as a control. The recall data confirmed earlier findings of Howard and Coe and showed that voluntary subjects under the lie detector condition recalled more than the other three samples that did not differ from each other. However, using another measure of voluntariness showed that both voluntary and involuntary subjects breached under lie detector conditions. Electrodermal response supported the subjects' reports of control in this case. Physiological measures were otherwise insignificant. The results are discussed as they relate to (a) studies attempting to breach posthypnotic amnesia, (b) the voluntary/involuntary classification of subjects, and (c) theories of hypnosis subjects' reports of control in this case. Physiological measures were otherwise insignificant. The results are discussed as they relate to (a) studies attempting to breach posthypnotic amnesia, (b) the voluntary/involuntary classification of subjects, and (c) theories of hypnosis.

The authors suggest that subjects observe themselves not remembering (i.e. not reporting memories) and conclude that they therefore could not remember. Such subjects, they say, are deceiving themselves in so far as they could remember if they were to direct their attention to salient cues

1988

Bowers, Patricia G.; Laurence, Jean-Roch; Hart, David (1988). The experience of hypnotic suggestions. International Journal of Clinical and Experimental Hypnosis, 36, 336-349.

The experience of nonvolition in response to hypnotic suggestions was investigated for 126 Ss. 2 different scales, a new scale providing discrete options for response and a previously used volition rating scale, gave Ss an opportunity to describe some of their subjective experiences after completion of a 12-item adaptation for group administration of the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & Hilgard, 1962). Ratings of depth of hypnosis were also obtained. Ss had been previously administered the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962). Distribution of descriptions of experience for passed and failed items were obtained. Total scores on subjective indices were found to be highly correlated with the behavioral score on the Waterloo-Stanford Scale of Hypnotic Susceptibility: Group C. Items differed, however, in the degree to which responses seem to occur effortlessly. Some suggestions have a substantial number of passed responses lacking the "classic suggestion effect," but only 7% of Ss have more than 2 such responses.

Earlier research on the subjective perception of voluntary enactment of suggestions found from 20% (K. Bowers, 1981; P. Bowers, 1982) to 55% (Spanos, Radtke, Hodgins, Stam, & Bertrand, 1983) of hypnotic responses were described as voluntary in nature. Methodological differences could account for the range in probability levels, and rating scales used did not provide for absence of behavioral response to a particular suggestion.

This research investigated three issues: "1. Using a choice format to describe experiences during hypnosis, what is the distribution of the different descriptions used to index the construct of nonvolition? When S gives a mid-point rating on a volition rating scale, to what experiences does he/she refer? 2. How do two aspects of subjective experience: nonvolitional experience descriptions and hypnotic depth reports, covary with behavioral passing and failing of items and with levels of hypnotizability? 3. How frequently does S pass an item behaviorally but indicate either that he/she did not experience the response or that he/she purposefully enacted it? On what items is this a more or less frequent occurrence? Are there just a few people who pass items in this fashion or is it a common observation?" (p. 339).

The Ss were seen in small groups. Immediately after hypnosis they scored their own hypnotizability scales. Then they were asked to rate their subjective response to each suggestion: - how much they had experienced the suggestion (1-5) - how involuntary their response had been (1-5) (These two items comprised the Voluntary

Rating Scale (VRS) used by K. Bowers, 1981, and P. Bowers, 1982.) - how deeply hypnotized they had felt (1-10, Perry & Laurence format, 1980) - Choice Scale (example from the hand magnetism item below) "Choice Scale of Nonvolitional Experience:

1980) - Choice Scale (example from the hand magnetism item below) "Choice Scale of Nonvolitional Experience:

Listed below are various ways people experience the hands together item. Please check the description(s) that most closely describe your experiences: (1) My hands did not move together at all. (2) I purposefully directed the movement of my hands most of the time. (3) I found I directed the movement of my hands and then later they continued to move together with no effort on my part. (4) I found my hands moving together without my helping them. (5) During this experience, the feelings of purposefully moving my hands were completely mixed with feelings that they were moving on their own. None of the above" (p. 340).

Considering both the passed and failed items, and after excluding the 'None of the above' category, "37% of items [on the W-SGSHS:C] were not experienced, 12% were enacted purposefully, 14% were experienced as intertwined volition and nonvolition, 17% were experienced as beginning purposefully but becoming nonvolitional, and 20% 'happen by themselves'" (p. 341). See Table 2, taken from the article.

Thus of those failing an item, 60% reported that they did not experience the suggestion, while almost 26% reported some level of subjectively experienced nonvolition.

This research demonstrated that the Choice Scale is an improvement over the Voluntary Rating Scale, which has an ambiguous midpoint of '3' between voluntary and nonvoluntary extremes (on a 5-point scale). Almost half of the ambiguous '3' responses on the VRS were associated with a more meaningful response on the Choice Scale, indicating that the response started off voluntarily but then continued 'on its own.' Another third of the Ss indicated that there was an intertwining of volition and nonvolition.

The Choice Scale (transformed into an ordinal scale) was correlated with the VRS and hypnotizability and depth estimate scales. The correlations were "consistently high, suggesting that typically one reports feeling more deeply hypnotized when many suggestions are performed and passed, and more deeply hypnotized Ss report feeling that suggestions occur more 'by themselves' than do less hypnotizable Ss" (p. 342).

The authors note the complex relationship between behavioral and subjective experience. High hypnotizables report experience of nonvolition even with some failed items, and rate themselves as deeply hypnotized even when failing items. This is not true for low hypnotizables, whose self-rated depth varies directly with passing or failing items.

Mismatches were defined as passing an item behaviorally but reporting either that it was not experienced (Choice 1) or purposefully enacted (Choice 2). 93% of Ss had less than 3 mismatches; of the 8 Ss exhibiting 3 or more mismatches, 3 were medium-low hypnotizables, 4 were medium-highs, and 1 was highly hypnotizable.

When one corrects their total hypnotizability score for the mismatch, people remain close to their original score however.

Some items had many more mismatches than others (See Table 6). The 'classic suggestion effect' reflected in a low percentage of mismatches (3-9%) was found for five items; three items had a moderate level of mismatches (16-22%); but four suggestions had mismatches on 34-41% of the passed responses. Item difficulty could not account for whether the classic suggestion effect occurred: two very difficult items were at opposite ends of the spectrum--positive music hallucination had the fewest and negative visual hallucination the most frequent mismatches. "One might speculate that the nature of one's ordinary imaging during the day makes some hallucinations well practiced and easier to produce, while others are rarely practiced and seem to require cognitive effort to reconstruct. ... Thus, instead of a mismatch representing 'faked' responses, it may at times represent S's report of a hallucination's seeming real while simultaneously requiring effort. Ideomotor suggestions have few mismatches. If they feel 'real,' it is by virtue of their seeming to occur without effort or volition" (pp. 346-347).

Table 6 Item % Mismatch Hand Lowering 2.9 Hands Together 4.8 Arm Rigidity 5.6 Music Hallucination 7.7 Dream 8.7 Arm Immobilization 15.5 Amnesia 21.6 Age Regression 21.8 Taste Hallucination 33.8 Negative Hallucination 34.6 Mosquito 38.1 Post-hypnotic Suggestion 40.8

Since highly hypnotizable people experience nonvoluntariness even when they fail items, tested hypnotizability must reflect more than simply passing test items on suggestion. "Research focusing exclusively on the nonvolitional aspect of hypnotic experience may be somewhat 'off the mark,' at least for some types of suggestions. Reports of nonvolition may be tracking the experience of effortless responding which may be just one aspect of a complex hypnotic response to cognitive suggestions. ... It may be that studies using free reports from Ss responsive to hallucination suggestions would be necessary prior to devising an appropriate 'choice' scale for these items. The work of Sheehan and McConkey (1982) provides a solid basis for such a task. The Choice Scale in the present study was derived from an understanding of the 'classic suggestion effect,' the concept of which is closely tied to ideomotor suggestions. This concept may or may not prove to be of central relevance to hypnotic hallucinations or more generally to cognitively demanding suggestions" (p. 347).

Gorassini, Donald R.; Hooper, Cynthia L.; Kitching, Kathleen J. (1988). The active participation of highly susceptible hypnotic subjects in generating their hypnotic experiences. Imagination, Cognition and Personality, 7 (3), 215-226.

Hypnotized individuals have traditionally been considered to be detached from the control of their own suggested behavior. We tested this and the alternative notion that hypnotized subjects attempt to self-generate the experiences (i.e., mainly of involuntariness) as well as produce the behaviors thought to be prototypical of high hypnotic ability. In an experimental investigation, highly susceptible hypnotic subjects were found to engage in the kind of imaginative activity that would be expected of individuals who were attempting deliberately to generate their experiences of involuntariness; they engaged as actively in imagery-generation as did subjects who were specifically instructed to imagine during suggested responding, and they experienced as much involuntariness as subjects in whom suggested movements were produced by an external physical force. The implications of these findings for the neodissociation and social psychological theories of hypnotic responding are discussed.

Kumar, V. K.; Pekala, Ronald J. (1988). Hypnotizability, absorption, and individual differences in phenomenological experience. International Journal of Clinical and Experimental Hypnosis, 36, 80-88.

The phenomenological effects associated with a baseline condition of eyes- closed and a hypnotic induction condition were compared across individuals of differing absorption capacity and hypnotizability. The results indicated that individuals of differing absorption capacity and hypnotizability reported different intensities of phenomenological experience during the baseline eyes-closed condition. The induction further augmented intensity differences for low, medium, and high absorption and hypnotizable Ss, but more so for high (and medium) than low hypnotizable Ss. The results support both a trait and state interpretation of hypnotizability, and highlight the importance of the interaction between these factors on the resulting hypnotic experience of S.

-tizable Ss. The results support both a trait and state interpretation of hypnotizability, and highlight the importance of the interaction between these factors on the resulting hypnotic experience of S.

Based on a review of relevant literature, the authors predicted that (1) during hypnosis and a baseline condition (eyes-closed), high absorption and high hypnotizable Ss will report the phenomenological effects at greater intensity relative to low absorption and low hypnotizable Ss, respectively; (2) hypnotic induction will be associated with increased absorption; greater alterations in awareness and experience; and decreased volitional control, rationality, and memory; (3) phenomenological intensity differences (hypnosis compared to eyes-closed) will be significantly greater for high than for low hypnotizable Ss.

They used the Phenomenology of Consciousness Inventory (PCI) developed by Pekala (1982), which is a 53 item self-report instrument that is completed retrospectively in reference to a preceding stimulus condition. The PCI measures the following dimensions and subdimensions: internal dialogue; self-awareness; state of awareness; imagery (amount, vividness); positive affect (joy, sexual excitement, love); negative affect (anger, fear, sadness); altered experience (time sense, body image, perception, unusual meanings); attention (absorption, direction); memory; rationality; volitional control; and arousal.

The 217 Ss were administered the Tellegen Absorption Scale, then sat quietly with eyes closed for four minutes, then completed the PCI, Form 1, relative to that 4-minute period. They were administered a slightly shortened version of the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A); before the posthypnotic suggestion and amnesia suggestion they experienced another 4-minute silent period during which they were told to 'continue to experience the state you are in right now.' After the HGSHS:A they completed PCI, Form 2, in reference to the silent period during the HGSHS:A, before they completed the 11-point questionnaire on the HGSHS:A.

Subjects who did not have reliable PCI response forms were removed from the sample, leaving 173 Ss who were divided into high, medium, and low Absorption groups, and high, medium, and low hypnotizability groups. The statistical analysis employed MANOVA on intensity scores for first the major PCI dimensions and then the 14 subdimensions using Conditions (eyes closed, hypnosis) and Groups. There were significant main and interaction effects. Subsequent ANOVAs for each (sub)dimension, Conditions by Hypnotizability Groups (2 x 3) were then performed. Hypnosis "was associated with significantly less positive affect (joy, sexual excitement, love); negative affect (anger, sadness); visual imagery (amount, vividness); self-awareness, internal dialogue, rationality, volitional control, and memory; and significantly more altered experience (time sense, perception) and altered state of awareness.

"Significant main effects for Hypnotizability Groups were found for positive affect (joy, love); altered experience (body image, time sense, perception, meaning);

attention (direction, absorption); self-awareness; altered state of awareness; rationality; volitional control; and memory.

"Post-hoc comparisons for the eyes-closed condition revealed that high relative to low, hypnotizables reported significantly greater alterations in body image, time sense, meaning, and altered state of awareness. Medium hypnotizable Ss, compared to low hypnotizables,

, reported significantly increased alterations in body image and state of awareness.

"Post-hoc comparisons for the hypnotic induction condition revealed that high, viz-a-viz low, hypnotizables reported significantly increased absorbed attention; greater altered experience (body image, time sense, perception, meaning); and increased alterations in state of awareness. High hypnotizables also reported significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. Medium hypnotizable Ss, vis-a-vis low hypnotizables, reported significantly more altered experience (body image, time sense, perception, meaning); absorbed attention; and altered state of awareness; and significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. High hypnotizable Ss, relative to medium hypnotizables, reported significantly more altered experience (perception, meaning) and absorption, and significantly less rationality, volitional control, and memory.

"Concerning the significant interactions ( $\alpha = .01$ ), graphs of the means indicated significant ordinal interactions between Conditions and Hypnotizability Groups for altered experience (perception), imagery (vividness), self-awareness, altered state of awareness, rationality, volitional control, and memory. For all of the PCI (sub)dimensions, the hypnotic induction condition (compared to eyes-closed) was associated with a significantly greater increase in altered experience (perception), and altered state of awareness; and a significantly greater decrease in imagery (vividness), rationality, volitional control, and memory for the high (and medium) hypnotizable groups relative to the low hypnotizable group.

"Significant disordinal interactions were found for absorption and unusual meanings. Whereas high hypnotizable Ss reported a more absorbed attentional focus and more unusual meaning during hypnosis, low hypnotizable Ss reported being less absorbed (or more distracted) during the induction than eyes-closed. Low hypnotizables reported more unusual meanings in reference to eyes closed" (pp. 84-85).

Correlations among the major PCI dimensions, absorption, and hypnotizability differ between the two conditions. In hypnosis, the hypnotizability correlations that reached the .001 level were: --Self Awareness -.55 --State of Awareness .60 --Altered Experience .56 --Inward Absorbed Attention .44 --Rationality -.41 --Volitional control -.65 --Memory -.41 --Arousal -.28

In the eyes closed condition, the only PCI variables that Hypnotizability correlated with, at the .001 level, were: --Positive Affect .26 --Altered Experience .32

MANOVAs and ANOVAs were computed for Absorption groups in a similar fashion. Main effects but not interaction effects were significant. Results are not abstracted here.

In their Discussion, the authors note that "The three hypotheses were supported by the results. Several of the absorption group comparisons obtained in previous research (Pekala et al., 1985) involving alterations in subjective experience (body image, perception, meaning); state of awareness; and volitional control were replicated in the present research" (p. 85).

Lynn, Steven Jay; Weekes, John R.; Matyi, Cindy L.; Neufeld, Victor (1988). Direct versus indirect suggestions, archaic involvement, and hypnotic experience. Journal of Abnormal Psychology, 97 (3), 296-301.

This study examined the effects of direct (Harvard Group Scale of Hypnotic Susceptibility; Shore & Orne, 1962) versus indirect (Alman-Wexler Indirect Hypnotic Susceptibility Scales; Pratt, Wood, & Alman, 1984) suggestions on archaic involvement (Nash & Spinler, in press) with the hypnotists, objective responding, and subjective involvement and involuntariness ratings, when the scales were administered in all possible combinations (direct/indirect, N = 61; indirect/direct, N = 61, direct/direct, N = 57; indirect/direct, N = 95), across two sessions. At the initial testing, subjects who received indirect/direct, N = 61, direct/direct, N = 57; indirect/direct, N = 95), across two sessions. At the initial testing, subjects who received indirect suggestions reported a greater emotional bond with the hypnotist and increased fear of negative appraisal than subjects who received direct suggestions. Repeated testing resulted in response decrements on measures of objective responding, subjective involvement, and involuntariness that were paralleled by diminished involvement with the hypnotist. The most stable relation between scales was evident when scales were defined as direct hypnosis across both sessions. Although direct and indirect suggestions produced comparable effects in the first session, in the second session, direct suggestions fostered greater subjective involvement and feelings of involuntariness.

1987

Holroyd, Jean (1987). How hypnosis may potentiate psychotherapy. American Journal of Clinical Hypnosis, 29, 194-200.

Hypnotherapy is defined as doing psychotherapy in the hypnotic state. This article reviews cognitive, affective, and motivational changes associated with hypnotic trance, attempting to demonstrate how the hypnotic state might influence ordinary psychotherapy processes. Nine characteristics of trance probably potentiate psychotherapy: (1) changes in attention and awareness, (2) imagery enhancement, (3) increase in dissociation, (4) decrease of reality orientation, (5) increase in suggestibility, (6) increased accessibility of mind-body interactions, (7) diminution of initiative resulting in a sense of nonvoluntariness, (8) increased availability or manipulability of affect, and (9) development of a fusional relationship (rappport). This article touches upon the psychotherapeutic implications of these hypnosis attributes.

1986

Cole, Ronald William (1986, February). Posthypnotic suggestion and the production of creative imagination imagery (Dissertation, Mississippi State University). Dissertation Abstracts International, 47 (8), 2953-A.

"This investigation assessed the effect of posthypnotic suggestions in facilitating creativity in persons highly susceptible to hypnosis. Fifty college-age subjects from educational psychology and psychology classes at Mississippi State University who scored 9 or above on the Harvard Group Scale of Hypnotic Susceptibility were used. Groups of 10 subjects were randomly assigned to one of five conditions: a) hypnosis/creative learning set instructions b) relaxation/creativity learning set instructions c) hypnosis only d) relaxation only e) posttest only "Subjects in the hypnosis/creative learning set instructions group received 25 min. of hypnosis and creativity instruction. The relaxation/creative learning set instructions group received 25 min. of relaxation and creativity instructions. The hypnosis-only group received 25 min. of hypnosis and then completed mazes. The relaxation-only group received 25 min. of relaxation and then completed mazes. And lastly, the control group received the posttest only. All groups were given the Torrance Test of Creative Thinking (TTCT), Verbal and Figural Forms A, 1 week after receiving their treatment conditions. The results indicated that the combination of hypnosis and creativity instructions produced significantly higher mean scores on the Verbal Form A -- fluency, flexibility, and originality subtests, and Figural Form A elaboration subtest, and lend support to the contention that posthypnotic suggestions can increase creativity (as measured by the TTCT) in high susceptible subjects. The components of both hypnosis and creativity instruction had to be present to increase creative performance. There was a tendency for relaxation combined with creativity instructions to show decreases in creativity scores. "The hypnotic state was seen as necessary for the unconscious acceptance of creativity instructions (low volitional control), while the relaxed state produced conscious contamination of suggestions for creativity (high volitional control). It was postulated that it was the difference in volitional control which produced the positive responses to posthypnotic suggestions to be more creative in the group receiving hypnosis and creativity instructions" (p. 2953).

1986

Miller, Mary E.; Bowers, Kenneth S. (1986). Hypnotic analgesia and stress inoculation in the reduction of pain. Journal of Abnormal Psychology, 95, 6-14.

Investigated the influence of hypnotic ability on 3 methods of reducing cold-pressor pain. Following a baseline immersion, 30 high- and 30 low-hypnotizable undergraduates were randomly assigned to 1 of 3 treatment groups: stress inoculation training, stress inoculation training defined as hypnosis, or hypnotic analgesia. Analysis of pain reports indicated a significant hypnotic ability x treatment interaction. Among Ss receiving hypnotic analgesia, high-hypnotizables reported significantly less intense pain than lows. There was no differential response for high- and low-hypnotizable Ss receiving stress inoculation training, whether or

not it was defined as hypnotic. Moreover, Ss in the stress inoculation condition (whether or not defined as hypnosis) reported using cognitive strategies to reduce pain, whereas this was not the case for Ss in the hypnotic analgesia condition. The present findings seem inconsistent with the social psychological account of hypnosis and are discussed from a dissociation perspective, which views hypnosis as involving changes in the way information is processed.

Mitchell, George P.; Lundy, Richard M. (1986). The effects of relaxation and imagery inductions on responses to suggestions. International Journal of Clinical and Experimental Hypnosis, 34, 98-109.

Theoretical attempts to understand the meaning and importance of induction procedures in producing hypnotic phenomena suggest that 2 critical components, relaxation and imagery, should be isolated and their relative effect on hypnotic responding studied. Objectively and subjectively scored responses to 12 hypnotic suggestions, which had followed relaxation, imaginal, or combined inductions, were obtained from 59 Ss, divided into 3 levels of hypnotizability. Regardless of hypnotizability level, the combined induction led to a greater subjective report of hypnotic response than did either the relaxation or the imagery inductions; and the relaxation led to a greater subjective report than the imagery induction. It may follow that the subjective experience of hypnosis is facilitated by inductions which include relaxation. The inductions were equally effective in producing objectively measured behavioral responses. There were no significant interactions found between induction type and hypnotizability level.

As suggested by Sacerdote (1970), the combination procedure was the most generally effective in producing hypnotic responses. The difference between combined and imagery inductions reached statistical significance on four dependent variables, and the difference between combined and relaxation reached significance on three. It may also be of interest that Ss receiving the combined procedure scored consistently higher on all nine dependent variables.

A somewhat unexpected finding was that the relaxation induction produced scores on four of the dependent variables that were statistically higher than the imagery induction scores. Considering the difficulty of isolating relaxation and imagery components, it is quite noteworthy that these differences between inductions were found.

The four variables in which the combination and relaxation conditions produced significantly higher scores than the imagery condition were subjective reports--subjective score, degree hypnotized, response volition, and Field Inventory. In contrast to Ss in the imagery induction,

Ss in the other two induction conditions believed that they were responding more, felt that their responses were more nonvolitional, and felt that they were more deeply hypnotized.

The fact that relaxation instructions were present in both conditions that were superior to the imagery condition would appear to support Edmonston's (1981) position which posits relaxation as essential for the production of the state of neutral

hypnosis. For Edmonston the condition of neutral hypnosis is defined as the relaxed state and precedes other phenomena, such as dissociation and increased suggestibility, which other theoreticians may include in the definition of hypnosis.

However, the statistically significant superior effect of the combined over the relaxation induction on three measures casts doubt on Edmonston's position. The S believes that he or she is more deeply hypnotized and is responding less volitionally when an imagery component is combined with relaxation. The Ss also responded more to the Field Inventory when the combined induction was used.

Another explanation for imagery's relatively poor showing may lie in Ss' differential expectations. The Ss, especially those with previous experience with a traditional hypnotic induction, as was the case in the present study, may not expect to be hypnotized when presented with an imagery alone induction. Such expectations, of course, might reduce responses. On the other hand, there is no reason to believe that the reduced expectation in the imagery condition would not affect the behavioral responses as well, and such was not the case.

Thus, we may be left with the explanation that relaxation adds to the subjective experience of hypnosis. This is in keeping with Edmonston's (1981) position as well as with previous research, such as that by Hilgard and Tart (1966), which finds traditional inductions, with their relaxation components, superior to nontraditional inductions, such as fantasy or task-motivational. If future research should find that bodily involvements such as the physical exertion or repetitive motor behavior (Banyai and Hilgard, 1976) lead to the same level of subjective experience as relaxation did, then we may need to broaden the concept of the somatic component beyond relaxation alone.

In terms of the behavioral compliance of Ss, the results of the present study are in accord with some previous studies in finding all procedures equally effective. Neither imagery, relaxation, nor the combined procedure was superior for the behavioral measure.

Personality factors (social desirability, internality/externality, and absorption) did not affect the basic findings. To the degree that the Tellegen scales measure the ability to engage in imagery there seems to be little basis for believing that imagery ability is related to the general findings.

Sarbin (1983) would call the inductions studied here 'entrance rituals,' and he has recently asked in his review of Edmonston's book, "Which ritual is more suitable... [p. 58]' for preparing S to respond in various hypnotic ways? One answer from the present results is that an entrance ritual should include muscular relaxation if one wants a better subjective response from S. From Sarbin's point of view, the relaxation component may be more ego-involving, producing more subjective experience and meaning for S.

If one wants to produce only a behavioral response, either a relaxation or imagery ritual will serve.

Pereira, Robert Peter (1986, July). The role of organismic involvement in hypnotic emotional behavior (Dissertation, Wayne State University). Dissertation Abstracts International, 47 (1), 385-B. (Order No. DA8605027)

Two hundred college undergraduates were pretested via the Harvard Group Scale of Hypnotic Susceptibility: Form A. Fifty subjects scoring in the range 7-12 were designated as Reals, while 25 subjects scoring in the range 0-4 were designated as Simulators. Reals and Simulators were given differential instructions before the administration of a second hypnotic induction procedure, which was accompanied by a task in which subjects were asked to relive each of three emotional experiences, i.e., fear, anger, and happiness. Reals were given instructions encouraging cooperation, while Simulators were instructed to try to convince a group of experienced hypnotists that they were deeply hypnotized, when, in fact, they would not be. "Physiological, overt-behavioral, and cognitive measures taken either during or following the relived-emotions task served as indices of Sarbin's organismic involvement construct. A post-experimental measure of the realness of subjects' relived emotional experience was regressed on these organismic indices in order to test Sarbin's assumption of a positive linear relationship between organismic involvement and belief-in imaginings, using data from the Real group only. Results indicated that, across all three emotions, the linear composite of organismic indices shared statistically significant amounts of variance with the criterion of experiential realness. Obtained amounts of shared variance ranged from 22% (during anger) to 55% (during happiness). These findings were interpreted as offering clear and robust support for Sarbin's theory of hypnosis. Suggestions for further research were offered. "The question of Real-Simulator differences was explored through several multivariate analyses of variance and covariance, using the organismic indices as dependent variables. These analyses were performed on the original sample of Reals and Simulators, and on two subsamples of Reals/Highs and Simulators/Lows which were created through the use of pre- and/or post-experimental exclusion criteria. Reals/Highs showed statistically higher levels of effort than did Simulators/Lows during all three emotions, as well as higher levels of skin conductance and finger temperature during anger. These findings were interpreted as being of theoretical and practical significance. Multiple replications of the physiological findings were recommended in order to assess the extent to which the skin conductance and finger temperature variables might be used in practical, i.e., forensic contexts" (p. 385-B).

Register, Patricia A.; Kihlstrom, John F. (1986). Finding the hypnotic virtuoso. International Journal of Clinical and Experimental Hypnosis, 34, 84-97.

Measures of hypnotizability based on the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) correlate only moderately with those based on the Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C). Ss (N = 148) scoring in the high range (10-12) on HGSHS:A were classified according to whether they scored in the "virtuoso" range (11-12) or not on a subsequent administration of SHSS:C. Significant group differences were found on items comprising the cognitive distortion subscale of HGSHS:A, whether assessed in terms of overt behavior or subjective impressions of success. The 2 groups also differed on global self-ratings of hypnotic depth and on those subscales of Field's Inventory Scale of Hypnotic Depth concerned with subjective feelings of loss of control, automaticity, transcendence of

normal functioning, and fluctuating depth. Assessments of hypnotizability are enhanced when investigators consider subjective involvement as well as behavioral measures of hypnotic response. This is particularly important when the more dissociative aspects of hypnosis are under scrutiny.

The correlation between Harvard Group and Stanford Scale scores is usually about  $r = .60$  (Bentler & Roberts, 1963; Coe, 1964; Evans & Schmeidler, 1966). This is much lower than one would expect ( $r = .82$ ), based on the tests' individual reliabilities (Evans & Schmeidler, 1966).

The authors developed a Table to show the cross-classification of Ss in terms of Harvard and SHSS:C. Only a minority (33%) of Ss scoring in the highest range of HGSHS:A also scored in the highest range on the SHSS:C (or 50% if cutting points are different).

The Absorption scale correlated  $r = .38$  ( $p < .001$ ) with the Harvard Scale, which fell to  $r = .31$  ( $p < .01$ ) when corrected for expansion of range. The correlation between Absorption and SHSS:C was  $.35$  ( $p < .001$ ).

The issue of predicting Stanford 'virtuosos' from Harvard 'virtuosos' was addressed. HGSHS:A predictor variables were used to determine which items determined whether or not one of the HGSHS:A 'virtuosos' (the 20% who scored 11-12) would also be a SHSS:C 'virtuoso.' It was found that 70% of the SHSS:C virtuosos, but only 53% of the nonvirtuosos, had reversible posthypnotic amnesia on the HGSHS:A. None of the ideomotor or challenge subscale items demonstrated this ability to predict group association. Although the 'virtuosos' differed from the 'nonvirtuosos' in self reported depth, none of the coding categories associated with the depth variable differentiated the groups; also, judges could not predict who would be a Stanford 'virtuoso' based on subjects' descriptions of depth following the Harvard scale administration.

The Experimenters also could not predict who among the Harvard 'virtuosos' would be classified as a Stanford 'virtuoso' based on either their Absorption Scale score or previous experience with hypnosis.

It was found that subjects' subjective experience of the suggestions for hallucinations, amnesia, and posthypnotic behavior (all considered to be cognitive alterations) were the most highly correlated with the subsequent total SHSS:C score. On the Field scale, which measures subjective experience, the most predictive items had to do with feelings of automaticity and loss of control (referred to as nonvoluntary behavior in other literature). Predicting SHSS:C score by 5 items (Harvard behavioral score, Harvard subjective score, Field total score, Tellegen Absorption total score, and self reported depth rating),  $r = .44$ . "The 5-element regression, employing only total scores, explained 17% ... of the variance of SHSS:C; thus, the feelings of subjective success accounted for the vast proportion (79%) of the explainable variance. For the 16 element regression, employing subscales derived from factor analysis of HGSHS:A and Inventory Scale of Hypnotic Depth, the cognitive subscale was dominant, accounting for 65.5% of explainable variance" (p. 92).

A discriminant function analysis employing the same five total score variables correctly classified 63.3% of the virtuosos.

In their Discussion, the authors suggest that investigators use subjective response as well as behavioral response when identifying hypnotic talent (virtuosos) for research. Particularly, the subjective experience of success seems to be important. Little is known, to date, about the determinants of that sense of success with hypnotic suggestions. "In part, they may relate to the 'classic suggestion effect' (K. S. Bowers, 1981; P. G. Bowers, 1982; Weitzenhoffer, 1974): the quasi-automatic, compulsory, involuntary quality which distinguishes hypnotic response from compliance with simple social requests. If so, then a direct assessment of perceived involuntariness might enhance the predictive validity of HGSHS:A even more. This is especially true for the perceptual-cognitive alterations which relate to Ss' capacity for dissociation" (p. 94).

The authors further recommend, "In those situations where HGSHS:A must stand alone for economic reasons, however, and especially where HGSHS:A is employed as a convenient preliminary screening device in the search for hypnotic virtuosos, it would seem that some assessment of the subjective experience of hypnosis would provide useful supplementary information at very little cost" (p. 94).

preliminary screening device in the search for hypnotic virtuosos, it would seem that some assessment of the subjective experience of hypnosis would provide useful supplementary information at very little cost" (p. 94).

Schacter, Daniel L. (1986). Amnesia and crime: How much do we really know?. American Psychologist, 41, 286-295.

Claims of amnesia occur frequently after the commission of violent crimes and can have a significant bearing on the outcome of criminal trials. This article considers the relation between amnesia and crime within the broader context of research on memory and amnesia and provides a critical evaluation of current knowledge concerning the issue. Particular attention is paid to the problem of distinguishing between genuine and simulated claims of amnesia. It is suggested that reliable data concerning the nature of amnesic episodes that occur after the commission of a crime are sparse, and that there is as yet little evidence that genuine and simulated amnesia can be distinguished in criminal cases. The results of several laboratory studies are summarized that indicate that feeling-of-knowing ratings distinguished between genuine and simulated amnesia under conditions in which psychologists and psychiatrists did not.

Stam, Henderikus J.; McGrath, Patricia A.; Brooke, Ralph I.; Cosier, Frances (1986). Hypnotizability and the treatment of chronic facial pain. International Journal of Clinical and Experimental Hypnosis, 34, 182-191.

The Carleton University Responsiveness to Suggestion Scale (CURSS) of Spanos, Radtke, Hodgins, Bertrand and Stam and Spanos, Radtke, Hodgins, Stam, and Bertrand (1983) was individually administered to a sample of 61 facial pain patients. The mean scores on the 3 CURSS suggestibility dimensions were higher than those of the college student norms. As in previous studies using the CURSS, however, objective scores were smaller when experienced involuntariness was taken into

account. Observer scores of overt responses were highly related to self-scores of overt responses. The CURSS also proved a good predictor of reductions in clinical pain following a psychologically based treatment program.

The CURSS has 7 items: 2 ideomotor (arm-levitation, arms moving apart); 2 motor-challenge (arm rigidity, arm immobility); and 3 cognitive (auditory hallucination, visual hallucination, amnesia). The CURSS yields 3 suggestibility scores: O = Objective (number of suggestions to which S made appropriate overt response; 0-7 range) S = Subjective (the degree to which S reports experiencing the subjective events called for; 0-21 range) O-I = Objective-Involuntariness (number of suggestions that were passed objectively and that were rated as involuntary to either a moderate or great degree; 0-7 range) VC = Voluntary Cooperation; items that are passed objectively and are primarily experienced as voluntary occurrences

They tested 61 patients in facial pain clinic, mean age 26 years, who were diagnosed with temporo-mandibular pain and dysfunction syndrome (TMPDS). This syndrome includes pain, limitations in mandibular movements, and sounds during condylar movements. 41 of the patients completed a cognitive behavioral pain treatment program (results reported elsewhere, in Stam, H. J., McGrath, P. A., & Brooke, R. I. The effects of a cognitive-behavioral treatment program on temporo-mandibular pain and dysfunction syndrome. *Psychosom. Med.*, 1984, 46, 534-545).

Patients rated degree they expected to be hypnotized on a visual analog scale. Expectations for becoming hypnotized were not significantly correlated with any of the dimensions, except for the CURSS:O observer-scored dimension ( $r = .29$ ). Age was also related to the CURSS:O observer-scored dimension ( $r = -.25$ ) as well as to the CURSS:S dimension ( $r = -.28$ ).

Several measures of treatment outcome were employed--change scores of weekly self ratings, and post-treatment ratings by the dental surgeon (worse, same, improved, alleviated).

"Whereas the CURSS:V-C dimension is not at all related to any of the outcome measures, the objective, subjective, and objective-involuntariness measures are highly and significantly correlated with the reduction in patients' peak pain scores and the posttreatment pain ratings. The correlations between measures of hypnotizability and pain reductions are not significant for the control group, though these are based on small sample size. Table 3 also indicates a lack of relationship between measures of hypnotizability and the weekly pain ratings. Stam et al. (1984a) point out that it may have been due to the relative instability of the global weekly ratings of pain versus the daily ratings obtained from the home logs that were used to calculate the peak pain scores" (p. 187).

Table 3 Correlation Coefficients between Dimensions of the CURSS and Reductions in Pain

Susceptibility Dimension Pain Reduction O S O-I V-C Measures

Pre-post .60\*\*(36) .51\*\*(19) .44\*(-.21) .18(.42) Peak Pre-post .19 -.01 .15 .07  
Weekly rated Posttreatment .54\*\*(-.05) .58\*\*(.26) .58\*\*(.01) -.02(.37) Surgeon's  
rating

Note: Correlations in parentheses are for the Waiting List Control group (N = 14; N = 10 for Peak Pain); all others are for combined treatment groups, N = 27.

\*p<.05 \*\*p<.01

In their Discussion, the authors note that this research is in accord with other studies that indicate that "objective responding and the experience of those responses involuntarily are not necessarily equivalent. ... Ss in both the laboratory and the clinic are almost twice as likely to pass suggestions when assessed overtly than by the combined objective-involuntariness criterion. ... [and] objective scores alone confound responses experienced as voluntary with those experienced as involuntary" (pp. 188-189). They report that earlier studies from their laboratory indicated that "only CURSS suggestibility dimensions, and not the VC dimension, correlated significantly with absorption and Field's (1965) Inventory Scale of Hypnotic Depth. ... [and] correlations between hypnotizability and reductions in pain were not due to compliance factors but were related to each of the other three ways of assessing hypnotizability" (p. 189).

"The objective, subjective, and objective-involuntariness dimensions were all significantly correlated with the reductions in peak pain and posttreatment ratings for the treatment groups but not for the control groups. These results replicate the laboratory demonstrations that hypnotizability is correlated with suggested analgesia regardless of the presence or absence of a hypnotic induction procedure (E. R. Hilgard & J. R. Hilgard, 1975; Spanos, Radtke-Bodorik, Ferguson, & Jones, 1979; Stam & Spanos, 1980). There is some evidence, however, that this depends on the hypnotic induction procedure being defined as a component of the analgesia testing situation (Spanos, Kennedy, & Gwynn, 1984).

"Despite the differential predictions between CURSS dimensions and pain reductions, there were no increases in the predictions of pain reductions when objective scores were corrected for involuntariness or when using subjective scores. (This was apparent for the combined treatment groups as well as for each group examined separately.) The reasons for this are not obvious and await further research" (p. 189).

The authors conclude from their research that the general practice of self-scoring hypnotizability scales that is used in laboratory research appears to be equally reliable in a clinical situation.

await further research" (p. 189).

The authors conclude from their research that the general practice of self-scoring hypnotizability scales that is used in laboratory research appears to be equally reliable in a clinical situation.

1985

Coe, William C.; Yashinski, Edward (1985). Volitional experiences associated with breaching posthypnotic amnesia. Journal of Personality and Social Psychology, 48 (3), 716-722.

Highly responsive hypnotic subjects classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia were compared during posthypnotic recall. Subjects reported their voluntariness after the experiment. Two contextual conditions were employed (2 x 2 design): a lie detector condition meant to create pressure to breach amnesia and a relax control condition. In contrast to earlier findings, the recall data showed that both voluntary and involuntary subjects breached under the lie detector condition compared with their counterparts in the relax condition; however, the degree of breaching was not great in any condition. The results are discussed as they relate to studies attempting to breach posthypnotic amnesia and characteristics of the voluntary-involuntary dimension

Kelly, Paul James (1985, November). The relationship between hypnotic ability and hypnotic experience (Dissertation). Dissertation Abstracts International, 46 (5), 1690-B.

"This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experiences were: dissociation, the experience of involuntariness, altered state effects, such as perceptual alterations and diminished reality sense rapport, transference-like involvement with the hypnotist, and relaxation. A 47-item scale, the Hypnotic Experience Questionnaire was developed to measure types of hypnotic experience. It was given to 484 subjects and then to a subsample of 272 students. When the scale was factored, four stable factors emerged: Nonconscious/Trance, Rapport, Relaxation, and Cognitive Rumination. A Group Profile Scale was also developed to measure students and when it was factor analyzed four factors were extracted: Hallucinations and Fantasies, Amnesias and Post-Hypnotic Compulsions, Motor Inhibition, and Direct Motor Suggestion. "Two statistical approaches were used to investigate the connections between hypnotic ability and hypnotic experience . Canonical analysis was used to identify the main relationships between hypnotic ability and hypnotic experience and factor analysis was used to explore the relationship among measures of hypnotizability and hypnotic experience. Two canonical variates from the canonical analysis were significant. The first variate was characterized by a dissociative-imaginative involvement process, and the second variate tapped a rapport-social compliance process. "When 25 variables, representing components of hypnotic ability and hypnotic experience, were factored, five factors were extracted. Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. The results of the factor analysis suggested that dissociative experience and altered state experience are related to hypnotic ability but rapport and relaxation are not. "The results of study, taken as a whole, suggest that relaxation and rapport may happen in the hypnotic situation, but neither experience is related to the condition of being hypnotized in any essential way. The results suggest that the hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. From a theoretical point of view, the results strongly supported Hilgard's theory, partially supported Shor's theory, and failed to support Edmonston's theory" (p. 1690).

point of view, the results strongly supported Hilgard's theory, partially supported Shor's theory, and failed to support Edmonston's theory" (p. 1690).

Neufeld, Victor; Lynn, Steven Jay; Jacquith, Leah; Weekes, John (1985, November). Fantasy style, imagination, and hypnotizability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

Authors discuss three fantasy styles: 1. Positive constructive daydreaming 2. Guilt / fear of failure 3. Poor attentional control. Fantasy style has been related to many personality variables, usually based on questionnaires.

They examined subjects in hypnosis and waking states using hypnotic dreams, Short Imaginal Processes Inventory, Tellegen Absorption, Betts QMI Imagery Vividness, Hypnosis (HGSHS and suggested dream) involvement, Wilson and Barber ICI, Nonvoluntary experience, Fantasy Proneness, Content of fantasies.

137 student volunteers participated in the study. 82 had HGSHS-A and hypnotic dream, and gave involuntariness ratings. Ss self-rated pleasant and unpleasant for hypnotic dreams. Experimenter rated dream for 1) positive emotion, 2) negative emotion, and 3) anxiety. Correlations were significant for female Ss, but not for male Ss.

#### **RESULTS.**

Fantasy-style, at least of negative affect, was consistent for waking and hypnotic states. Positive constructive fantasy correlated to HGSHS but the other two fantasy styles did not. [Other results reported are not included in this brief summary.]

Schlesinger, Jay Lawrence (1985). Hypnotizability in relation to success in learning biofeedback training: Attentional involvement (Dissertation, Adelphi University). Dissertation Abstracts International, 45 (n8-B), 2701. (Order No. DA 8424937)

"This study investigated the role of attentional focus in the relationship between hypnotizability and success in learning two types of biofeedback training. 40 female college students, aged 18-25, were measured for hypnotic responsiveness, and given one session of EMG biofeedback and one session of temperature biofeedback. For the biofeedback training, 20 Ss received written instructions designed to establish a passive, non-volitional attentional focus on the feedback signal, and 20 received written instructions intended to establish an active, volitional attentional focus on the feedback signal.

"It was hypothesized that level of hypnotizability would be positively related to success in learning EMG and temperature biofeedback training for the Ss given passive, non-volitional attentional instructions, while level of hypnotizability would be negatively related to success in learning biofeedback training for the Ss given active, volitional attentional instructions. It was also hypothesized that higher hypnotizables would perform better with temperature biofeedback than with EMG

biofeedback, and that lower hypnotizables would perform better with EMG biofeedback than with temperature biofeedback.

"The hypotheses were not supported, nor was any overall relationship between level of hypnotizability and success in learning biofeedback demonstrated. There was support to suggest that an active, volitional attentional focus on the biofeedback signal was most adequately maintained by the 20 Ss given the active volitional instructions. Clinical implications of these findings and directions for future research were discussed" (p. 2701).

-ings and directions for future research were discussed" (p. 2701).

Stone, Jennifer A.; Lundy, Richard M. (1985). Behavioral compliance with direct and indirect body movement suggestions. Journal of Abnormal Psychology, 94 (3), 256-263.

Investigated the effectiveness of 2 types of suggestions in eliciting body movement by presenting 96 high-, medium-, and low-susceptible undergraduates, in hypnotic or nonhypnotic conditions, with either of 2 series of body movement suggestions. The indirect suggestions were designed to represent the approach of M. H. Erickson (see PA, vol 60:11116 and 12262) and resulted in greater compliance in the hypnotic condition. Direct suggestions resulted in greater compliance in the nonhypnotic condition. Susceptibility to hypnosis was related to compliance in the hypnosis condition, but no interactions were found between susceptibility and type of suggestion. Sense of volition in responding was unrelated to the major findings. Discussion of the results includes a call for the accurate reporting of the wording of hypnotic suggestions in future research.

1984

Crabtree, Adam (1984, October/1986). Explanations of dissociation in the first half of the twentieth century. In Quen, Jacques M. (Ed.), Split minds/split brains (pp. 85-108). New York: New York University Press. (Based on symposium in Bear Mt., N.Y., by Section on the History of Psychiatry of Cornell University Medical Center)

In 1907 Morton Prince, Editor of Journal of Abnormal Psychology, introduced a symposium by listing 6 meanings of subconscious: 1. that portion of our field of consciousness which is outside the focus of attention 2. (Janet's idea) - split off ideas which may be isolated sensations like the lost tactile sensation of anesthesia, or maybe aggregated into groups or systems. The author quotes Janet as stating that "they form a consciousness coexisting with the primary consciousness and thereby a doubling of consciousness results" (p. 87). The primary consciousness is usually dominant, but sometimes is reduced under exceptional conditions (e.g. automatic writing). 3. the subconscious self or hidden self -- a part of every human, not just seen in psychopathology; this is a personalized entity; every mind has a double, with the unconscious self having powerful effects on feelings, thoughts, and reactions of the conscious self 4. extends #3 to include not only ideas that remain active below

surface but also those which are inactive -- forgotten or out of mind 5. Frederic Myers' concept of the 'subliminal self' which had 3 functions:

- a) inferior - seen in processes of dissociation
- b) superior - seen in works of genius, arising from 'subliminal rush' of information, feelings, and thoughts which lie below consciousness
- c) mythopoeic - the unconscious tendency to create fantasies 6. physiological meaning, e.g. William Carpenter's 'unconscious cerebration' in which unconscious phenomena are interpreted in terms of pure neural processes unaccompanied by mental activity.

Prince suggested some redefinitions to clarify unconscious and subconscious. He would replace Janet's subconscious with co-conscious and reserve unconscious for physiological processes that lack the attributes of consciousness. Prince noted that co-conscious ideas have been called unconscious (e.g. by Freud) but said that is confusing and to be avoided.

"Coconscious ideas include states we are not aware of because they are not the focus of our attention, and also pathologically split-off and independently active ideas or systems of ideas, such as occur in hysteria and reach their most striking form in co-conscious personalities and automatic writing.

"Prince prefers the term coconscious to Janet's subconscious for two reasons. First, because it expresses the simultaneous coactivity of a second consciousness. And second, because the coactive ideas or idea systems may not be outside the awareness of the personal consciousness at all. They may be recognized by the personal consciousness as a distinct consciousness existing alongside it.

"Thus, through his redefinition of terms, Prince makes simultaneous activity of two or more systems of consciousness in one individual the key element in dissociation. He thereby moves the issue of amnesia or lack of awareness by one system of another into the background, making it a secondary, nonessential element. Prince was one of the few to provide a theoretical framework for dissociation in which any combination of interawareness among the coconscious systems was possible" (p. 91). Two researchers at the turn of the century came to opposite conclusions about the nature of the Subconscious Self that every human has. Morris Sidis saw it as "a brutelike consciousness with a tendency toward personalization. Frederic Myers held that it included those functions and much more, being the source of all that is human, including the highest intuitive powers" p. 96.

Bernard Hart, in 1910, did an analysis of Janet and Freud. Janet's work is essentially descriptive: "he is always talking about a consciousness which manifests itself in a way we can \_perceive\_, whether by listening to it talk, reading its written communications, or watching its movements" (p. 97). However Janet's spatial model of dissociation cannot explain the presence of the same material (e.g. memories) in two or more dissociated systems. According to Hart, Freud offered the conceptualization that Janet lacked, in his idea of the Unconscious .

Freud's Unconscious is not in competition with Janet's subconscious. "Janet's subconscious is the arena of dissociated phenomena which manifest in observable form as elements coactive with the personal self. Freud's unconscious is a

conceptual, nonobservable construction put forward to explain certain facts of human experience. In this way Hart equates the unconscious with the atomic theory in physics or the theory of heredity in biology" p. 99. But Hart also thought Freud's theory did not do justice to dissociative phenomena. Not only do psychoanalysts show little interest in double personality or multiple personality, they also neglected dissociation on the phenomenal level.

In 1915 Freud denied the existence of a second consciousness and wrote, "there is no choice for us but to assert that mental processes are in themselves unconscious, and to liken the perception of them by means of consciousness to the perception of the external world by means of the sense organs" (p. 101). Janet claimed that Freud had simply taken over his own system and given it a new terminology, and in 1924 Freud wrote an angry rebuttal. For him, "dissociated systems are simply separate groups of mental but unconscious elements. As our consciousness turns now to one group, now to another, as a searchlight shines now on one object and now on another, the dissociated groups manifest in conscious life. ... There exists no doubling of consciousness" p. 102.

Jung's ideas were closer to those of Janet, and like Janet he made dissociation a key concept in his theory. The complex is unconscious, has an archetypal core clothed in personal experience, is like a self-contained psyche within the big psyche, sometimes called a fragmentary personality dwelling inside us. Dissociation for him meant being cut off from the Ego, which is the center of an individual's field of consciousness. "Dissociated or autonomous complexes are those which have no direct association with the ego" (p. 103). If complexes are charged with enough energy they will become manifest--as a neurotic symptom, as projected into idea of a god or demon, or perhaps as an alternate personality. Therefore Jungian treatment aims at assimilating dissociated complexes into the ego.

center of an individual's field of consciousness. "Dissociated or autonomous complexes are those which have no direct association with the ego" (p. 103). If complexes are charged with enough energy they will become manifest--as a neurotic symptom, as projected into idea of a god or demon, or perhaps as an alternate personality. Therefore Jungian treatment aims at assimilating dissociated complexes into the ego.

Crouse, Eric; Kurtz, Richard (1984). Enhancing hypnotic susceptibility: The efficacy of four training procedures. American Journal of Clinical Hypnosis, 27, 122-136.

In this study, we have compared the effects on hypnotic susceptibility of several components of training procedures based on a social learning model, which have been reported to be successful in enhancing hypnotic susceptibility. These included: 1) attitude-conception of hypnosis information, 2) involvement instructions, 3) goal-directed fantasy instructions, and 4) practice vs. no practice in responding to hypnotic suggestions. A 3 x 2 x 2 repeated measures factorial design was used for the experiment with 60 female volunteers serving as subjects in the study. Contrary to expectations, no differential treatment effects were obtained on either objective or subjective measures of hypnotizability. Furthermore, it was questionable whether or

not any of the three information-based components even produced gains in hypnotic susceptibility. None produced clinically significant gains. They also were not found to alter either the subjects' attitudes or their use of hypnosis-related skills. Similarly, practice was found to be ineffective in enhancing responsiveness to suggestions. Taken as a whole, the results of this study suggest that the gains in hypnotic susceptibility reported for social learning-type training procedures may be due to causes other than those posited by social learning theory.

Diamond (1977) posited 3 core components to modification procedures: attitudinal and set factors, cognitive strategy factors, and optimal learning factors (specific ways subjects are taught the internal responses).

"The present study was undertaken to more fully clarify the extent to which each of the critical components hypothesized by Diamond contributes to increasing susceptibility. It was predicted that subjects receiving attitude-conception of hypnosis information and subjects receiving involvement instructions would show a significantly greater gain in hypnotizability than Ss receiving goal-directed fantasy instructions. Secondly, it was predicted that a significantly greater gain in subjects' hypnotizability would result from an opportunity to practice responding to hypnotic suggestions when coupled with involvement instructions than when accompanied by goal-directed fantasy instructions or attitude-conception of hypnosis information" (p. 125).

A revised SHSS:C was used; it deleted words that explicitly suggested goal directed fantasies (GDF's) on several items: hand lowering, moving hands apart, taste hallucinations, arm rigidity, arm immobilization. Experimenters used audiotaped presentation. Subjects in 3 of 6 experimental groups were also given opportunity to practice 30 minutes on 3 occasions spaced no more than one week apart. They were given 2 practice trials on each of 5 hypnotic suggestions taken from several different scales.

"While differential treatment effects were not found, there was a general facilitation of hypnotic responsiveness for all Ss across treatment conditions on both objective and subjective hypnotizability measures. The mean change in the objective hypnotizability score for all subjects was  $+ .68$ ,  $...p < .001$ ; was  $+ .68$ ,  $...p < .001$ ; the corresponding mean change in the subjective hypnotizability scores was  $+ 3.11$   $... p < .001$ . Although statistically significant, neither of the shifts appear to indicate clinically significant shifts in hypnotic responsiveness" (p. 129). The changes in the positive direction in hypnotizability were not correlated with hypnotizability. Subjects appear to change in their conceptualization of hypnosis, in the direction of it being more a self-induced phenomenon ( $p < .001$ ).

In their Discussion, the authors write, "Taken as a whole, results of this study challenge assumptions which have been made about how training procedures based on a social learning model affect gains in hypnotic susceptibility" (p. 131). Each experimental manipulation was intended to influence a mediating variable, and that apparently did not happen. Teaching subjects to use GDFs on a few items did not generalize so that subjects would generate GDFs on novel items. The results suggest

"caution against assuming that social learning base training procedures are effective in altering subjects' attitudes and/or their use of skills thought to mediate hypnotic responsiveness" (p. 133). Nevertheless, the correlational data support previous studies that relate hypnotizability to the mediating factors under investigation.

Continuing their Discussion, the authors write, "Clearly, more attention should be paid in future studies to assessing changes in mediating variables produced by such training procedures. This is particularly important in terms of subjects' use of GDF's and their use of cognitive strategies to increase the extent of their involvement in the hypnotic experience. It is significant that in this study neither involvement instructions nor GDF instructions were found to alter subjects' use of cognitive strategies. Changes in these skill-related factors need to be demonstrated if social learning based training procedures are to be proven effective in altering subjects' hypnotic abilities rather than simply in raising subjects to their optimal level of responsiveness.

"One explanation which has been offered for the reported success of such training procedures is that they work by changing subjects' attitudes, motivation and/or expectations of hypnosis while leaving any aptitudinal component to hypnosis unaltered (Perry, 1977). From this point of view the gains in susceptibility reported for such procedures result from subjects moving closer to their optimal or 'plateau' level of responsiveness rather than from real changes in subjects' hypnotic abilities" (p. 134).

Alternatively, it is possible that the increases observed following training programs have something to do with the hypnotist-subject relationship. For example, increases in hypnotizability are more modest when the training is given in written instructions than when it is given in person by a hypnotist.

Kelly, Paul James (1984, December). The relationship between hypnotic ability and hypnotic experience. Newsletter of Division 30, Psychological Hypnosis, of the American Psychological Association, 5.

This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experience were: dissociation, the experience of involuntariness; altered state effects, such as perceptual alterations and diminished reality sense; rapport, transference-like involvement with the hypnotist; and relaxation. A sample of 230 students was given the HGSHS:A, a group version of the SHSS:C, and the Hypnotic Experience Questionnaire (Kelly, 1984), a 47-item multidimensional scale of hypnotic experience. Items were taken from these tests to form 11 hypnotic ability variables (Positive Hallucinations, Dreams and Regressions, Post- Hypnotic Compulsions, Amnesia (HGSHS:A), Amnesia (SHSS:C), Arm Rigidity, Arm Immobilization, Other Motor Inhibitions, Head Falling, Moving Hands Together, and Hand Lowering). Fourteen hypnotic experience variables were also formed (Generalized Dissociative Effects, Dissociative

Immobilization, Other Motor Inhibitions, Head Falling, Moving Hands Together, and Hand Lowering). Fourteen hypnotic experience variables were also formed (Generalized Dissociative Effects, Dissociative Inhibition, Trance, Unawareness,

Transference-like Involvement, Trust, Friendliness, Physical Relaxation, Mental Relaxation, Imagery Presence, Imagery Vividness, Imagery Detail, Self Consciousness, and Analytic Thoughts). The 25 variables were intercorrelated and factored with principal axis factoring. Five factors with eigenvalues greater than 1 were extracted and rotated to varimax criteria. These factors, which accounted for 54.4 percent of the variance, were called: Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. Hypnotic ability variables loaded significantly on three of the factors (Imaginative Involvement, Ideomotor Response, and Cognitive Inhibition) and these three factors also tapped some aspect of altered state experience and/or dissociative experience. It was concluded therefore that dissociative experience and altered state experience are related to hypnotic ability. The remaining two factors, Rapport and Relaxation, showed significant loadings only for rapport variables and relaxation variables, respectively. Neither of these two factors were related to any of the traditional measures of hypnotic ability or to the experience of dissociative effects or altered state effects. The results of this study suggest that rapport and relaxation may happen in the hypnotic situation but neither experience is related to the condition of being hypnotized in any essential way. The hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. The results also raise questions about Edmonston's (1981) theory that relaxation is the essence of hypnotic responsiveness. The finding that the experience of relaxation is unrelated to hypnotic ability is more congruent with Hilgard's (1977) view that relaxation is a nonhypnotic process.

Lynn, Steven Jay; Nash, Michael R.; Rhue, Judith W., Frauman, David C.; Sweeney, Carol A. (1984). Nonvolition, expectancies, and hypnotic rapport. Journal of Abnormal Psychology, 93 (3), 295-303.

Prior to hypnosis, subjects were informed either that hypnotizable subjects can resist motoric suggestions or that such control does not characterize good hypnotic subjects. During hypnosis, susceptible and simulating subjects received countering suggestions involving inhibiting suggestion-related movements. Susceptible subjects' responses were found to be sensitive to prehypnotic normative information. There was a corresponding tendency for reports of involuntariness to be sensitive to the expectancy manipulation. Furthermore, subjects were able to feel deeply hypnotized and to rate themselves as good subjects yet concomitantly experience themselves as in control over their actions when normative information supported this attribution. Reports of suggestion-related sensations but not imaginative involvement were associated with movements in response to countersuggestion. Simulators were unable to fake susceptibles' reports of sensations and involuntariness. However, for all subjects, movements paralleled expectancies about appropriate response, supporting the hypothesis that involuntary experiences are sensitive to the broad expectational context and are mediated by active cognitive processes. Also, rapport with the hypnotist was found to be a factor. Susceptible subjects with highly positive rapport resolved hypnotic conflict, in part, by achieving a compromise between meeting normative expectations and complying with the hypnotist's counterdemand.

**Pekala, Ronald J.; Kumar, V. K. (1984). Predicting hypnotic susceptibility by a self-report phenomenological state instrument. American Journal of Clinical Hypnosis, 114-121.**

**In an attempt to predict hypnotic susceptibility (as measured by the Harvard Group Scale of Hypnotic Susceptibility, HGSHS) the phenomenological experiences of an hypnotic induction (HI) procedure and a baseline comparison condition (eyes closed, EC, sitting quietly) were assessed. After each experience the subjects (n=217) completed the Phenomenology of Consciousness Inventory (PCI), a self-report phenomenological state instrument, dealing with that condition. Step-wise multiple regression and discriminant analyses were then performed on data using the subject's HGSHS score as the dependent variable and the PCI (sub)dimensions as the independent variables. Regression analyses that held up under cross-validation during HI suggest that the PCI may be an appropriate instrument for predicting susceptibility. The possible clinical usefulness of this approach is discussed.**

**Spanos, Nicholas P.; Tkachyk, M.; Bertrand, L. D.; Weekes, J. R. (1984). The dissipation hypothesis of amnesia: More disconfirming evidence. Psychological Reports, 55, 191-196.**

**Hypnotic subjects were administered a suggestion to forget a previously overlearned word list. Before cancellation of the suggestion they were challenged twice to try and recall the words. Subjects in one group received a second challenge immediately after response to the first. Those in the second group were given a 15-min. delay before their second challenge. Subjects in both groups showed less amnesia after the second challenge than after the first, but the length of delay between challenges had no effect on amnesia scores. These findings are inconsistent with the hypothesis that hypnotic amnesia involves an involuntary blockage of memory that decays spontaneously with time.**

**Zamansky, Harold S.; Bartis, Scott P. (1984). Hypnosis as dissociation: Methodological considerations and preliminary findings. American Journal of Clinical Hypnosis, 26, 246-251.**

**Three criteria are proposed to be met by any experience labeled as "dissociation." A preliminary experiment is described that illustrates one way in which two of these criteria may be operationalized, and that assesses the relationship between successful performance on the two criteria and hypnotic susceptibility. The results are viewed as consistent with Hilgard's (1977) hypothesis that hypnotic susceptibility and the ability to dissociate are positively related.**

**The authors propose that for dissociation to be present: "1) The individual must be engaged in two or more cognitive processes concurrently. 2) These processes must occur simultaneously, i.e., without recourse to alternation between them. 3) One of these processes must be perceived (by the subject) to occur below the level of**

conscious awareness, i.e., must seem to be autonomous or nonvolitional" (p. 247). In this study they focus on the first two criteria, as well as the relationship between ability to perform two cognitive tasks simultaneously and Subjects' hypnotizability. The authors used a dichotic listening task, with Ss instructed to listen to both auditory inputs at once. One input was a short story that was to be followed with 12 multiple choice questions. The other ear received 3 tones every 2 seconds (the higher tone 60% of the time, lower tone 40% of the time) and S was to press a button in response to the low tones. Speed of presentation of tones was intended to reduce the opportunity for alternating back and forth between tasks.

of tones was intended to reduce the opportunity for alternating back and forth between tasks.

Of 28 volunteer students, 22 passed criteria for accuracy on both tasks when performed singly: 10 high hypnotizables (Harvard Group Scale of Hypnotic Susceptibility; HGSHS > 8); 10 medium hypnotizables (HGSHS 5-8); and 2 low hypnotizables who were dropped from the data analysis. They were considered 'dissociators' if they met the criterion of passing 9 or more items of the story and simultaneously having fewer than 15% errors on the tones, on two separate trials with two different stories.

"Of the 20 subjects, four scored above criterion on both test trials and were classed as dissociators; these four also scored as highly hypnotizable on the HGSHS. Accordingly, 40% of the highly hypnotizable subjects met our criteria, while not one of the moderately hypnotizable subjects reached this level of performance" (p. 249).

In their Discussion, the authors wrote, "The results demonstrated that highly hypnotizability Ss are significantly better able to attend to two inputs simultaneously than are moderately hypnotizability Ss. These results provide preliminary empirical evidence that dissociative ability, assessed independently of hypnosis, may be an important factor underlying hypnotic behavior" (p. 249).

The authors speculated about why only 40% of the highly hypnotizable people performed successfully, suggesting that it may be because they had misclassified Ss with the HGSHS which may be less demanding than other scales, or that "while dissociation represents an important cognitive factor in hypnosis, the Harvard measures mostly ideomotor performance" (p. 250). They suggest using a hypnotizability scale that uses more cognitive items to select highly hypnotizable Subjects who would demonstrate a high degree of dissociative ability. The other possibility that they mention is that dissociation may be only one of several alternate paths to hypnosis, citing Hilgard (1965).

The Experimenters added two control groups, one given the stories without the competing tones, the other given identical questions but without actually hearing the stories. The first group answered a mean of 9.7 and 8.6 questions correctly; the second control group answered a mean of 2.9 and 3.8 questions correctly

1983

Levitt, Eugene E.; Baker, Elgan L. (1983). The hypnotic relationship--another look at coercion, compliance and resistance: A brief communication. International Journal of Clinical and Experimental Hypnosis, 31, 125-131.

The purpose of the present investigation was to assess the ability of hypnotic Ss to voluntarily resist neutral suggestions on a monetary reward incentive. The results were ambiguous; Ss resisted with a mean of 1.2 of 2 suggestions each. Postexperimental interviews disclosed that all Ss felt that the instructions to resist were asking them to be disloyal to the hypnotist or to betray him. Ability to resist was positively correlated with Ss' impressions of the "resistance instructor" and tended to be negatively correlated with the impression of the hypnotist. These findings are interpreted to suggest support for an interactional conception of the hypnotic state.

Lynn, Steven Jay; Nash, Michael R.; Rhue, Judith W.; Frauman, David; Stanley, Scott (1983). Hypnosis and the experience of nonvolition. International Journal of Clinical and Experimental Hypnosis, 31 (4), 293-308.

Consistent with theoretical perspectives on hypnosis and the experience of nonvolition (e.g., Arnold, 1946; Hilgard, 1977, 1979; Spanos, 1981, 1982), hypnotic Ss, when faced with a conflict between experiencing motoric suggestions and inhibiting movements, resolved the conflict by following the hypnotist's suggestions. Imagining and simulating Ss, by and large, showed no movements. Hypnotic Ss' reports of their experience reflected more conflict, sensations, imaginative involvement, and involuntariness than simulating Ss. Arnold's (1946) theory was not supported in that imagining Ss reported feeling as absorbed and involved in imaginings as hypnotic Ss but resisted responding to suggestions. The findings were more compatible with theoretical accounts which emphasize dissociation (Hilgard, 1977, 1979) and the importance of the experimental context in determining the experience of nonvolition (Spanos, 1981).

McConkey, Kevin M. (1983). Behaviour, experience, and effort in hypnosis. Australian Journal of Clinical and Experimental Hypnosis, 11, 73-81

Subjects were administered the Harvard Group Scale of Hypnotic Susceptibility, Form A, and were afterwards asked to rate the degree to which they experienced the items; subjects also scored their behavioural performance on the items. Data were analyzed to explore the relationships among behaviour, experience, and effort. Findings indicated a significant positive relationship between behaviour and experience on all of the HGSHS:A items, a significant negative relationship between behaviour and effort on the ideomotor items, and a significant positive relationship between behaviour and effort on the cognitive items. A similar pattern was observed between experience and effort. Also, subjects of varying HGSHS:A responsivity differed in terms of overall experience of the scale but not in terms of the overall amount of effort that they expended. Implications of the data are discussed in terms of the factors influencing subjects' experiential response and behavioural performance as well as the attributions that they make concerning effort during hypnosis.

**Bowers, Patricia G. (1982). The classic suggestion effect: Relationships with scales of hypnotizability, effortless experiencing, and imagery vividness. International Journal of Clinical and Experimental Hypnosis, 30 (3), 270-279.**

**How well the Stanford Hypnotic Susceptibility Scales assess what Weitzenhoffer (1978) terms the "classic suggestion effect" is addressed by developing an index of nonvolitional behavior (N-VB) for a group form of the Stanford Hypnotic Susceptibility Scale, Form C of Weitzenhoffer and Hilgard (1962) given to 43 Ss. The N- VB index, reflecting the classic suggestion effect's dual criteria of both behavioral responsiveness to suggestion and nonvolition ratings, was correlated highly with the traditional scoring of the group SHSS:C and moderately with the Harvard Group Scale of Hypnotic Susceptibility, Form A. Effortless experiencing of imagination and imagery vividness relate similarly to traditional and N-VB scores of hypnotizability. In addition, the relationship between involuntary ratings and passing and failing an item of the group SHSS:C was examined for each of the 10 items. There was a significant relationship for 7 of the items.**

**Schuyler, Bradley A. (1982). Further investigation of volitional and nonvolitional experience during posthypnotic amnesia (Dissertation, California School of Professional Psychology, Fresno). Dissertation Abstracts International, 44 (n6-B), 1977. (Order No. DA 8324472)**

**"Electrodermal responses were compared between highly responsive hypnotic Ss who were classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia. Three contextual conditions were employed: Two were meant to create pressure to breach posthypnotic amnesia (lie detector instructions alone or with feedback that Ss had been detected as not having told all they could remember); the other provided feedback, in addition to the lie detector instructions, that Ss had told all they could remember. The recall data confirmed earlier findings of Coe and Yashinski and showed that voluntary and involuntary Ss did not differ in response to the contextual conditions. However, lie detector instructions alone did not create pressure to breach as in previous studies. In addition, electrodermal results were insignificant. The results are discussed as they relate to (a) amnesia, (b) the physiological detection of deception and physiological activation, (c) the voluntary/involuntary classification of Ss, and (d) theories of hypnosis" (p. 1977).**

**Spiegel, David; Tryon, Warren W.; Frischholz, Edward J.; Spiegel, Herbert (1982). Hilgard's illusion. Archives of General Psychiatry, 39 (8), 972-4.**

**Examines E. R. Hilgard's (see PA, Vol 68:11932) critique of the hypothesis that eye roll (ER) is related to hypnotizability, clarifying the nature of the data relevant to the ER hypothesis. The authors contend that there are a number of factual errors in Hilgard's article: his (1) explanation of the procedure used in determining the Hypnotic Induction Profile (HIP) grades, (2) characterization of the HIP as a single-item test, and (3) his contention that the levitation score is the sole determinant of manifest hypnotic response. (9 ref.)**

1981

Bowers, Kenneth (1981). Has the sun set on the Stanford Scales?. American Journal of Clinical Hypnosis, 24, 79-88.

There have been recent expression of concern regarding the adequacy of the Stanford Scales of Hypnotic Susceptibility. Concern about the Scales' utility involve the fact that they do not explicitly assess the experience of nonvolition that is classically associated with the concept of suggestion. Concern about the Scales' validity suggest that the individual differences they assess are not clinically relevant. A review of the available literature shows that neither of these concerns stands up to inspection, and that the Stanford Scales have a crucial role to play in both laboratory and clinical contexts

Gross, Meir, M. D. (1981). Hypnosis for dissociation -- diagnostic and therapeutic. Journal of the American Society of Psychosomatic Dentistry and Medicine, 28 (2), 49-56.

Dissociative disorders might be at times very difficult to diagnose and treat, especially since they are very similar to epilepsy in general and to temporal lobe epilepsy in particular. Amnesia, fugue, changing personality and depersonalization are part of both disorders. Patients who suffer from dissociative disorders might be diagnosed and treated for epilepsy with anticonvulsive medications without any beneficial results. These patients are labeled as epileptics and have to face the social stigmata associated with being epileptic. The wrong label could even reinforce the sick role and make it become fixed and chronic.

-lusive medications without any beneficial results. These patients are labeled as epileptics and have to face the social stigmata associated with being epileptic. The wrong label could even reinforce the sick role and make it become fixed and chronic.

Hypnosis was used to diagnose the dissociative disorder by using the hand levitation technique for the differential diagnosis. It was found by the author that patients who suffer from dissociative disorders would get into spontaneous hypnotic trance during the hand levitation. Hypnosis was used also for successful therapy of these patients.

Seven cases are presented in which the hand levitation technique was used to diagnose the dissociative disorder. They were also treated by hypnotherapy. Their treatment by hypnosis is discussed. The purpose of this paper is to introduce the hand levitation technique for the differential diagnosis of dissociative disorder and to emphasize the effectiveness of hypnotherapy in the treatment of this disorder. Sorting out the cases of dissociative disorders from the epileptics is very important clinically, since it can save many patients from the anguish of having to take anti-convulsants unnecessarily and having to face the social stigmata of being labeled as epileptic.

1980

Hilgard, Ernest R. (1980, October). Hypnotic modification of sensitivity and control. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Chicago.

The author presents a factor analysis of several scales in the hypnosis domain: HGSHS:A, Wilson-Barber CIS, Stanford Hypnotic Susceptibility Scale Form C, Questionnaire on Mental Imagery (Sheehan's modification of Betts) and the Tellegen- Atkinson Absorption Scale. Scales were broken down into components first. He didn't report all of the factors, but shows how these tests fall on a graph defined by Factor 1 (Amnesia/Cognitive) and Factor 4 (Absorption/Imagery). "Capacity for fantasy and amnesia are so different that hypnosis probably includes both."

Hilgard concludes that he doesn't like a state theory for hypnosis or the idea of "trance" because it is unidimensional. He prefers "dissociation" because we think of it as a continuum. Even Highs differ one from another in the nature of their responses. Altered- state-of-consciousness theories don't readily explain partial dissociation (e.g. persistence of a suggestion such as arm rigidity after hypnosis is terminated; or hysterical paralysis).

Weitzenhoffer, Andre M. (1980). Hypnotic susceptibility revisited. American Journal of Clinical Hypnosis, 22, 130-146.

The concept and measurement of hypnotic susceptibility are re-examined in their relation to hypnotizability, hypnotic depth and suggestibility. The Stanford Scales and similar instruments are found to have failed to take into account essential features defining traditional hypnosis and suggestibility and to have created confusion in the scientific inquiry into hypnotism. Other available measures have not been particularly successful, but some bear further attention. Recent claims that hypnotizability can be trained have failed to distinguish between hypnotizability proper and accessory processes, leaving some question about what is actually being trained. Possible future directions of work on susceptibility are considered. Attempts to distinguish between 'clinical' and 'laboratory' hypnotizability are examined and found to have been premature and loosely based on facts.

'clinical' and 'laboratory' hypnotizability are examined and found to have been premature and loosely based on facts.

1978

Bowers, Patricia G. (1978). Hypnotizability, creativity and the role of effortless experiencing. International Journal of Clinical and Experimental Hypnosis, 26, 184-202.

Creative people and highly hypnotizable people describe their experience of finding creative solutions or responding to hypnotic suggestions as "effortless." It is suggested that receptiveness to subconscious work accounts for the experience of effortlessness in both tasks. An experiment using 32 high and low hypnotizable men and women was designed to explore the hypothesis that the aptitude for such

effortless experiencing accounts for the relationship found between creativity and hypnotizability.

Analyses of variance indicate highly significant effects of level of hypnotizability on composite scores reflecting effortless experiencing of several tasks and creativity. Intercorrelations of these indices are about .60. As predicted, effortless experiencing accounts for much of the relationship between high versus low hypnotizability and composite creativity. The role of imagery vividness and of absorption in both hypnotizability and creativity were also explored.

1977 Anderson, J. W. (1977). Defensive maneuvers in two incidents involving the Chevreul pendulum: A clinical note. International Journal of Clinical and Experimental Hypnosis, 25, 4-6.

"Hypnosis frequently facilitates increased access to the unconscious. In both of these cases, the hypnotized subject gained contact with a thought which otherwise would likely have remained out of awareness. Then the ego quickly resorted to defensive maneuvers in order to deny the thought" (p. 6).

Erickson, Milton H.; Rossi, Ernest L. (1976). Two level communication and microdynamics of trance and suggestion. American Journal of Clinical Hypnosis, 18, 153-171.

The authors provide the transcript and commentaries of an hypnotic induction and an effort to achieve automatic writing. An unusual blend of Erickson's approaches to two level communication, dissociation, voice dynamics and indirect suggestion are made explicit in the commentaries. The junior author offers a 'context theory of two level communication' that conceptualizes Erickson's clinical approaches in terms consonant with Jenkins' (1974) recent contextual approach to verbal associations and memory. A summary of the microdynamics of Erickson's approach to trance induction and suggestion is outlined together with a utilization theory of hypnotic suggestion.

Spanos, Nicholas P.; Spillane, Jeanne; McPeake, John (1976). Cognitive strategies and response to suggestion in hypnotic and task-motivated subjects. American Journal of Clinical Hypnosis, 18, 254-262.

Thirty-two male and 32 female subjects, exposed to an hypnotic induction or task-motivational instruction, were administered either three suggestions which provided a cognitive strategy (i.e., a goal-directed fantasy, GDF) for experiencing suggested effects, or three suggestions that did not provide such a strategy. Subjects provided with GDF strategies were more responsive overtly and subjectively to two out of the three suggestions. Subjects in the No GDF Strategy treatment who spontaneously devised their own goal-directed fantasies were more responsive to suggestions than

subjects who failed to devise such a strategy. These results support the contention that goal-directed fantasy helps both hypnotic and non-hypnotic subjects experience suggested effects.

**1974**

Weitzenhoffer, Andre M. (1974). When is an 'instruction' an 'instruction?'. International Journal of Clinical and Experimental Hypnosis, 22 (3), 258-269.

In the course of validating with 100 undergraduate Ss the concept of a "classical suggestion-effect" (i.e., the existence of a class of nonvoluntary behaviors elicited by communications intended to serve as traditional "suggestions"), evidence was incidentally obtained showing that many "instructions" given to presumably hypnotized Ss also function like "suggestions." In these circumstances it is not possible to state a priori that a verbal communication will function as an "instruction" rather than as a "suggestion." Such a statement can be made with certainty only a posteriori, on the basis of the nature of the resulting behavior. The implications of this finding for research and for the clinical uses of hypnotic suggestion are discussed. 1957

Weitzenhoffer, Andre M. (1957). Posthypnotic behavior and the recall of the hypnotic suggestion. Journal of Clinical and Experimental Hypnosis, 5 (2), 41-58.

1. Posthypnotic phenomena may be spontaneous or suggested in origin. Although no single mechanism appears to exist which will account for all of the spontaneous manifestations, their explanations are relatively straightforward. On the other hand, suggested posthypnotic phenomena are not so readily dealt with.

2. ... It seems likely that a relation exists between posthypnotic suggestions and waking instructions of the everyday variety; however, lack of basic information regarding the retention and activation of the latter has made this line of approach unproductive to date. Nor is it possible to talk of posthypnotic phenomena as learned if one regards the posthypnotic signal as stimulus and the suggested act as response. The definition of learning excludes this case because of the presence of hypnosis at the time the response is acquired. In addition, the acquisition and evocation of the posthypnotic effect does not follow any standard paradigm for learning.

3. If, however, one views the posthypnotic suggestion as a whole as being the stimulus, and the act of subjectively, if not objectively, giving reality to the content of the suggestion as the response, then suggested posthypnotic phenomena can be fitted within the framework of modern learning theory. They appear to arise through some form of classical conditioning, abstract conditioning being the most likely form at present. Seen in these terms, posthypnotic suggestions function through the same mechanisms as any other hypnotic suggestion, being merely a special instance of a deferred suggestion. It must be emphasized that posthypnotic phenomena are learned in the sense only that they are brought into being through the use of previously acquired response tendencies. The learning process has usually reached completion by the time the hypnotic subject is capable of giving good posthypnotic responses.

4. The posthypnotic signal holds a unique position in posthypnotic phenomena which allows it to acquire unique and distinctive features with respect to the elicitation of the suggested behavior, among which is the capacity to cause reintegration.

5. The spontaneous [sic] trance said to accompany the initiation of any posthypnotic act appears to be a natural outcome of the learning process involved in the acquisition of posthypnotic behavior. There is a reinstatement of the original trance state because the posthypnotic trance is the result of associations taking place between the stimulus-suggestion and the symptoms of the initial hypnosis, these symptoms acting as responses.

6. Acquisition and retention of the contents of the suggested posthypnotic act may need to be differentiated from the acquisition and retention by the posthypnotic signal of the capacity to initiate the posthypnotic act. In the light of this observation, experimental data showing that posthypnotic suggestions are forgotten just like any other instructions may hold true only for the memory of the content. The capacity to initiate posthypnotic action, although subject to the same laws of forgetting may be far more enduring because of certain features of the learning process which underlie it" (pp. 55-56).

1956

Dittborn, Julio M. (1956). Toward a semeiology of hypnosis. Journal of Clinical and Experimental Hypnosis, 4 (1), 30-36.

"19 subjects were chosen among two hundred that in the year the experiment took place (1954) were to be 20 years old. 11 of these subjects qualified themselves as good swayers, whereas the 8 others were considered somehow refractory to the postural swaying test.

"All 19 went under a standard hypnotic induction: the operator employed the same words in all cases, and requested from all the execution of the same acts.

"Several involuntary signs of standard induction are described, which reveal that the subject has attained a convenient degree of muscular relaxation after appropriate suggestions.

"Fatigue is apparently an important source of spontaneous amnesia in good swayers.

"In the analyzed cases no involuntary sign has been detected, that could reveal us whether the inducted subject will or not present spontaneous post-hypnotic amnesia" (p. 36).

Includes standardized tests of depth.

LeCron, Leslie M. (1954). A hypnotic technique for uncovering unconscious material. Journal of Clinical and Experimental Hypnosis, 2, 76-79. (Abstracted in Psychological Abstracts, 54: 7497)

"Summary. A technique is given whereby unconscious material and information may be learned under hypnosis through automatic movements of the fingers, or of Chevreul's pendulum. The movements are controlled by the unconscious mind of the patient. Questions are asked which can be answered either 'yes' or 'no.' With most people the movements of the pendulum can even be elicited in the waking state. Essentially, the method is a variation of automatic writing with movements substituted for writing. A brief case history is given wherein knowledge was gained in this way as to the causes for severe menstrual pains" (p. 79).

1953

Marcuse, F. L. (1953). Anti-social behavior and hypnosis. Journal of Clinical and Experimental Hypnosis, 1, 18-20.

"The problem of whether an individual under hypnosis can be caused to commit an act contrary to his or her moral code must be paraphrased to ask whether an individual under hypnosis can be caused to commit an act which is socially and objectively reprehensible. When the question is so phrased and suitable technique is used, it is the writer's opinion that the answer is yes" (p. 20).

Nursing

1987

Patterson, David R.; Questad, Kent A.; Boltwood, Michael D. (1987). Hypnotherapy as a treatment for pain in patients with burns: Research and clinical considerations. Journal of Burn Care and Rehabilitation, 8 (3), 263-268.

Hypnotherapy has increasingly been included in the management of burn patients, particularly in the area of acute pain. To better understand such issues as (1) overall efficacy of hypnotherapy to alleviate acute burn pain, (2) instances in which hypnotherapy is contraindicated, (3) interaction of hypnotherapy with medication, (4) standard induction techniques to use with various age groups, (5) role of nursing and other staff in facilitating hypnotic effects, and (6) future methodological directions, they examined the clinical and methodological merits of recent studies of hypnoanalgesia. A literature search found 17 studies in which hypnotherapy was applied to the management of burns. The literature generally supports the efficacy of this approach to reduce burn pain; however, little else can be concluded from

these studies. Several recent studies have applied hypnotherapy to aspects of burn care other than pain using excellent experimental designs. It is suggested that future studies of acute pain management follow suit.

1971 Aiken, Linda H.; Henrichs, Theodore F. (1971). Systematic relaxation as a nursing intervention technique with open heart surgery patients. Nursing Research, 20, 212-217.

Psychiatric problems frequently occur after open heart surgery, usually from day 2 to day 7 postoperatively. Symptoms include impairment of consciousness, disorientation, sensory disturbances like visual and auditory hallucination, and sometimes delusions and paranoid behavior. Authors defined a postoperative adverse reaction as "when the patient experienced impairment of consciousness with motor restlessness, disordered thinking, sensory disturbances, visual and/or auditory illusions or hallucinations, and paranoid ideation. All of these symptoms do not usually occur together and an additional definition was given for a minor reaction which occurred if only one of the above symptoms was present for 12 hours or less" (p. 214).

The population from which samples were drawn consisted of adult male patients admitted to a university medical center for open heart surgery. The experimental group (N = 15) consisted of all patients admitted from September 1969 through June 1970 (omitting two who were not willing to participate). Controls were 15 adult males admitted for open heart surgery in the prior year.

A relaxation and systematic desensitization technique was used for the experimental group, each patient being given a tape recorder with a 15-minute tape of the exercise "to use whenever he wanted to relax" (p. 214) but at the least four times a day.

Outcome

**2002**

Montgomery, Guy H.; David, Daniel; Winkel, Gary; Silverstein, Jeffrey H.; Bovbjerg, Dana H. (2002). The effectiveness of adjunctive hypnosis with surgical patients: A meta-analysis. Anesthesia and Analgesia, 94, 1639-1645.

Hypnosis is a nonpharmacologic means for managing adverse surgical side effects. Typically, reviews of the hypnosis literature have been narrative in nature, focused on specific outcome domains (e.g., patients' self-reported pain), and rarely address the impact of different modes of the hypnosis administration. Therefore, it is important to take a quantitative approach to assessing the beneficial impact of adjunctive hypnosis for surgical patients, as well as to examine whether the beneficial impact of hypnosis goes beyond patients' pain and method of the administration. We conducted meta-analyses of published controlled studies (n = 20) that used hypnosis with surgical patients to determine: 1) overall, whether hypnosis has a significant beneficial impact, 2) whether there are outcomes for which hypnosis is relatively more effective, and 3) whether the method of hypnotic induction (live versus audiotape) affects hypnosis efficacy. Our

results revealed a significant effect size ( $D = 1.20$ ), indicating that surgical patients in hypnosis treatment groups had better outcomes than 89% of patients in control groups. No significant differences were found between clinical outcome categories or between methods of the induction of hypnosis. These results support the position that hypnosis is an effective adjunctive procedure for a wide variety of surgical patients.

**IMPLICATIONS:** A meta-analytical review of studies using hypnosis with surgical patients was performed to determine the effectiveness of the procedure. The results indicated that patients in hypnosis treatment groups had better clinical outcomes than 89% of patients in control groups. These data strongly support the use of hypnosis with surgical patients. [National Library of Medicine Abstract]

Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. [American Journal of Clinical Hypnosis, 43 \(1\), 17-40.](#) (July)

This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies;

(3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

-cing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

Green, Joseph P.; Lynn, Steven Jay (2000, August). [Hypnosis and suggestion-based approaches to smoking cessation: An examination of the evidence.](#) [Paper] Presented at the annual meeting of the American Psychological Association, Washington, D. C..

This article reviews 59 studies of hypnosis and smoking cessation from the point of view of whether the research provides support for hypnosis as an empirically supported treatment (Chambless and Hollon, 1998). Whereas hypnotic procedures generally yield higher rates of abstinence relative to wait list and no treatment conditions, hypnotic

interventions are generally comparable to a variety of nonhypnotic treatments. The evidence for whether hypnosis yields outcomes superior to placebos is mixed. In short, hypnosis can not be considered to be a specific and efficacious treatment for smoking cessation. Furthermore, in many cases, it is impossible to rule out cognitive/behavioral and educational interventions as the source of positive treatment gains associated with hypnotic treatments. Hypnosis can not, as yet, be regarded as a well-established treatment for smoking cessation. Nevertheless, it seems justified to classify hypnosis as a "possibly efficacious" treatment for smoking cessation. - Abstract taken from Psychological Hypnosis: A Bulletin of [Amer Psychol Assn] Division 30. Fall, 2000.

Horton-Hausknecht J.; Mitzdorf U.; Melchart D. (2000). The effect of hypnosis therapy on the symptoms and disease activity in rheumatoid arthritis . Psychology and Health, 14 (6), 1089-1104..

from: [http://www.imp-muenchen.de/The\\_effect\\_of\\_hypnos.698.1.html](http://www.imp-muenchen.de/The_effect_of_hypnos.698.1.html)

In this study we aimed to assess the effectiveness of clinical hypnosis on the symptoms and disease activity of rheumatoid arthritis (RA). 66 RA patients participated in a controlled group design. 26 patients learnt the hypnosis intervention, 20 patients were in a relaxation control group, and 20 patients were in a waiting-list control group. During hypnosis , patients developed individual visual imagery aimed at reducing the autoimmune activity underlying the RA and at reducing the symptoms of joint pain, swelling, and stiffness. Subjective assessments of symptom severity and body and joint function, using standardized questionnaires and visual analogue scales, were obtained. Objective measures of disease activity via multiple blood samples during the therapy period and at the two follow-ups were also taken. These measurements were of erythrocyte sedimentation rate, C-reactive protein, hemoglobin, and leukocyte total numbers. Results indicate that the hypnosis therapy produced more significant improvements in both the subjective and objective measurements, above relaxation and medication. Improvements were also found to be of clinical significance and became even more significant when patients practiced the hypnosis regularly during the follow-up periods.

Lang, E. V.; Benotsch, E. G.; Fick, L. J.; Lutgendorf, S.; Berbaum, M. L.; Berbaum, K. S.; Logan, H.; Spiegel, D. (2000, Apr 29). Adjunctive non-pharmacological analgesia for invasive medical procedures: A randomised trial. Lancet, 355 (9214), 1486-90.

BACKGROUND: Non-pharmacological behavioural adjuncts have been suggested as efficient safe means in reducing discomfort and adverse effects during medical procedures. We tested this assumption for patients undergoing percutaneous vascular and renal procedures in a prospective, randomised, single-centre study.

METHODS: 241 patients were randomised to receive intraoperatively standard care (n=79), structured attention (n=80), or self-hypnotic relaxation (n=82). All had access to patient-controlled intravenous analgesia with fentanyl and midazolam. Patients rated their pain and anxiety on 0-10 scales before, every 15 min during and after the procedures.

FINDINGS: Pain increased linearly with procedure time in the standard group (slope 0.09 in pain score/15 min,  $p < 0.0001$ ), and the attention group (slope 0.04/15 min;  $p = 0.0425$ ), but remained flat in the hypnosis group. Anxiety decreased over time in all

three groups with slopes of -0.04 (standard), -0.07 (attention), and -0.11 (hypnosis). Drug use in the standard group (1.9 units) was significantly higher than in the attention and hypnosis groups (0.8 and 0.9 units, respectively). One hypnosis patient became haemodynamically unstable compared with ten attention patients ( $p=0.0041$ ), and 12 standard patients ( $p=0.0009$ ). Procedure times were significantly shorter in the hypnosis group (61 min) than in the standard group (78 min,  $p=0.0016$ ) with procedure duration of the attention group in between (67 min).

INTERPRETATION: Structured attention and self-hypnotic relaxation proved beneficial during invasive medical procedures. Hypnosis had more pronounced effects on pain and anxiety reduction, and is superior, in that it also improves haemodynamic stability.

Mauer, Magaly H.; Burnett, Kent F.; Ouellette, Elizabeth Anne; Ironson, Gail H.; Dandes, Herbert M. (1999). Medical hypnosis and orthopedic hand surgery: Pain perception, postoperative recovery, and therapeutic comfort. International Journal of Clinical and Experimental Hypnosis, 47 (2), 144-161.

Orthopedic hand-surgery patients experience severe pain postoperatively, yet they must engage in painful exercises and wound care shortly after surgery; poor patient involvement may result in loss of function and disfigurement. This study tested a hypnosis intervention designed to reduce pain perception, enhance postsurgical recovery, and facilitate rehabilitation. Using a quasi-experimental research design, 60 hand-surgery patients received either usual treatment or usual treatment plus hypnosis. After controlling for gender, race, and pretreatment scores, the hypnosis group showed significant decreases in measures of perceived pain intensity (PPI), perceived pain affect (PPA), and state anxiety. In addition, physician's ratings of progress were significantly higher for experimental subjects than for controls, and the experimental group had significantly fewer medical complications. These results suggest that a brief hypnosis intervention may reduce orthopedic hand-surgery patients' postsurgical PPI, PPA, and anxiety; decrease comorbidity; and enhance postsurgical recovery and rehabilitation. However, true experimental research designs with other types of controls must be employed to determine more fully the contribution of hypnosis to improved outcome.

### 1998

Felt, Barbara T.; Hall, Howard; Olness, Karen; Schmidt, Wendy; Kohen, Daniel; Berman, Brad D.; Broffman, Gregg; Coury, Daniel; French, Gina; Dattner, Alan; Young, Martin H. (1998). Wart regression in children: Comparison of relaxation-imagery to topical treatment and equal time interventions. American Journal of Clinical Hypnosis, 41 (2), 130-137.

Relaxation mental imagery (RMI), standard topical treatment (Top Tx), and equal time-control interventions were compared on measures of wart regression in sixty one, 6-12-year-old children. Subjects chose one common ("index") wart and attended 4 visits over 8 weeks. At each visit, total and "index" extremity wart number were counted and a photo

was taken of the "index wart" for later measurement. On average, total wart number decreased by 10% and "index wart" area decreased by 20% with no significant group differences during the first eight weeks. Phone follow [sic] was conducted 6 to 18 months from study entry. At phone follow up, there was a trend for more RMI and Top Tx subjects to report complete wart resolution ( $p = 0.07$ ) with a majority of RMI children reporting use of RMI or no specific treatment pursuit. We conclude there was no significant short-term benefit for RMI in this randomized controlled trial of wart regression in children. However, longer term benefits for RMI and Top Tx groups are suggested.

## 1997

Faymonville, M. E.; Mambourg, P. H.; Joris, J.; Vrijens, B.; Fissette, J.; Albert, A.; Lamy, M. (1997). Psychological approaches during conscious sedation. Hypnosis versus stress reducing strategies: A prospective randomized study. *Pain*, *73* (3), 361-367.

Stress reducing strategies are useful in patients undergoing surgery. Hypnosis is also known to alleviate acute and chronic pain. We therefore compared the effectiveness of these two psychological approaches for reducing perioperative discomfort during conscious sedation for plastic surgery. Sixty patients scheduled for elective plastic surgery under local anesthesia and intravenous sedation (midazolam and alfentanil upon request) were included in the study after providing informed consent. They were randomly allocated to either stress reducing strategies (control: CONT) or hypnosis (HYP) during the entire surgical procedure. Both techniques were performed by the same anesthesiologist (MEF). Patient behavior was noted during surgery by a psychologist, the patient noted anxiety, pain, perceived control before, during and after surgery, and postoperative nausea and vomiting (PONV). Patient satisfaction and surgical conditions were also recorded. Peri- and postoperative anxiety and pain were significantly lower in the HYP group. This reduction in anxiety and pain were achieved despite a significant reduction in intraoperative requirements for midazolam and alfentanil in the HYP group (alfentanil:  $8.7 \pm 0.9$  microg kg<sup>(-1)</sup>/h<sup>(-1)</sup> vs.  $19.4 \pm 2$  microg kg<sup>(-1)</sup>/h<sup>(-1)</sup>,  $P < 0.001$ ; midazolam:  $0.04 \pm 0.003$  mg kg<sup>(-1)</sup>/h<sup>(-1)</sup> vs.  $0.09 \pm 0.01$  mg kg<sup>(-1)</sup>/h<sup>(-1)</sup>,  $P < 0.001$ ). Patients in the HYP group reported an impression of more intraoperative control than those in the CONT group ( $P < 0.01$ ). PONV were significantly reduced in the HYP group (6.5% vs. 30.8%,  $P < 0.001$ ). Surgical conditions were better in the HYP group. Less signs of patient discomfort and pain were observed by the psychologist in the HYP group ( $P < 0.001$ ). Vital signs were significantly more stable in the HYP group. Patient satisfaction score was significantly higher in the HYP group ( $P < 0.004$ ). This study suggests that hypnosis provides better perioperative pain and anxiety relief, allows for significant reductions in alfentanil and midazolam requirements, and improves patient satisfaction and surgical conditions as compared with conventional stress reducing strategies support in patients receiving conscious sedation for plastic surgery.

Schoenberger, Nancy E.; Kirsch, Irving; Gearan, Paul; Montgomery, Guy; Pastyrnak, Steven L. (1997). Hypnotic enhancement of a cognitive behavioral treatment for public speaking anxiety. Behavior Therapy, 28, 127-140.

The effectiveness of a multidimensional cognitive behavioral treatment for public speaking anxiety was compared with that of the same treatment supplemented by hypnosis. The hypnotic treatment included all components of the cognitive behavioral treatment. It differed from the nonhypnotic treatment only in that relaxation training was presented as a hypnotic induction, automatic thoughts were referred to as self-suggestions, and explicit hypnotic suggestions for improvement were added. Participants in both treatment conditions improved more than those in a wait-list control group. Moreover, labeling the treatment "hypnotic" appeared to enhance treatment effectiveness. The hypnotic treatment generated expectancies for greater change among participants than did the nonhypnotic treatment, and these expectancies were correlated with treatment outcome. Implications for the use of hypnosis in treatment are discussed.

## 1996

Kirsch, Irving (1996). Hypnotic enhancement of cognitive-behavioral weight loss treatments--Another meta-reanalysis. Journal of Consulting and Clinical Psychology, 64 (3), 517-519.

In a 3rd meta-analysis of the effect of adding hypnosis to cognitive-behavioral treatments for weight reduction, additional data were obtained from authors of 2 studies, and computational inaccuracies in both previous meta-analyses were corrected. Averaged across posttreatment and follow-up assessment periods, the mean weight loss was 6.00 lbs. (2.72 kg) without hypnosis and 11.83 lbs. (5.37 kg) with hypnosis. The mean effect size of this difference was 0.66 SD. At the last assessment period, the mean weight loss was 6.03 lbs. (2.74 kg) without hypnosis and 14.88 lbs. (6.75 kg) with hypnosis. The effect size for this difference was 0.98 SD. Correlational analyses indicated that the benefits of hypnosis increased substantially over time ( $r=.74$ ).

Sapp, Marty (1996). Three treatments for reducing the worry and emotionality components of test anxiety with undergraduate and graduate college students: Cognitive-behavioral hypnosis, relaxation therapy, and support counseling. Journal of College Student Development, 37 (1), 79-87.

The effects of cognitive-behavioral hypnosis, relaxation therapy, and supportive counseling in reducing the worry and emotionality components of test anxiety among undergraduate and graduate students were examined. Relaxation therapy was more effective with graduate students undergraduate responded more to supportive counseling. Similarly, cognitive-behavioral hypnosis and relaxation therapy were both more effective in reducing the worry and emotionality components of test anxiety and in improving grade point averages than was supportive counseling

Nash, Michael R. (1995, November). [What we don't know](#). [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

In the past few years the quality of psychotherapy research has improved, supporting the position that therapy works. Hypnosis outcome research to date is conceptually and methodologically substandard.

APA's Division 12 published a list of 25 treatments considered well established in efficacy or probably effective. Hypnosis was not on the list, and wasn't mentioned as not on the list!

The criteria for "well established or probably effective therapies" are: At least two good group design studies, conducted by different investigators, demonstrating efficacy in one or more of the following ways:

Superior to pill or psychological placebo or to another treatment.

Equivalent to an already established treatment in studies with adequate statistical power (about 30 per group; cf Kazdin & Bass, 1989) or a large series of single case design studies demonstrating efficacy. Such single case studies must have used good experimental designs and compared the intervention to another treatment as in above.

Further criteria: --Studies must be conducted with treatment manuals. --Characteristics of the client samples must be clearly specified.

David Orlinsky has a useful model, in which hypnosis would be classified as a therapeutic operation, a process variable that could be examined in relationship to outcome. But this approach will not meet the above criteria. We must move ahead to establish the usefulness of hypnosis for a finite number of clinical problems. However doing so would go against the long-standing policy of considering hypnosis not a therapy in itself, but simply adjunctive to another therapy.

APA's list includes broad therapies, and we should not try to validate "hypnosis treatment for depression" or "hypnosis treatment for marital problems." But many of the therapies on the APA list of therapies with demonstrated efficacy are very prescribed, e.g. behavior therapy for headache and for irritable bowel syndrome.

Some may say that we cannot demonstrate efficacy for hypnosis because during hypnotherapy we use other things like advice, emotional support, etc. That's also true for behavior therapy approaches. Why apologize that we use non-hypnosis procedures in addition to hypnosis?

We need to show interventions work, not necessarily why they work. There doesn't have to be a "model of treatment" as there is a behavioral model of treatment, a psychoanalytic model of treatment, etc. We can nevertheless demonstrate efficacy.

We should conceptualize some of our work in terms of hypnotic treatment modules, a brief hypnotic treatment for some specific disorder (and call them that-- hypnotic treatment modules).

## 1994

Rapkin, David; Holroyd, Jean (1994, February). Letter to the Editor (Cost-benefits of presurgery hypnosis) [Letter]. [Society for Clinical and Experimental Hypnosis Newsletter, 35 \(1\), 8.](#)

"In her presidential address to the annual meeting of SCEH this autumn, Dr. Karen Olness made a plea for more investigation of cost-benefits in clinical research. To further that end, we would like to share some data that were not published when our article, "Guided Imagery, Hypnosis and Recovery from Head and Neck Cancer Surgery: An Exploratory Study," was published in IJCEH (1991). The data were withdrawn from the article because a reviewer had difficulty believing the cost figures, but it is just such important cost benefits that really ought to be publicized.

difficulty believing the cost figures, but it is just such important cost benefits that really ought to be publicized.

"In our research, 15 head and neck cancer surgery patients volunteered for hypnosis prior to surgery; they were compared with 21 patients who received usual care (no hypnosis) on medical outcome measures. Postoperative hospital stay was 8.7 days for the hypnosis group and 13.9 days for the usual care group ( $p < .05$ ). The average savings for the intervention group was \$6,725. While this difference fell short of statistical significance on the Wilcoxon test ( $Z = -1.5402$ ,  $p < .10$ ), it is rather striking on its face. The range actually was \$7849 to \$27,782 for Intervention Group patients and \$9,390 to \$53,627 for Usual Care group patients.

"In 1990 a semi-private room at UCLA Center for the Health Sciences cost \$405 to \$529 per day, depending on quality; standard ICU care (one nurse for two patients) was \$1236 per day, and more intensive care (one nurse for one patient) was \$2471/day. Head and neck surgery patients may remain in the ICU, driving up costs, solely because they have not learned to suction their own tracheostomies, usually a motivational factor that might be affected by hypnosis. UCLA is a tertiary care hospital in a high-cost area (and is therefore reimbursed at higher rates than many other hospitals), and costs may be driven up by the many additional procedures required for long-stay patients. Therefore the cost savings could not be expected to be as great where expected length of stay is brief, ICU use is limited, and community costs are lower" (p. 8).

Ter Kuile, Moniek M.; Spinhoven, Philip; Linssen, A. Corry G.; Zitman, Frans G.; et al. (1994). Autogenic training and cognitive self-hypnosis for the treatment of recurrent headaches in three different subject groups. *Pain*, 58 (3), 331-340.

The aims of this study were to (a) investigate the efficacy of autogenic training (AT) and cognitive self-hypnosis training (CSH) for the treatment of chronic headaches in comparison with a waiting-list control (WLC) condition, (b) investigate the influence of subject recruitment on treatment outcome and (c) explore whether the level of hypnotizability is related to therapy outcome. Three different subjects groups (group 1, patients ( $n = 58$ ) who were referred by a neurological outpatient clinic; group 2, members ( $n = 48$ ) of the community who responded to an advertisement in a newspaper; and group 3, students ( $n = 40$ ) who responded to an advertisement in a university newspaper) were allocated at random to a therapy or WLC condition. During treatment, there was a significant reduction in the Headache Index scores of the subjects in contrast with the controls. At post-treatment and follow-up almost no significant differences were observed between the 2 treatment conditions or the 3 referral sources regarding the Headache Index, psychological distress (SCL-90) scores and medication use. Follow-up

measurements indicated that therapeutic improvement was maintained. In both treatment conditions, the high-hypnotizable subjects achieved a greater reduction in headache pain at post-treatment and follow-up than did the low-hypnotizable subjects. It is concluded that a relatively simple and highly structured relaxation technique for the treatment of chronic headache subjects may be preferable to more complex cognitive hypnotherapeutic procedures, irrespective of the source of recruitment. The level of hypnotic susceptibility seems to be a subject characteristic which is associated with a more favourable outcome in subjects treated with AT or CSH.

### 1993

Banerjee, Sanjay; Srivastav, Anita; Palan, Bhupendra M. (1993). Hypnosis and self-hypnosis in the management of nocturnal enuresis: A comparative study with imipramine therapy. [American Journal of Clinical Hypnosis](#), 36, 113-119.

Various therapeutic modalities have been used for treating enuresis due to the lack of a single identifiable cause. We carried out a comparative study of imipramine and direct hypnotic suggestions with imagery used for the management of functional nocturnal enuresis. Enuretic children, ranging in age from 5 to 16 years, underwent 3 months of therapy with imipramine (N = 25) or hypnosis (N = 25). After termination of the active treatment, the hypnosis group continued practicing self-hypnosis daily during the follow-up period of another 6 months. Of the patients treated with imipramine, 76% had a positive response (all dry beds); for patients treated with hypnotic strategies, 72% responded positively. At the 9-month follow-up, 68% of patients in the hypnosis group maintained a positive response, whereas only 24% of the imipramine group did. Hypnosis and self-hypnosis strategies were found to be less effective in younger children (5-7 years old) compared to imipramine treatment. The treatment response was not related to the hypnotic responsivity of the patient in either group

Barber, Joseph (1993). The clinical role of responsivity tests: A master class commentary. [International Journal of Clinical and Experimental Hypnosis](#), 41 (3), 165-168.

"What is the proper role of hypnotic responsivity tests in the clinical context? If a patient demonstrates a low score, should the clinician proceed to use hypnosis? To what extent should the patient's level of hypnotic responsivity guide the clinical use of hypnosis? If the initial hypnotic response is minimal, should the clinician proceed with the use of hypnosis?" (p. 165) These are the questions that guide this discussion.

What is the proper role of hypnotic responsivity tests in the clinical context? If a patient demonstrates a low score, should the clinician proceed to use hypnosis? To what extent should the patient's level of hypnotic responsivity guide the clinical use of hypnosis? If the initial hypnotic response is minimal, should the clinician proceed with the use of hypnosis? This often-asked question does not have a single, simple answer. This very complex issue is addressed more fully elsewhere (Barber, 1992). Let me approach this more limited discussion by suggesting three important points.

1. The single administration of a test of hypnotic responsiveness does not provide a valid and reliable indication of a patient's responsiveness.
2. A responsivity score is only an estimate of probable responsiveness.
3. Clinical efficacy depends on a variety of hypnotic and nonhypnotic factors, and not solely on responsiveness.

Everett, John J.; Patterson, David R.; Burns, G. Leonard; Montgomery, Brenda; Heimbach, David (1993). Adjunctive interventions for burn pain control: Comparison of hypnosis and Ativan. Journal of Burn Care and Rehabilitation, 14, 676-683.

Thirty-two patients hospitalized for the care of major burns were randomly assigned to groups that received hypnosis, lorazepam, hypnosis with lorazepam, or placebo controls as adjuncts to opioids for the control of pain during dressing changes. Analysis of scores on the Visual Analogue Scale indicated that although pain during dressing changes decreased over consecutive days, assignment to the various treatment groups did not have a differential effect. This finding was in contrast to those of earlier studies and is likely attributable to the low baseline pain scores of subjects who participated. A larger number of subjects with low baseline pain ratings will likely be necessary to replicate earlier findings. The results are argued to support the analgesic advantages of early, aggressive opioid use via PCA or through careful staff monitoring and titration of pain drugs.

Olness, Karen N. (1993, October). Hypnosis, research, and public affairs. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Bill Moyers' TV show on public television, *Healing and the Mind*, was seen by 15 million when first shown, and the book became a Book of the Month selection. Consumer Reports published *Mind-Body Medicine*. A TV program, *Heart of Healing*, sponsored by Noetic Sciences, will be shown; their teaching guides refer to the Society for Clinical and Experimental Hypnosis (SCEH).

The federal government's NIH Office of Alternative Medicine (OAM) now has grants providing up to \$30,000; in first year they received 800 letters of intent, ultimately 500 applications. In Nursing Research they also have sponsored research with OAM. OAM and the Cancer Institute are evaluating studies on using visual imagery with cancer patients. July of this year there was a 3-day working conference, with 80 scientists--1/2 of them from NIH--; David Spiegel and Karen Olness were there. Forty draft RIA's will be coming out. She will give us a draft of the RIA's.

Fetzer Institute of Michigan has been involved, with Robert Lehman--new director--who vows to make it the leading institute for research on the mind. They funded the NIH Conference, but don't give direct research support to investigators.

Marketing information on science and clinical medicine is not an interest for me, but Fetzer's marketing effort has resulted in research support that previously we would not have had. We do not have enough research on the value (cost vs benefits) of hypnotherapy.

Jacknow & Associates looked at nausea in children; hypnotized patients had less nausea than the control group. Syrjala's study (*Pain*, 1992) and this one did not have a cost benefit component.

A medical student and I learned that even HMOs don't know the average costs for various treatments for migraine headaches. There are only 3 controlled studies on child migraine that compare drugs to placebos! 5-7% of children in U.S. have migraines; 18% of men and 22% of women also have migraines.

We need more studies of how hypnotic ability can be modified, to increase beneficial outcomes.

We are forming a pediatric multi-site group to study Tourette's Syndrome and warts. A Wart Sensor is being developed to measure what is going away and in what order; by Case Western Reserve.

There should be increased funds available in the next 5-7 years. The magazine Scientific American, Sept 24 1993, predicts more support for the behavioral sciences

It's time to explain the mechanisms of what happens in hypnosis.

Patterson, David R. (1993, October). [Managing burn pain through hypnosis](#). [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Since 1955 there were 13 published reports on managing burn pain through hypnosis, with generally positive results; but almost all were anecdotal, with a lack of standardized measures. Time, location, and duration of the hypnotic interventions were not specified, cost-effectiveness was hard to detect, and medications used were not reported.

Publications don't even report the type of hypnotic intervention used.

Hypnosis is indicated for procedural pain more than for during resting periods. Going through dressing changes is typically more painful than the burn itself. Opioid medications don't control all the pain. In our research we use J. Barber's Rapid Induction Analgesia, which entails suggestions for: 1. Slow breathing 2. Going down 20 steps 3. Confusion and amnesia 4. Anchoring post-hypnotic suggestions 5. Touching cue for reinstating the hypnosis 6. Relaxing scenario (Patterson added this to the Barber script) 7. Returning up the steps

This intervention is good because it's replicable, and it's easy to train students to use it.

The hypnosis is done the morning before the dressing change.

Instructions for nurses are: 1. Read the card 2. Have patient lie down comfortably, etc. 3. Provide post hypnotic cue (usually a touch on the shoulder)

In the first study we used patients refractory to opioids, and also used a historical control group. This was published in the American Journal of Clinical Hypnosis. Our subsequent study was published in the Journal of Consulting and Clinical Psychology (1992). We stabilized administration of opioids; then patients had hypnosis or anxiolytics or were in the control condition. There was significant reduction in pain for hypnosis.

Patterson et al (current study). Compared Benzodiazapines to hypnosis using four groups: Hypnosis plus Lorazepam Hypnosis and placebo Lorazepam Hypnosis attention control and Lorazepam Placebo hypnosis and placebo pills

Analgesia stabilized on 2 days. There was not an effect, no significant drop in pain scores for either hypnosis or Lorazepam. Perhaps we didn't get a significant drop in pain ratings because in this study we were taking all patients who applied and their initial pain ratings were not as high as in the other study. We have found no relationship or pain reduction with hypnotizability either.

Why did we not get the positive results found previously for hypnosis? There are several possibilities. There is always a trend toward a drop in pain ratings over time. People generally bottom out with a rating of 3 or 4, and it looks like a floor effect. Also, the efficacy of hypnosis may be partly contingent on baseline pain level, and motivation to cooperate with the intervention.

Could there be the same relation to baseline for benzodiazepines?

We have noted that improved application of opioids early on means pain is lower. Marks & Sacher, *Annals of Internal Medicine*, 1973, indicate physicians under-prescribe opiates. Also Melzack in the *Scientific American* states this.

We feel that we should not push hypnotherapy so much that we feed in to opioidphobia. Hypnosis is a useful adjunct to opiates. We believe that you should stabilize the patient with opioids, and if they are not responding well, then use hypnosis.

In future research we want to find out which patients do best with hypnosis.

In future research we want to find out which patients do best with hypnosis.

Saperstein, Guy; Montgomery, Guy; Kirsch, Irving (1993, August). [Cognitive-behavioral hypnotherapy: A meta-analysis.](#) [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.

Meta-analysis was used to compare the effectiveness of cognitive-behavior therapy (CBT) to that of cognitive-behavior therapy with hypnosis (CBHT). A review of the literature revealed 18 studies in which 20 hypnotic treatments were compared to similar non-hypnotic treatments and in which sufficient data were presented for the calculation of effect sizes. Effect sizes were weighted for sample size and then averaged. This resulted in a mean effect size of 1.37 standard deviation units, indicating that the average client receiving cognitive-behavioral hypnotherapy is better off than 90 percent of clients who receive the same treatment in a nonhypnotic context. Substantial variance in effect sizes was found, indicating the presence of a moderator variable. Further analyses indicated that this variance was limited to treatments in which obesity was the presenting problem. The mean effect size for the addition of hypnosis to treatments of obesity was larger ( $M = 1.98$ ) and more variable (variance = 4.10) than that for the addition of hypnosis to treatments for other presenting problems ( $M = .52$ ; variance = .06). Also, studies of clinical samples yielded larger effects ( $M = 1.72$ ) than analogue studies with college student samples ( $M = .07$ ). The effect of hypnosis was independent of whether relaxation training was included in the nonhypnotic treatment or whether the hypnotic treatment included suggestions that were not included in the nonhypnotic treatment. Consistent with response expectancy theory, these data indicate that the substantial positive effect obtained was due to labeling the treatment 'hypnosis,' rather than to any substantive change in clinical procedure. (ABSTRACT from *Bulletin of Division 30, Psychological Hypnosis*, Fall 1993, Vol. 2, No. 3.)

Hollander, Ellen L.; Baw, Saul D. (1992, October). [Improving outcomes in sex therapy through the use of hypnotic methods.](#) [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

This is a report on the Cornell University Medical College Human Sexuality Program and Behavior Therapy Program. Cognitive-behavioral treatment is the principal approach in sex therapy these days (in contrast to insight treatment before 1954).

The authors find hypnosis to be useful in cases that were previously thought to be treatment refractory. Insensuality, inability to be absorbed, seems at the root of these problems. Hypnosis is useful for diagnosis and for developing task relevant immersion.

Three types of disorders: Desire phase Excitement phase Orgasm phase

Each phase has specific obstacles that can be elicited with a detailed interview: 1. Desire: anti-fantasy or the person focuses on unpleasant images 2. Excitement: performance anxiety or rumination about sexual potency (especially in men) 3. Orgasm: spectating or self-observation

Basic treatment strategy is to promote maintenance of absorption while dealing with the material that had been eliciting anxiety. In past we traditionally assumed absorption was present. Often this isn't the case. It can be addressed with hypnotic methods.

Conceptualized as a skill, hypnosis can improve the patient's ability to shift from peripheral to focal awareness.

Reports in the literature address sexual dysfunction as one unitary phenomenon, using direct suggestions, anxiety/stress reduction techniques, metaphorical suggestions, ego strengthening devices, hypnoanalytic procedures to uncover the unconscious determinants of dysfunction.

devices, hypnoanalytic procedures to uncover the unconscious determinants of dysfunction.

Kirsch, Irving (1992, August). [Cognitive-behavioral hypnotherapy.](#) [Paper] Presented at the annual meeting of the American Psychological Association, Washington, DC.

The use of hypnosis to augment cognitive behavior therapy was described. Hypnotic inductions establish a context in which the effects of therapeutic interventions can be potentiated for clients with positive attitudes and expectancies toward it. Hypnosis can also provide a disinhibiting context for both clients and therapists, allowing them to behave in ways that are therapeutic, but that might seem awkward in other contexts. A meta-analysis of outcome studies in which the effects of a cognitive-behavioral treatment were compared to the effects of the same treatments supplemented by hypnosis resulted in a mean effect size of 0.87 standard deviations, indicating the average client receiving cognitive-behavioral hypnotherapy is better off at the end of it than more than 80 percent of clients who receive the same treatment in a nonhypnotic context. (ABSTRACT from the Bulletin of Division 30, Psychological Hypnosis, Fall, 1992, Vol. 1, No. 3.)

Patterson, David R.; Everett, John J.; Burns, G. Leonard; Marvin, Janet A. (1992). [Hypnosis for the treatment of burn pain.](#) *Journal of Consulting and Clinical Psychology*, *60*, 713-717.

The clinical utility of hypnosis for controlling pain during burn wound debridement was investigated. Thirty hospitalized burn patients and their nurses submitted visual analog scales (VAS) for pain during 2 consecutive daily wound debridements. On the 1st day, patients and nurses submitted baseline VAS ratings. Before the next day's wound debridement, Subjects received hypnosis, attention and information, or no treatment. Only hypnotized Subjects reported significant pain reductions relative to pretreatment baseline. This result was corroborated by nurse VAS ratings. Findings indicate that hypnosis is a viable adjunct treatment for burn pain. Theoretical and practical implications and future research directions are discussed.

The treatment of burn patients involves a number of very painful procedures, including frequent removal of necrotic tissue, application of antiseptics, and bandaging. "Dressing changes often present pain so severe that the maximum dosages of opioids, even when supplemented by anxiolytics or inhalants, are often inadequate (Everett et al., 1990; Perry et al., 1981)" (p. 713). Previous research on the use of hypnosis with burn pain patients demonstrates many of the limitations found in the literature on clinical hypnosis and pain: nonrandomization of samples, nonstandardized hypnotic inductions, unreliable pain measures, inadequate control groups, unreported levels of analgesias used.

The present research controls for experimenter/therapist attention as well as 'expectancy' of both patient and hospital staff. (Both patients and their nurses were blind to group assignment.)

Patients who rated their most recent dressing change as 5 or greater (on a 1-10 scale) were invited to participate and then were randomly assigned to one of three groups: hypnosis, attention/information (pseudo hypnosis), or no treatment control. Interventions began within three days of admission to the acute burn care unit (though some had previously been on an intensive care unit). The patients were continued on opioid medication during the two days of the study, and an attempt was made to keep medication dosage constant. On Day 1 the patients received opioid medication before the dressing change, and on Day 2 they received the same medication plus their assigned treatment.

Hypnosis - Induction was administered by psychologist in patient's room before the dressing change. It was based on Barber's Rapid Induction Analgesia, modified specifically for burn wound debridement as described by Patterson, Questad, and deLateur (1989), and required 25 minutes

Attention and information (pseudo hypnosis) - The psychologist told patients they would get hypnosis, then spent 25 minutes with them, during which time the psychologist took a history of the accident and their emotional response; educated them about burn pain; encouraged them to differentiate sensations felt during dressing changes from signals of harm or danger; and informed them that their "sensation" indicated the presence of viable tissue and was a sign of healing. Toward the end of the session, patients were told "we have found that it is useful to close your eyes, count to 20, and imagine yourself in a relaxing place prior to dressing change" and were given 30 seconds to practice the "hypnosis." They were told after that brief practice session that the nurse would prompt them to begin hypnosis before their next dressing change by giving them some instructions and touch them on the shoulder.

No-treatment control condition - Patients received only the opioid medication.

"A standard set of instructions for dressing changes was given to the nurse for each S in the hypnosis and attention and information groups ... (a) having the subject sit comfortably in the tank (or lie on the table), (b) instructing the S to picture the staircase and count from 1 to 20, (c) touching the subject on the shoulder four times during wound care, and (d) telling the subject to let the area being worked on 'become relaxed and numb'" (p. 714).

No treatment control condition - Subjects received only opioid medication for both Day 1 and Day 2 dressing changes.

A Visual Analog Scale (VAS) for rating pain was used by both the patients and the nurses, within three hours of the dressing change.

-tive hospital stay included: the frequency of administration of analgesic and antiemetic drugs; opioid doses; the incidence of fever; nausea, retching, and vomiting; other gastrointestinal and urinary symptoms; ratings of pain; ratings of anxiety; global ratings of the patients' physical and psychological recoveries by the patients and their nurses; and length of postoperative hospital stay. There were no meaningful, significant differences in postoperative recovery of patients receiving therapeutic suggestions and controls. These negative results were not likely to be due to insensitivity of the assessments of recovery, as they showed meaningful interrelations among themselves and numerous differences in recovery following different types of surgery. Widespread utilization of therapeutic suggestions as a routine operating room procedure seems premature in the absence of adequate replication of previously published positive studies. (Key words: Anesthesia, depth: Awareness, Memory, Recall, Learning.)

Patients ages 19-55 were accepted into the study and they were paid for participation. (Older patients were excluded to guard against memory or hearing problems.) Other criteria for exclusion were: ASA physical status 4 or 5 indicating significant systemic disease, visual or hearing problems, middle ear disease (because it increases probability of nausea and vomiting), if their condition might require heavy sedation, if they were currently taking medication that interferes with memory (e.g. benzodiazepines, if there were intolerance to opioids, or if there were a likelihood of using postoperative pain treatment other than opioids).

The Spielberger State-Trait Anxiety Inventory was administered before surgery. Either suggestions (lasting 6 minutes) or a blank tape were played through headphones, starting 5 minutes after the surgical incision. The tape was played once for the first 59 patients, continuously for the remaining 150 patients. The first 139 patients received additional verbal materials on the tape, for memory tests to test possibility of learning under anesthesia. Operating room sounds were recorded by a tape recorder near the patient's head, throughout period of unconsciousness (except when tape was being played).

After the first 25% of cases, the team decided that lack of effect on therapeutic suggestions attributable to type of anesthesia did not warrant restriction to a single anesthetic method; also, multiple presentations of the suggestions on tape did not show an effect different from a single presentation.

After the patient regained consciousness and was reoriented, pain, nausea, retching, and vomiting were assessed every 30 minutes. Pain was rated orally on a scale from 1 to 10 in the recovery room, then on visual analogue scales every 2 hours on the day of surgery and the second day, and every 4 hours on subsequent hospital days during waking hours.

Variables that were rated by staff every 24 hours included: opioids, other analgesics, antiemetics, nausea, vomiting, retching, presence or absence of nasogastric tube, passage of flatus, bowel movement, fluid intake, solids intake, urination. Temperature was recorded every 4 hours for the first 2 days after surgery, and after that less often. The anxiety measures were repeated on Day 3 postsurgery, as well as self ratings and nurse ratings on physical and psychological recovery. Staff recorded length of postoperative hospital stay and reasons for any delay of discharge. Separate analyses were performed for patients receiving opioids via patient-controlled analgesia (52%) vs traditional administration (48%), but no differences were found for effects of therapeutic suggestions except on postoperative Day 8.

"The inability to detect beneficial effects of therapeutic suggestions probably was not due to insensitivity of the measures of recovery. These measures were sensitive enough to show numerous significant differences in recovery after different types of surgery" (p. 751). The authors supported their contention that the measures were sufficiently sensitive by demonstrating meaningful correlations among the measures themselves; and by demonstrating adequate statistical power for detecting the effects of theoretical interest--at least 1 day in postoperative hospital stay or one half day in fever.

Discussion: The authors note that a recent investigation that found positive results in a double-blind, randomized design with 39 hysterectomy patients (Evans & Richardson, 1988. Improved recovery and reduced postoperative stay after therapeutic suggestions during general anaesthesia. *Lancet*, 2:491-493) may not have controlled for variables such as presence of malignancy, physical status of patients before surgery, or ethnicity. Authors note that Evans and Richardson observed shorter periods of pyrexia despite there being no relevant suggestions, but no differences in pain intensity, nausea, vomiting, or urinary difficulties despite there being suggestions relating to those symptoms. There also were no differences in mood and anxiety test scores postoperatively for the experimental and control groups.

plus their assigned treatment.

Hypnosis - Induction was administered by psychologist in patient's room before the dressing change. It was based on Barber's Rapid Induction Analgesia, modified specifically for burn wound debridement as described by Patterson, Questad, and deLateur (1989), and required 25 minutes

Attention and information (pseudo hypnosis) - The psychologist told patients they would get hypnosis, then spent 25 minutes with them, during which time the psychologist took a history of the accident and their emotional response; educated them about burn pain; encouraged them to differentiate sensations felt during dressing changes from signals of harm or danger; and informed them that their "sensation" indicated the presence of viable tissue and was a sign of healing. Toward the end of the session, patients were told "we have found that it is useful to close your eyes, count to 20, and imagine yourself in a relaxing place prior to dressing change" and were given 30 seconds to practice the "hypnosis." They were told after that brief practice session that the nurse would prompt them to begin hypnosis before their next dressing change by giving them some instructions and touch them on the shoulder.

No-treatment control condition - Patients received only the opioid medication.

"A standard set of instructions for dressing changes was given to the nurse for each S in the hypnosis and attention and information groups ... (a) having the subject sit

comfortably in the tank (or lie on the table), (b) instructing the S to picture the staircase and count from 1 to 20, (c) touching the subject on the shoulder four times during wound care, and (d) telling the subject to let the area being worked on 'become relaxed and numb'" (p. 714).

No treatment control condition - Subjects received only opioid medication for both Day 1 and Day 2 dressing changes.

A Visual Analog Scale (VAS) for rating pain was used by both the patients and the nurses, within three hours of the dressing change.

Of 87 patients who met the inclusion criteria (for age, psychiatric and language status, and length of hospital stay) only 30 were in the final group. (31 had pain rating scores below 5; 13 declined to participate; 5 were in other investigations; 5 were not able to participate because of hypnotherapist unavailability; and 3 who began the study did not complete it. Those in the final subject group averaged 34.1 years old; mean total burn surface area was 16%.

No subjects in the placebo group questioned whether they had actually been hypnotized. Nevertheless, Experimenters did a manipulation check to determine whether the pseudo hypnosis group thought they were hypnotized. Subjects rated on a scale of 1-5 the extent to which they believed the hypnotic intervention was 'effective'; means were 4.0 for hypnosis and 3.4 for placebo, a non-significant difference.

Pain medication was converted to morphine equivalents (MD) and was equivalent across the three groups.

"The hypnosis group reported a significant reduction in pain from pre- to posttreatment, whereas the attention and information and the no-treatment control groups did not change significantly ... In addition, the hypnosis group had a significantly lower posttreatment pain rating than both the attention and information and the no-treatment control groups, which did not differ significantly" (p. 715).

"Nurses' ratings of subjects in the hypnosis group showed a significant reduction in pain from pretreatment to posttreatment, whereas there were no significant pain reductions for the attention and information and the no-treatment control groups ... The three posttreatment means did not differ significantly ... [and] correlations between patient baseline and posttreatment pain ratings and those submitted by nurses were  $r(27) = .16$ ,  $p = .423$ , for baseline ratings and  $r(27) = .29$ ,  $p = .127$ , for posttreatment ratings" (p. 716).

In their Discussion, the authors note that patients' reports evidenced more treatment effect than that of nurses. Also, they observed that the treatment effects might have been stronger if they had not been following a research protocol very strictly. "We might also mention that hypnotized subjects reported lower pain scores in spite of problems that they may have had in remembering the actual amount of pain they experienced. There is an increasing body of evidence suggesting that subjects have difficulty remembering clinical pain (Carlsson, 1983). Considering these factors, we feel that the treatment effect was a robust one" (p. 716).

The low correlation between nurses' ratings and patients' ratings is consistent with earlier reports that nurses are often unable to assess patients' pain accurately (Choiniere et al., 1990; Iafrafi, 1986; Walkenstein, 1982). The authors discuss why this might be, giving references. "Yet in this study, nurses [blind to group assignment] still reported a significant pain reduction for the hypnosis group" (p. 716).

"Our findings were consistent with theoretical approaches that argue that hypnotized subjects undergo an altered state--or at least a different form of cognitive processing--as opposed to a placebo effect" (p. 716).

"The question of whether hypnosis is superior to opioid pain medication, or can be used in its stead, was never addressed in this study. All subjects received opioids throughout hospitalization, including the study period. Our bias is that opioid drugs are the primary treatment of choice for burn pain. Attempting to replace opioids with hypnosis for the purpose of satisfying the hypnotist's curiosity or convictions, while occasionally successful, may often result in unnecessary patient suffering" (p. 716).

-tings and those submitted by nurses were  $r(27) = .16$ ,  $p = .423$ , for baseline ratings and  $r(27) = .29$ ,  $p = .127$ , for posttreatment ratings" (p. 716).

Spanos, Nicholas P.; Simulates, Ann; de Faye, Barbara; Mondoux, Thomas J.; Gabora, Natalie J. (1992-93). A comparison of hypnotic and nonhypnotic treatments for smoking. [Imagination, Cognition and Personality, 12, 23-43.](#)

Three experiments administered variants of Spiegel's (1970) smoking cessation procedure to smokers in hypnotic and nonhypnotic treatments. Follow-up periods were from twelve to twenty-four weeks depending on the experiment. Complete abstinence was an infrequent outcome in all three experiments. Greater-than-control reductions in smoking for treated subjects were obtained in two of the experiments but, in both cases treatment and control subjects failed to differ significantly before the end of the follow-up period. Hypnotic and nonhypnotic treatments produced equivalent smoking reductions in all

studies, and neither hypnotizability nor questionnaire assessments of motivation to quit correlated significantly with treatment outcome. Implications are discussed.

When the experimenters compared number of treatments they simply compared two sessions of Spiegel's one-session treatment with four sessions of it. The authors make the point that perhaps they should vary the four sessions.

"In all three of the present experiments the abstinence rates associated with the Spiegel treatment were very low. Our abstinence rates were similar to those reported in one earlier study [4 - Perry et al.], but substantially lower than those reported in three other studies [2, 22, 25]. The reasons for these discrepancies between studies remains unclear, but experiment 3 suggests that these discrepancies cannot be accounted for simply in terms of whether the subjects were drawn from a university or nonuniversity population, and experiment 2 suggests that the discrepancies are unrelated to the number of treatment sessions administered to subjects.

"The finding that hypnotic and nonhypnotic subjects in all three experiments attained equivalent reductions in smoking is consistent with other comparison studies in this area which indicate that hypnotic treatments are no more effective than various nonhypnotic procedures at inducing reductions in smoking [22, 25, 30]. More generally, these findings are consistent with comparison studies on a wide variety of clinical disorders (headache pain, warts, phobias, obesity) which indicate that hypnotic treatments are no more effective than nonhypnotic ones at producing therapeutic change (see [3] for a review).

"The failure to find significant correlations between smoking reduction and hypnotizability among treated subjects is also consistent with the findings of most studies in this area [3], but the reasons why significant correlations between these variables are found in some studies and not others remains unclear. Spanos [3] suggested that significant correlations between these variables are particularly likely when hypnotizability testing is integrated into the treatment protocol. Under these circumstances subjects are likely to form strong expectations about treatment success on the basis of their self-observed responses to the hypnotizability scale. Such expectations may, in turn, influence subjects' motivations to comply with the treatment regimen, the self-statements they make concerning their likelihood of quitting, etc. In all of the present experiments hypnotizability was assessed at the end of the follow-up period and, therefore, could not influence subjects' expectations of treatment success" (pp. 40-41).

## 1991

Block, Robert I.; Ghoneim, M. M.; Sum Ping, S. T.; Ali, M. A. (1991). Efficacy of therapeutic suggestions for improved postoperative recovery during general anesthesia. *Anesthesiology*, 75, 746-755.

There have been claims that the postoperative course of patients may be improved by presentation during general anesthesia of therapeutic suggestions which predict a rapid and comfortable postoperative recovery. This study evaluated the effectiveness of such therapeutic suggestions under double-blind and randomized conditions. A tape recording predicting a smooth recovery during a short postoperative stay without pain, nausea, or vomiting was played during anesthesia to about half the patients (N = 109), while the remaining, control patients were played a blank tape instead (N = 100). The patients were primarily undergoing operations on the fallopian tubes, total abdominal hysterectomy,

vertical banding gastroplasty, cholecystectomy, and ovarian cystectomy or myomectomy. The anesthesia methods consisted of either isoflurane with 70% nitrous oxide in oxygen to produce end-tidal concentrations of 1.0, 1.3, or 1.5 MAC; or 70% nitrous oxide in oxygen combined with high or low doses of opioids. Assessments of the efficacy of the therapeutic suggestions in the recovery room and throughout the postoperative hospital stay included: the frequency of administration of analgesic and antiemetic drugs; opioid doses; the incidence of fever; nausea, retching, and vomiting; other gastrointestinal and urinary symptoms; ratings of pain; ratings of anxiety; global ratings of the patients' physical and psychological recoveries by the patients and their nurses; and length of postoperative hospital stay. There were no meaningful, significant differences in postoperative recovery of patients receiving therapeutic suggestions and controls. These negative results were not likely to be due to insensitivity of the assessments of recovery, as they showed meaningful interrelations among themselves and numerous differences in recovery following different types of surgery. Widespread utilization of therapeutic suggestions as a routine operating room procedure seems premature in the absence of adequate replication of previously published positive studies. (Key words: Anesthesia, depth: Awareness, Memory, Recall, Learning.)

supported their contention that the measures were sufficiently sensitive by demonstrating meaningful correlations among the measures themselves; and by demonstrating adequate statistical power for detecting the effects of theoretical interest--at least 1 day in postoperative hospital stay or one half day in fever.

Discussion: The authors note that a recent investigation that found positive results in a double-blind, randomized design with 39 hysterectomy patients (Evans & Richardson, 1988. Improved recovery and reduced postoperative stay after therapeutic suggestions during general anaesthesia. *Lancet*, 2:491-493) may not have controlled for variables such as presence of malignancy, physical status of patients before surgery, or ethnicity. Authors note that Evans and Richardson observed shorter periods of pyrexia despite there being no relevant suggestions, but no differences in pain intensity, nausea, vomiting, or urinary difficulties despite there being suggestions relating to those symptoms. There also were no differences in mood and anxiety test scores postoperatively for the experimental and control groups.

The authors note that McLintock, Aitken, Downie, & Kenny (Postoperative analgesic requirements in patients exposed to positive intraoperative suggestions. *Br M J* 301:788-790. 1990) reported a 23% reduction in opioids by patients receiving suggestions, but no reduction in pain, nausea, or vomiting. They contrast the present study with these earlier studies that had obtained positive results.

"We studied patients who had more than one type of surgery to obtain a large sample size and to assess the possibility that beneficial effects of therapeutic suggestions would be restricted to certain types of operations. Had this been the case, interactions of therapeutic suggestions with type of surgery would have been significant in the overall analyses, and follow-up analyses would have indicated that they were attributable to beneficial effects of therapeutic suggestions for certain surgeries. This did not occur. The two types of surgeries involving the largest numbers of patients seemed particularly promising for demonstrating beneficial effects. It has been reported that therapeutic suggestions presented during anesthesia are likely to be less successful with major and extensive surgery. Certainly, surgery on the fallopian tubes and gastric stapling did not involve a

great deal of tissue trauma and blood loss. Patients were motivated to have the surgery and to recover quickly; particularly motivated were those having operations on the fallopian tubes, who were very eager to become pregnant, and those having vertical banding gastroplasties, who wanted desperately to lose weight" (pp. 753-754).

"In practice, we observed no beneficial effects of therapeutic suggestions, and there was no hint that anesthesia methods influenced the efficacy of the therapeutic suggestions. Interestingly, anesthetic methods also did not influence learning under anesthesia in the implicit memory tests we have used previously. Patients anesthetized with nitrous oxide and opioids did not differ from those anesthetized only with inhalational agents. In general, implicit or unconscious memory occurs in patients regardless of anesthesia methods or dosages of drugs" (p. 754).

"The few significant effects of therapeutic suggestions in our study did not point toward a beneficial influence of these suggestions. We found, in fact, an increased frequency of retching (but not nausea or vomiting) in the experimental group. The multiple variables examined in this study increased the likelihood of significant differences arising by chance, such that the null hypothesis was rejected when it should have been accepted. This is the way we interpret the effect on retching--i.e., as a type I error. We used in our therapeutic suggestions one negative or exclusionary sentence, 'You won't feel nauseous or have to vomit', among several positive or affirmative statements, e.g., 'You will enjoy eating, drinking...You will swallow to clear your throat and everything will go one way, straight down. . . The food will taste good....Your stomach will feel fine.' We do not think that the negative sentence led to paradoxical results. Evans and Richardson (personal communication) used in their therapeutic suggestions a negative sentence ('You will not feel sick'), which they repeated, yet the reported incidence of nausea and vomiting did not differ between the experimental and control groups" (p. 754).

-ach will feel fine.' We do not think that the negative sentence led to paradoxical results. Evans and Richardson (personal communication) used in their therapeutic suggestions a negative sentence ('You will not feel sick'), which they repeated, yet the reported incidence of nausea and vomiting did not differ between the experimental and control groups" (p. 754).

Evans, Frederick J. (1991). *Hypnotizability: Individual differences in dissociation and the flexible control of psychological processes*. In Lynn, Steven J.; Rhue, Judith W. (Ed.), [Theories of hypnosis: Current models and perspectives](#) (pp. 144-170). New York: Guilford Press.

"In summary, some of our recent data suggest that there are a number of interacting reliable correlates of hypnotizability ... . None relate to suggestibility in the traditional sense. ... Hypnotizability is related to the ability to process cognitive information during sleep, to the physiological ease of falling asleep, and to a dimension of subjective sleep characteristics we have labeled the 'control of sleep' (involving ... the ability to fall asleep easily and readily at will, and the tendency to take naps). Additional data have suggested that the concept of absorption can be meaningfully divided into subfactors that reflect the volitional control over the absorption process that correlates with hypnotizability in both normal and patient populations. ... (C)ontrolled absorption correlates significantly with

hypnotizability in both normal and patient populations--a result that might be predicted from the concept of multiple pathways as correlates of hypnotizability (J. R. Hilgard, 1970). ... Finally, both the control-of-sleep dimension and hypnotizability relate to the reductions of symptoms and psychopathology even when psychiatric patients are not treated with hypnotic techniques" (pp. 164-165).

Haanen, Huub C.M.; Hoenderdos, Henk T.W.; Van Romunde, Leo K.J.; Hop, Win C.J.; Malle, Constant; Terwiel, Jack P.; Hekster, Gideon B. (1991). Controlled trial of hypnotherapy in the treatment of refractory fibromyalgia. Journal of Rheumatology, 18 (1), 72-75.

In a controlled study, 40 patients with refractory fibromyalgia were randomly allocated to treatment with either hypnotherapy or physical therapy for 12 weeks with followup at 24 weeks. Compared with the patients in the physical therapy group, the patients in the hypnotherapy group showed a significantly better outcome with respect to their pain experience, fatigue on awakening, sleep pattern and global assessment at 12 and 24 weeks, but this was not reflected in an improvement of the total myalgic score measured by a dolorimeter. At baseline most patients in both groups had strong feelings of somatic and psychic discomfort as measured by the Hopkins Symptom Checklist. These feelings showed a significant decrease in patients treated by hypnotherapy compared with physical therapy, but they remained abnormally strong in many cases. We conclude hypnotherapy may be useful in relieving symptoms in patients with refractory fibromyalgia.

The patients in this study were 38 women and 2 men, ages 30-65, who had had fibromyalgia for an average of 8.5 years (range 1.5 - 40 years). Of these, 25 were on sick leave or incapacitated, and 6 were unemployed. Patients were randomly assigned to hypnotherapy, or to training in muscle relaxation plus massage (designated "physical therapy"). They were withdrawn from analgesics, except for paracetamol (like Tylenol), at the beginning of this program. Hypnotizability was not measured. Hypnosis treatment consisted of an

Hypnosis treatment consisted of an arm levitation induction, imagery deepening techniques, ego strengthening suggestions, and suggestions for control of muscle pain, relaxation, and improved sleep. Patients received eight one-hour sessions in decreasing frequency over three months; after Session 3 they were given a 30-minute audiotape to assist in daily self hypnosis. Seventeen patients completed hypnotherapy but three were dissatisfied and withdrew after 3 sessions.

Patients did self ratings on (1) duration of morning stiffness, (2) muscle pain, (3) fatigue on awakening, (4) sleep disturbance, and (5) global assessment, the last four using visual analog scales (VAS). Patient assessment at 12 and 24 weeks was the primary outcome measure, since fibromyalgia is diagnosed principally from patient's self described symptoms.

Independent observers did not know to which group the patient belonged. The physician's evaluation included (1) dolorimeter measures of point tenderness (for a Total Myalgic Score, TMS), (2) presence of tender points at 30 points, with 5 control points, (3) overall pain rating with visual analogue scale.

The Hopkins Symptom Checklist (HCL-90) also was used to evaluate outcome.

Using analysis of variance techniques and correcting for initial values, the study found significantly more favorable values in the hypnosis group than in the physical therapy group for muscle pain, fatigue on awakening, sleep disturbance, patient's overall assessment, and HCL total score. However, differences were not significant for morning stiffness, physician's overall assessment, or T.S. There were no differences between Weeks 12 and 24 for both groups; therefore the mean value for weeks 12 and 24 for each patient were used to calculate percentage change relative to baseline.

The reduction in pain medication used by the hypnosis group was quite remarkable.

"Median (range) analgesic drug use at the initiation of the study (mostly paracetamol) was in the hypnotherapy group 3.0 (0-42) tablets/week and in the physical therapy group 4.5 (0-21)/week. At Week 12 this was 1.0 (0-21) tablet/week for the hypnotherapy group and 7.0 (0-34) tablets/week for the physical therapy group. At the end of the study, 10 of 12 patients in hypnotherapy group and 3 of 12 patients in the physical therapy group had reduced their paracetamol use (Fisher exact test:  $p = 0.006$ )" (pp. 73-74).

Although it was observed that the total number of tender points decreased (regardless of treatment group), the Total Myalgic Score assigned by the physician had not changed either at week 12 or at week 24. In fact, even the control points were tender in 44% of the patients; most patients showed some pain response to a control point in one or two sessions of the three. "Only 12 of 40 patients had consistently nontender control points, 4 in hypnotherapy group and 8 in the physical therapy group. ... No relation was found between the initial HCL total score and the changes in the other variables studied" (p. 74).

Figures taken from Table 2, showing percent change as compared to baseline:

Physical Therapy (%)	Hypnotherapy (%)	Morning stiffness (minutes)	0.0	-25.0	
Muscle pain (VAS)	-6.8	-10.2**	Fatigue on awakening (VAS)	-0.3	-16.7**
Sleep disturbance (VAS)	-1.0	-23.1**	Overall assessment patient	-8.4	-33.2**

physician	+5.7	-3.2	T.S. (kg/3 cm <sup>2</sup> )	-11.1	-2.4	HCL total score	-0.9	-13.0**
-----------	------	------	------------------------------	-------	------	-----------------	------	---------

In their Discussion, the authors write, "In this controlled therapeutic trial in patients with refractory fibromyalgia hypnotherapy was more successful than physical therapy in improving complaints. The assessment of fatigue on awakening, sleep disturbance, muscle pain, the patient's overall assessment and the total score of the HCL showed a significant decrease in the hypnotherapy group at the end of the hypnotherapy at 12 weeks. This decrease persisted for 3 months after finishing the hypnotherapy. The variables studied in the physical therapy group had not changed significantly at 12 and 24 weeks.

"However, the patients in the hypnotherapy group improved only subjectively. This improvement was not seen via more objective variables (T.S. and number of tender points), in accordance with others [Carette et al., 1986]. This suggests that coping with the disease may be positively influenced by hypnotherapy though the underlying disorder is still present.

"Correction of the sleeping disturbance by hypnotherapy was the most consistent finding and possibly played an important role in the subjective improvement of fibromyalgia" (p. 74).

The authors noted that the HCL yielded scores in the pathological range during the baseline period. "Thus, in our study, patients with long-standing fibromyalgia often showed pathological feelings of discomfort. In the hypnotherapy group the total score of the HCL decreased significantly suggesting that the physical disturbance may be secondary to long-standing fibromyalgia. It is worth noting that only 3 of the 57 questions on the HCL-90 concern fibromyalgia" (p. 74).

The authors express the opinion that their data do not support a distinction between fibromyalgia and psychogenic rheumatism [Simms, Goldenberg, Felson, & Mason, 1988; Campbell, Clark, & Tindall, 1983] based on pain reported at control points. "Most patients in our study had variable tender control points. The finding of tender control points in fibromyalgia is consistent with others [Wolfe, Smythe, Yunus, et al., 1990; Scudds, Rollman, Harth, & McCain, 1987]. Also we found a positive correlation between the number of tender points and the presence of tender control points. Therefore, it seems more likely that there is a fairly large overlap between fibromyalgia and psychogenic rheumatism (tender all over)" (p. 75).

Holroyd, Jean (1991). The uncertain relationship between hypnotizability and smoking treatment outcome. International Journal of Clinical and Experimental Hypnosis, 39, 93-102.

Literature on the relationship between hypnotizability and smoking treatment outcome was reviewed. 91 private patients treated for smoking with hypnotherapy participated in an investigation designed to correct problems in some of the earlier research. 43% quit smoking by the end of treatment but only 16% abstained at least 6 months. Neither immediate quitting nor continued abstinence correlated with hypnotizability. Other variables hypothesized to predict smoking cessation also were not correlated with outcome: number of treatment sessions, need to smoke, motivation to quit, and gender. The low abstention rate may have impeded verification of a relationship between hypnotizability and treatment outcome.

In the Discussion, the author notes that the low overall abstention rate works against finding the predicted relationships, as did restricted range on the hypnotizability measure. "Secondly, the present research design in effect tested the potency of hypnosis (hypnotizable patients) against nonhypnotic treatment (nonhypnotizable control patients) in a research design recommended by Orne (1977). Intensive nonhypnotic involvement with the nonhypnotizable individuals over several sessions may have worked against finding differences between low and high hypnotizables" (p. 99).

"Patients generally did not complete the recommended four sessions ... and they generally were non-adherent to recommended follow-up telephone contact. The observed relationship between initial quitting and number of treatment sessions may exist because people who are responding to treatment to treatment stay in treatment longer, or because more treatment sessions provide a more potent intervention, or both" (p. 99). "Treatment contracts between patients and therapist increased the number of sessions that patients completed but did not increase their abstinence rate" (p. 100).

Millis, P. M.; Rooimans, W.; Spierings, E. L.; Hoogduin, C. A. (1991). Treatment of chronic tension-type headache with hypnotherapy: A single-blind controlled study. Headache, 31, 686-689.

Compared effectiveness of a special hypnotherapy technique with chronic tension headache with a waitlist control group. There were significant reductions ( $p < .05$ ) in number of headache days, hours, and intensity. Improvement was confirmed by subjective evaluation and questionnaire data showing a significant anxiety scores ( $p < .01$ ).

Miller, Mary Frances; Barabasz, Arreed F.; Barabasz, Marianne (1991). Effects of active alert and relaxation hypnotic inductions on cold pressor pain. Journal of Abnormal Psychology, 100 (2), 223-226.

Contrasted relaxation and active alert hypnotic inductions with or without a specific suggestion for cold pressor pain analgesia. Groups of high ( $n = 38$ ) and low ( $n = 27$ )

hypnotizability subjects were tested; hypnotizability had been determined from results of the Stanford Hypnotic Susceptibility Scale, Form C. Cold pressor pain data were obtained after counterbalanced exposure to relaxation and active alert inductions. Highly hypnotizable subjects demonstrated lower pain scores than did low hypnotizability ones. Pain reports did not differ between induction conditions. Highly hypnotizable subjects given an analgesic suggestion showed lower pain scores than did those exposed only to hypnosis. The findings, conceptualized within E. R. Hilgard's (1977a) neodissociation theory, show that relaxation is not necessary for hypnotic analgesia.

The relaxation induction was the SHSS, Form B. The active alert induction used the same instructions except suggestions for alertness, invigoration, and freshness were substituted for drowsiness and relaxation. During the active alert induction, the subjects rode a bicycle ergometer at a constant load of 1-3 kg and a constant rate of 1-2 rotations per s (Banyai & Hilgard, 1976).

Primavera, J. P.; Patterson, S. (1991). A tape-recorded test of hypnotic susceptibility for screening headache patients: A feasibility study of the Harvard Group Scale of Hypnotic Susceptibility, Form A. Headache, 31, 619-621.

In 9 chronic, daily headache patients, compared with 10 control subjects, results did not suggest a correlation between hypnotic susceptibility and reduction of headache pain.

Rapkin, David A.; Straubing, Marsha; Holroyd, Jean (1991). Guided imagery, hypnosis and recovery from head and neck cancer surgery. International Journal of Clinical and Experimental Hypnosis, 39, 215-226.

The value of a brief, preoperative hypnosis experience was explored with a sample of 36 head and neck cancer surgery patients. 15 patients volunteered for the experimental hypnosis intervention. 21 patients who received usual care (no hypnosis) were followed through their hospital charts and were used as a comparison group. Hypnotic intervention and usual care groups were comparable in terms of relevant demographic variables. Postoperative hospitalizations for the hypnotic intervention group were significantly shorter than for the usual care group. Within the hypnotic intervention group, hypnotizability was negatively correlated with surgical complications and there was a trend toward a negative correlation between hypnotizability and blood loss during surgery. Findings suggest that imagery-hypnosis may be prophylactic, benefitting patients by reducing the probability of postoperative complications and thereby keeping hospital stay within the expected range. Recommendations are presented for a controlled, randomized, clinical trial with a sufficiently large sample to provide the opportunity for statistical analysis with appropriate power.

Actual stay in hospital, post-surgery, was 8.7 days (SD = 3.7) for the Hypnosis group and 13.9 days (SD = 9.7) for the Usual Care group; the range was 3-17 days for the Hypnosis group and 5-42 days for the usual care group.

The hypnosis script included an indirect, permissive induction; positive suggestions for relaxation and healing imagery; images of calm situations that would lead to expectation for healing (e.g. a 'healing pool'); suggestions for patients to develop their own images of

pleasurable, comforting situations. The only direct suggestions were for minimal blood loss during surgery, modeled after those given in the waking situation by Bennett, Benson, and Kuiken (1986).

As measured by the Stanford Hypnotic Clinical Scale, there were five highly hypnotizable patients (scores 4-5), six mediums (scores 2-3), and four lows (scores 0-1). "Hypnotizability correlated negatively with complications ( $r = -.54$ ,  $p < .04$ , two-tailed test). There was a trend toward a negative correlation with length-of-stay ( $r = -.37$ ,  $p < .18$ , two-tailed test) and estimated blood loss ( $r = -.40$ ,  $p < .15$ , two-tailed test). Note that these correlations represent moderate to large effects, and the significance levels are due in part to low power associated with a small N (Cohen, 1988). The means for blood lost during surgery for the three hypnotizability groups were: highs = 904 cc, mediums = 1465 cc, and lows = 2056 cc" (p. 222).

Data on cost could not be published in this article but later was published in a letter to the Editor of the Newsletter of the Society of Clinical and Experimental Hypnosis (February 1994, Vol. 35, No. 1, p.8). "The average savings for the intervention group was \$6,725. While this difference fell short of statistical significance on the Wilcoxon test ( $Z = -1.5402$ ,  $p < .10$ ), it is rather striking on its face. The range actually was \$7849 to \$27,782 for Intervention Group patients and \$9,390 to \$53,627 for Usual Care group patients. "In 1990 a semi-private room at UCLA Center for the Health Sciences cost \$405 to \$529 per day, depending on quality; standard ICU care (one nurse for two patients) was \$1236 per day, and more intensive care (one nurse for one patient) was \$2471/day. Head and neck surgery patients may remain in the ICU, driving up costs, solely because they have not learned to suction their own tracheostomies, usually a motivational factor that might be affected by hypnosis. UCLA is a tertiary care hospital in a high-cost area (and is therefore reimbursed at higher rates than many other hospitals), and costs may be driven up by the many additional procedures required for long-stay patients. Therefore the cost savings could not be expected to be as great where expected length of stay is brief, ICU use is limited, and community costs are lower" (p. 8).

Schwarz, Shirley P.; Blanchard, Edward B. (1991). Evaluation of a psychological treatment for inflammatory bowel disease. [\*Behaviour Research and Therapy\*, 29 \(2\), 167-177.](#)

Compared the effectiveness of a multicomponent behavioral treatment package, which included inflammatory bowel disease (IBD) education, progressive muscle relaxation, thermal biofeedback, and training in use of cognitive coping strategies, with the effectiveness of symptom-monitoring as a control condition. The treatment group consisted of 11 IBD patients (aged 25-62 yrs); 8 of 10 persons (aged 25-71 yrs) in the control group completed treatment. At posttreatment, the treatment group showed fewer reductions in symptoms (5) than the symptom-monitoring controls (8). However, treated Ss perceived themselves as coping better with IBD and as feeling less IBD-related stress. It is hypothesized that the differences in treatment responses may be related to differences between Ss with ulcerative colitis and Ss with Crohn's disease.

Prior, A.; Colgan, S. M.; Whorwell, P. J. (1990). Changes in rectal sensitivity after hypnotherapy in patients with irritable bowel syndrome. [Gut, 31](#), 896-898.

Fifteen patients with irritable bowel syndrome were studied to assess the effect of hypnotherapy on anorectal physiology. In comparison with a control group who received no hypnotherapy, significant changes in rectal sensitivity were found in patients with diarrhoea-predominant irritable bowel syndrome both after a course of hypnotherapy and during a session of hypnosis ( $p < .05$ ). Although patient numbers were small, a trend towards normalization of rectal sensitivity was also observed in patients with constipation-predominant syndrome. No changes in rectal compliance or distension-induced motor activity occurred in either subgroup nor were any changes in somatic pain thresholds observed. The results suggest that symptomatic improvement in irritable bowel syndrome after hypnotherapy may in part be due to changes in visceral sensitivity. This research involved 15 patients diagnosed with irritable bowel syndrome (IBS), which was defined as abdominal pain with abdominal distension and 'an altered bowel habit'--10 had diarrhea mostly and 5 had constipation mostly. Patients with this disease usually have an exaggerated colon sensitivity to many different stimuli, as well as lower threshold to a balloon inflated in the bowel for diagnostic purposes.

The patients were treated with ten sessions of hypnosis, 30 minutes each, over a three month period. Dependent variables included self ratings of abdominal pain, abdominal distention, and 'bowel habit disturbance.' Each of the three variables received a score of 0-10; the total score therefore could range from 0-30.

Other ratings were obtained using the inflation of a rectal balloon as stimulus. "After a basal period of at least 15 minutes the rectal balloon was serially inflated with air at intervals of 1 min in 20 ml increments up to 100 ml and then in 50 ml increments up to the sensation of discomfort. The study was repeated after a rest period of 15 minutes. After hypnotherapy the S was restudied first in the waking state and then, after 15 min, following induction of hypnosis" During this procedure they measured balloon volume,

rectal compliance (a function of volume and pressure), and presence or absence of repetitive rectal contractions.

In order to learn whether the analgesia being experienced in the rectal or bowel area transferred to other areas, patients experienced cold water immersion induced pain on one hand, for a measure of time until discomfort was felt (pain threshold, essentially).

The control group of 15 patients diagnosed with IBS received the same measures of balloon volume, rectal compliance, and presence or absence of repetitive rectal contractions.

The total symptom score (which might have ranged 0-30) dropped from 23.5 to 9.6, and 13 of the 15 patients rated their symptoms as much improved. The two Ss who did not experience improvement also did not return for the assessment using the balloon.

Therefore, the physiological assessment included only 13 Subjects, the ones who rated themselves as 'improved.'

"In patients with diarrhoea-predominant irritable bowel syndrome a decreased rectal sensitivity occurred after hypnotherapy which was significant for the sensations of gas and urgency. This was most pronounced in patients who could initially tolerate only small rectal balloon volumes (Fig 1). During hypnosis the results for rectal sensitivity in the diarrhoea-predominant group were similar to those noted after the course of hypnotherapy but were of a greater magnitude, reaching significance for all sensations (Fig 2).

"In the constipation-predominant Subjects there was a tendency for rectal sensitivity to move towards normal values both after the course of hypnotherapy and during hypnosis. Patient numbers in this subgroup were small, however, and the changes were not significant (Figs 1 and 2). Rectal compliance and distension induced motor activity were unaffected by hypnotherapy in both the diarrhoea and constipation- predominant patients" (p. 897).

It was noted that of patients who had manifested depression and/or anxiety (8 of 13), most showed psychological improvement--3 of them to a great degree--but there was no correlation between psychological improvement and the degree that visceral sensitivity was diminished. Also, the ten sessions of hypnotherapy did not affect length of time subjects could tolerate hand immersion in cold water.

"In the control group of 15 patients with the irritable bowel syndrome who did not receive hypnotherapy no changes in rectal sensory or motor parameters occurred when manometry was repeated on the same day or on a second study day nine to 12 weeks later (Table II)" (p. 897).

In their Discussion, the authors remark that "hypnotherapy seemed to produce a trend towards normalization of visceral sensitivity (Figs 1 and 2). This was most pronounced in the patients with diarrhoea-predominant irritable bowel syndrome who initially had particularly low sensation thresholds" (p. 898).

They continue, "The pathophysiological abnormalities which lead to the symptoms of the irritable bowel syndrome remain unclear. The increased visceral sensitivity found in the large [7-9] and small intestine [18, 19] in some patients with the irritable bowel syndrome may contribute to their perception of pain. In addition, an increase in rectal sensitivity might also contribute to the symptoms of urgency and frequency of defecation seen in many patients with diarrhoea-predominant irritable bowel syndrome. ... Hypnotherapy

also induces an improvement in well being by increasing coping capacities, and may therefore decrease perceived stress" (p. 898).

"The present study suggests therefore that hypnotherapy might operate by a variety of mechanisms in patients with the irritable bowel syndrome. In those with visceral hypersensitivity it seems to alter the perception of rectal sensation, although the mechanism by which this is achieved is unknown. Modification at a cortical level or more locally along afferent pathways are possibilities. This does not, however, explain the symptomatic improvement in all subjects and hypnotherapy is probably also acting in a non-specific psychotherapeutic sense" (p. 898).

with diarrhoea-predominant irritable bowel syndrome who initially had particularly low sensation thresholds" (p. 898).

Schwarz, Shirley P.; Taylor, Ann E.; Scharff, Lisa; Blanchard, Edward B. (1990). Behaviorally treated irritable bowel syndrome patients: A four-year follow-up. [Behaviour Research and Therapy](#), 28 (4), 331-335.

A 4-yr longitudinal study evaluated 19 patients (aged 23-60 yrs) suffering from Irritable Bowel Syndrome (IBS) who had completed a multicomponent treatment involving progressive muscle relaxation, thermal biofeedback, cognitive therapy, and IBS education at baseline. 17 Ss rated themselves as more than 50% improved. Six of the 12 Ss who submitted symptom monitoring diaries met the criteria for clinical improvement, (i.e., achieving at least a 50% reduction in primary IBS symptom scores). The means on all measures at long-term follow-up were lower than those obtained prior to treatment. When follow-up symptom means were compared with pretreatment means, significant reductions were obtained on abdominal pain/tenderness, diarrhea, nausea, and flatulence.

### **1989**

Palan, B.M.; Chandwani, S. (1989). Coping with examination stress through hypnosis: An experimental study. [American Journal of Clinical Hypnosis](#), 31, 173-180.

Fifty-six volunteer medical students participated in three groups balanced for number of subjects, performance at last examination, and hypnotizability. The hypnosis and waking groups attended eight group sessions once a week with general ego-strengthening and specific suggestions for study habits, with a ninth session of age progression and mental rehearsal. Subjects in these two groups practiced self-suggestions (in self-hypnosis or waking respectively) daily for the study period of 9 weeks. The control group experienced sessions of passive relaxation induced by light reading for the same period of time. The hypnosis group improved significantly in coping with examination stress, but there was no significant change in performance on examinations by any of the groups.

Patterson, David R.; Questad, Kent A.; deLateur, B. J. (1989). Hypnotherapy as an adjunct to narcotic analgesia for the treatment of pain for burn debridement. [American Journal of Clinical Hypnosis](#), 31, 156-163

This paper presents a hypnotherapeutic intervention for controlling pain in severely burned patients while they go through dressing changes and wound debridement. The technique is based on Barber's (1977) Rapid Induction Analgesia (RIA) and involves hypnotizing patients in their rooms and having their nurses provide posthypnotic cues for analgesia during wound cleaning. Five subjects who underwent hypnotherapy showed reductions on their pain rating scores (Visual Analogue Scale) relative to their own baselines and to the pain curves of a historical control group (N = 8) matched for initial pain rating scores. Although the lack of randomized assignment to experimental and control groups limited the validity of the results, the findings provide encouraging preliminary evidence that RIA offers an efficient and effective method for controlling severe pain from burns.

Spiegel, David; Bloom, J. R.; Kraemer, H. C.; Gottheil, E. (1989, October 14). The beneficial effect of psychosocial treatment on survival of metastatic breast cancer patients: A randomized prospective outcome study. [Lancet](#), 888-891.

The effect of psychosocial intervention on time of survival of 86 metastatic breast cancer patients was studied using randomized prospective design. The one-year treatment consisted of weekly supportive group therapy with training in self-hypnosis for pain management, and resulted in significant reductions in mood disturbance and pain. Both the treatment and control groups had routine oncologic care. At ten-year follow-up, only three of the original 86 patients were still alive, and death records were obtained for the other 83. Survival from the time of randomization and onset of intervention was 36.6 (sd = 37.6) months for the treatment group, compared with 18.9 (sd = 10.8) months for the control group, and this difference was highly significant ( $Z = 3.94$ ,  $p < .0001$ ) using the Cox life table regression model. Kaplan-Meier survival analysis indicated that the divergence in survival began at 20 months after entry into the study, or 8 months after the treatment intervention ended. These unexpected findings suggest that intensive psychosocial support affects the course of the illness, although the mechanism by which it does so is not clear.

Stanton, Harry E. (1989). Hypnosis and rational-emotive therapy--a de-stressing combination: A brief communication. [International Journal of Clinical and Experimental Hypnosis](#), 37 (2), 95-99.

It has been suggested that teacher stress might be reduced through cognitive restructuring which is aimed at improving the rationality of their thinking. To test this hypothesis, 40 high school teachers were paired on their level of reasonable thinking, operationalized in terms of scores on the Teacher Idea Inventory (Bernard, Joyce, & Rosewarne, 1983), and allocated at random to one of 2 groups. They also completed the Face Valid Stress Test. The experimental group participated in 4 weekly treatment sessions involving a hypnotic induction and suggestions derived from key elements of Rational-Emotive Therapy. These focused on the reduction of what Ellis (Ellis & Grieger, 1977), the originator of this treatment, calls "irrational thinking." The control group spent the same amount of time discussing stress reduction methods. Both the Face Valid Stress Test and the Teacher Idea Inventory were re-administered at the end of this period and again 12 months after conclusion of the experiment. Results indicated that both the experimental and control groups significantly reduced their levels of irrational thinking and stress, although the former's improvement was more marked, particularly at the 12-month follow-up.

Stress Test and the Teacher Idea Inventory were re-administered at the end of this period and again 12 months after conclusion of the experiment. Results indicated that both the experimental and control groups significantly reduced their levels of irrational thinking and stress, although the former's improvement was more marked, particularly at the 12-month follow-up.

Stanton, Harry E. (1989). Hypnotic relaxation and the reduction of sleep onset insomnia. [International Journal of Psychosomatics](#), 36, 64-68.

A hypnotic relaxation technique was compared to stimulus control and placebo conditions as a means of reducing sleep onset latency (SOL). Forty-five subjects were matched on their baseline SOL as measured through sleep diaries. They were randomly assigned to one of the three groups and experienced four weekly sessions of 30- minutes' duration, with demand effects being controlled through the use of counter- demand instructions. Data generated by the study suggested that the particular hypnotic relaxation treatment used was effective in helping Ss sleep more quickly. Neither stimulus control nor placebo groups recorded similar improvement.

Zane, Nolan W. S. (1989). Change mechanisms in placebo procedures: Effects of suggestion, social demand, and contingent success on improvement in treatment. [Journal of Counseling Psychology](#), 36, 234-243.

Investigated the treatment effects of three social influence variables frequently implicated in psychotherapy placebos. Socially anxious male Subjects participated in an experimental treatment for reducing dating anxiety. Subjects were either given or not given specific suggestions for decreasing social anxiety, placed in conditions of high or low social demand, and received feedback indicating either high or moderate success on

the therapy task. Results support the importance of social influence variables in therapeutic change. Contingent success had its greatest impact on personal attributes; suggestion affected skill behaviors; and social demand effects were found in the self-evaluation of heterosocial performance. Various social influences appear to mediate change differently and do not exert the generic effects commonly assumed to be characteristic of therapy placebos. Implications for outcome research are discussed.

## 1988

Boeke, S.; Bonke, B.; Bouwhuis-Hoogerwerf, M. L.; Bovill, J. G.; Zwaveling, A. (1988). Effects of sounds presented during general anaesthesia on postoperative course. British Journal of Anaesthesia, 60, 697-702.

In a double-blind, randomized study, patients undergoing cholecystectomy were administered one of four different sounds during general anaesthesia: positive suggestions, nonsense suggestions, seaside sounds or sounds from the operating theatre. The effect of these sounds on the postoperative course was examined to assess intraoperative auditory registration. No differences were found between the four groups in postoperative variables.

Postoperative course was evaluated by 5 variables: pain, nausea and vomiting, evaluation by nursing staff, subjective well-being, and duration of postoperative hospital stay. From the chart they used amount of postoperative analgesia, volume of nasogastric suction or drainage and fluid lost through vomiting over 6 days post-operatively; duration of postoperative hospital stay was registered after discharge. See p. 699 for details, including wording of questions. They cite their own earlier study that got positive results, and explain the difference as possibly due to use of only male voices on tapes, lack of difference in the sounds on tapes in this study, insensitivity of outcome measures (patients stayed longer in first study than in this one), and sample too small in this study (106).

Boeke et al. (1988) report that this double-blind, randomized study of positive suggestions, noise or sounds from the operating theatre presented to 3 groups of patients undergoing cholecystectomy during general anaesthesia had positive results for older patients. patients > 55 years who received positive suggestions had a significantly shorter postoperative hospital stay than the other patients in this age category.

Malone, M.; Strube, M. (1988). Meta-analysis of non-medical treatment for chronic pain. Pain, 34, 231-234.

Conducted a meta-analysis of 109 published studies which assessed the outcome of various nonmedical treatments for chronic pain, 48 of which had sufficient information to calculate effect sizes. The remainder were examined according to proportion of patients rated as improved. Mood and number of subjective symptoms consistently showed greater responses to treatment than did pain intensity, pain duration, or frequency of pain, indicating the importance of using a multidimensional framework for pain assessment. Effect sizes for treatments were 2.74 for autogenic training, 2.67 for hypnosis, 2.23 for pill placebo, 1.33 for package treatments that allowed patients to choose from diverse

pain management strategies, .95 for biofeedback, .76 for cognitive therapy, .67 for relaxation, .55 for operant conditioning, and .46 for TENS units. However, the largest numbers of studies were in the area of biofeedback, a treatment package, and relaxation, and we must be cautious in interpreting the effect sizes due to the small number of studies in the sample.

Neufeld, V.; Lynn, Steven Jay (1988). A single-session group self-hypnosis smoking cessation treatment: A brief communication. [International Journal of Clinical and Experimental Hypnosis](#), 36 (2), 75-79.

This study was designed to assess the efficacy of a manual-based, single-session group of self-hypnosis intervention. At 3 months follow-up, 25.92% of the total number of participants (14 male, 13 females) reported continuous abstinence, and at 6 months, 18.52% of the participants reported continuous abstinence. Reported social support and motivation to quit were both associated with successful outcome. Comparison of the current data with other findings reported by the American Lung Association (Davis, Faust, & Ordentlich, 1984) suggests that treatment effects may not be solely attributable to the use of a maintenance manual, education, and attention. Limitations of the research associated with issues of experimental control, generalizability of the findings, and outcome measures are discussed.

Spinhoven, Philip (1988). Similarities and dissimilarities in hypnotic and nonhypnotic procedures for headache control: A review. [American Journal of Clinical Hypnosis](#), 30 (3), 183-194.

Similarities and differences between hypnosis and similar psychological procedures in the treatment of headache are reviewed. A brief outline of various hypnotic and nonhypnotic interventions for headache reduction shows that none of these procedures has consistently proved to produce superior results. Possible common denominators such as control of physiological processes, placebo factors, and the alteration of cognitive factors are discussed. The positive relationship between hypnotic susceptibility and hypnotic pain reduction indicates that the value of hypnosis seems to be less a matter of therapeutic procedure per se than of which context activates a patient's hypnotic potential for pain reduction.

The author summarizes literature on biofeedback and relaxation: "(a) biofeedback with home practice of relaxation is, at least in some cases, effective in reducing migraine and tension headache; (b) relaxation training alone has also produced some success in reducing migraine and tension headaches; and (c) there is not sufficient evidence that biofeedback in the treatment of these pain problems yields results superior to relaxation training" (p. 184). Hypnotherapy for headache is not reviewed in detail, but he provides a table showing various controlled studies and their results. "With the exception of the methodologically problematic study of Anderson, Basker, and Dalton (1975), no differences in effect are found between hypnosis and biofeedback (Andreychuck & Skriver, 1975; Schlutter, Golden, & Blume, 1980; Friedman & Taub, 1984) and hypnosis

and relaxation (Friedman & Taub, 1984; Spinhoven, Van Dyck, Zitman, & Linnsen, 1985)" (p. 184). He notes that there are no studies that directly compare hypnosis and nonhypnotic relaxation interventions for headache.

"In all the studies in which hypnotizability was related to outcome, irrespective of patient selection method of measurement, and hypnotic procedure used, a significant positive relationship between hypnotizability and therapy results was found in more than 350 patients (Andreychuck & Skriver, 1975; Cedercreutz, Lahteenmaki, & Tulikoura, 1976; Cedercreutz, 1978; Friedman & Taub, 1984; Spinhoven et al., 1985). If we consider the level of hypnotizability rather than the details of the hypnotic procedure, it seems that headache patients who are highly hypnotizable benefit more from hypnosis in the reduction of headache.

"However, little reliable information is available concerning the underlying dimensions of hypnotic susceptibility relevant for pain reduction. In the neodissociation theory of Hilgard it is suggested that highly hypnotizable patients register pain covertly outside conscious awareness (Hilgard, 1977, 1979). In the social learning model of Spanos and his coworkers (Spanos, Radtke-Bodorik, Ferguson, & Jones, 1979; Spanos, Kennedy, & Gwynn, 1984), it is assumed that high susceptibles show a relatively greater preference for focusing attention on internal thoughts and images as a way of attenuating pain than low susceptibles.

"A recent experimental study of Miller and Bowers (1986), which directly compared hypnotic analgesia, cognitive-behavior therapy, and cognitive-behavior therapy defined as hypnosis in high and low susceptibles, suggests that pain reduction achieved by highly hypnotizable subjects during hypnosis is not mediated by the deliberate use of cognitive strategies (such as imaginative inattention). Cognitive strategy use resulted in pain reduction only during behavior therapy. Clinical studies about the experiential aspects of high and low susceptible headache patients during hypnosis, biofeedback, relaxation training, and cognitive-behavior therapy are urgently needed. If process research in a clinical setting validates that hypnotic analgesia involves the activation of a subsystem of pain control temporarily dissociated from conscious executive control, a therapy component specific for hypnosis will have been identified" (pp. 189-190).

### **1987**

[Wagstaff, Graham F. \(1988\). Comments on the 1987 Home Office Draft Circular. A response to the comments of Gibson, Haward, and Orne. \[Comment/Discussion\] .](#)

"Conclusions. Perhaps the most prudent recommendation to be made is that of Gibson to outlaw the forensic use of hypnotic procedures. However, at the same time, Haward could be right in arguing that such a recommendation would in practice result in the baby being thrown out with the bathwater" (p. 48). Author goes on to suggest that the police request the advice of professional hypnosis organizations so that memory enhancement procedures would be applied with "strict safeguards."

### **1986**

[Rogers, Malcolm; Reich, Peter \(1986\). Psychological intervention with surgical patients: Evaluation outcome. Advances in Psychosomatic Medicine, 15, 23-50.](#)

The Notes are a direct quotation of the authors' Conclusions. "There is well documented evidence that psychological and behavioral preparation prior to surgery can effect post-operative recovery. In almost all instances, except when patients are characterized by avoidance or denial defenses predominantly, the outcome results have been positive. The effect of interventions have been most consistently positive in reducing length of hospitalization and post-operative pain, but a variety of other improvements in affect and physiologic stability have been shown. As others such as Auerbach have pointed out [76], in all but a handful of studies different intervention approaches have been combined, making it impossible to sort out the specific effects of information, psychotherapeutic relationship, relaxation training, or suggestion given either with or without hypnosis. Indeed it is not only likely that each has had an effect, but there may also be synergistic effects.

"More recent investigations have begun to include measurements of personality differences between patients so that the nature of the intervention can be more specific and appropriate to the individual's coping style.

"The reduction in length of hospitalization alone (clearly shown to result from pre-operative psychologic preparation) argues forcefully on a cost benefit basis for the inclusions of careful pre-operative preparation. The reduction in pain is also of major importance, and may well reduce future avoidance behavior or post-traumatic disorders, although these latter potential outcomes have not been investigated. It should be kept in mind that there are also a number of studies which have failed to demonstrate the efficacy of psychological intervention on these outcome measures. Moreover, it is extremely difficult in studies of this nature to control adequately for the subtle effects on behavior of experimenter and subject expectation.

"A few points can be made about future strategies in this field. The evidence accumulated to date suggests that all patients undergoing surgery or certain difficult procedures be given the option of pre-operative psychological preparation. The preparation should emphasize what the patient will experience and when, and how to cope with it, i.e., how to move, or breathe, or relax. Rapidly evolving audiovisual capabilities and hospital televisions connected by cable to health education channels will routinely offer such preparation in the future. Patients could choose or not choose to watch (thereby protecting mechanisms of denial).

"Finally, future studies should focus on outcome measures uniquely important to a particular operation and also on longer term rehabilitation outcome measures. An example of the former might be post-operative sexual functioning after prostatectomy. A study by Zokar et al. [77] has shown that the likelihood of this post-operative function is correlated with not only the level of pre-operative anxiety and general 'life satisfaction', but also whether the patient received a pre-operative explanation of what to expect from the surgery" (pp. 45-46).

Sargent, Joseph; Solbach, Patricia; Coyne, Lolafaye; Spohn, Herbert; Segerson, John (1986). Results of a controlled, experimental, outcome study of nondrug treatments for the control of migraine headaches. Journal of Behavioral Medicine, 9, 291-323.

Headache variables were examined for 136 subjects who participated for 36 weeks in one of four groups: No Treatment, Autogenic Phrases, EMG Biofeedback, Thermal Biofeedback. All subjects kept daily records of headache activity and medication usage and participated in 22 laboratory sessions during which frontalis EMG and hand temperature measurements were taken; those in the 3 treatment groups practiced at home. There was a substantial reduction in headache variables in all groups. The No- Treatment Group differed significantly from the treatment groups combined, with the least reduction in headache variables. The thermal biofeedback group vs EMG biofeedback and autogenic phrases groups showed a suggestive trend toward improvement in the frequency and intensity of total headache.

Swirsky-Sacchetti, Thomas; Margolis, Clorinda G. (1986). The effects of a comprehensive self-hypnosis training program on the use of factor VIII in severe hemophilia. International Journal of Clinical and Experimental Hypnosis, 34, 71-83.

Hemophilia, the bleeder's disease, is characterized by internal bleeding episodes which have been associated anecdotally with psychological stress. The focus of the present investigation was to study the potential utility of a comprehensive self- hypnosis training program to decrease stress and to assess the amount of clotting factor used for bleeding by those individuals trained in self-hypnosis compared to a control group. 30 severe hemophiliacs on home therapy were randomly assigned to a treatment or to a waiting list control group. The treatment group received a comprehensive 6-week training program including support, education, deep relaxation, and self-hypnosis. Over the 18-week follow-up, the treatment group significantly reduced the amount of factor concentrate used to control bleeding in comparison to controls. The treatment group also significantly reduced general distress level as measured by a symptom checklist. The training was extremely cost effective, and the results support the efficacy of this comprehensive training program to augment the medical management of severe hemophiliacs on a home therapy regimen.

The authors begin with a discussion of the importance of being able to reduce the amount of blood factor concentrate required by hemophiliacs, including the problems of obtaining uncontaminated blood in an era of HTLV-III and LAV contamination and the fact that some patients with Hemophilia A have developed antibodies to Factor VIII (so-called inhibitor patients). When an inhibitor patient hemorrhages, it is potentially life-threatening. Earlier controlled clinical research by LaBaw (1975) indicated that hypnosis might be useful for decreasing blood usage. The current study builds upon that research and adds further control procedures.

The hypotheses of this study were: "(a) hemophiliacs who received the comprehensive training program including self- hypnosis along with education, support, and relaxation for stress management would significantly reduce the amount of factor concentrate used to control spontaneous bleeding in comparison to randomly assigned waiting list controls; (b) the general distress level, as measured by the SCL-90 (Derogatis, 1977), would significantly decrease for the treatment group from pretraining to follow-up; and (c)

hypnotizability as measured by the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. C. Orne (1962) would show a positive correlation with the treatment effect" (p. 74).

Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. C. Orne (1962) would show a positive correlation with the treatment effect" (p. 74).

The Subjects were patients of a hematologically severe status (less than 1% clotting factor present in the blood); ages 11-50, mean age 30; normally distributed on socioeconomic variables; and prescreened to rule out serious psychological dysfunction. The treatment and control groups did not differ in SES or pretest bleeding severity. Control Ss were informed that they would receive the same training after the initial follow-up period. Three Ss were lost from the treatment group because they did not complete the 6 weekly self-hypnosis training sessions, and three from the control group due to geographic move or decision to obtain treatment elsewhere.

Patients recorded their factor usage on log sheets, and their reports were checked with distribution records kept at the clinic. (Factor received during hospital stays was not included. Also 3 "inhibitor" patients--2 treatment, 1 control--were removed from some analyses because they must infuse Factor IX at a level that far exceeds the amount appropriate for body were an inhibitor not present.)

The Ss, in groups of 3-4 people, were educated about the effects of stress on bleeding, physiological signals of overstress, and then trained as a group in self hypnosis. Each training session began with a group hypnosis induction followed by various suggestions and imagery. They were given a cassette tape with suggestions for decreased bleeding, ego-strengthening, relaxation, and sensations of floating. In addition to listening to the tape at least once each day, they were taught rapid (1-2 minute) inductions to combat stress, and were to develop their own self-hypnosis procedure.

In terms of results, 9 of 11 (82%) treatment Ss and 4 of 10 (40%) control Ss decreased in blood factor usage ( $p < .05$ ). There was a great deal of variability between Subjects. While the treatment group demonstrated an overall decrease in factor usage, the control group actually had an overall increase in usage. The authors speculate that possibly a change in season caused the increase, because several Ss reported that a change in season ordinarily caused an increase due to their arthritic joints. Also, a change to warmer weather might have led to increased physical activity. General distress, measured by General Severity Index of the SCL-90, was reduced significantly for the treatment group. (Results of SCL-90 aren't reported for control group.)

The third hypothesis was not supported. In fact, the correlation between HGSHS:A and treatment effect was in the opposite direction from what was expected ( $- .25$ , n.s.).

However, "there was a significant correlation ( $\rho = .56$ ,  $p < .025$ ) between Ss' self-reported trance usage and change scores, indicating that those Ss who practiced self-hypnosis more were more likely to have decreased factor usage. There was also a trend ( $\rho = .44$ ,  $p < .10$ ) between treatment Ss' change scores and their initial distress levels (GSI), suggesting that those Ss who were initially more distressed tended to profit more from treatment" (pp. 78-79).

In their Discussion, the authors suggest that the fact that the treatment effect of decreased factor usage was consistent throughout the follow-up period suggests that reduced usage was not due to a placebo effect. They note that placebo responses are usually brief, and situation-specific (Frank, 1976). They see the need for further research to clarify which component(s) of the treatment program are effective (self-hypnosis, relaxation, education, social support), and to extend the length of follow-up period. Since hypnotizability did not correlate with outcome, the results might be due to some other component. Since outcome did correlate with amount of self hypnosis practice, motivation may be an important determiner of effect.

Decreased stress was not only reported by Ss but also reflected in changes on the test scores (SCL-90). Also, several Ss spontaneously used the self hypnosis for school and occupational performance, and to relieve headaches. In terms of financial benefits, "the one patient who had the most significant decrease in factor usage noted an average monthly savings of \$850. For the entire treatment group (including those few Ss whose factor usage increased), the training resulted in savings of \$1240 per month over the follow-up period" (p. 81).

performance, and to relieve headaches. In terms of financial benefits, "the one patient who had the most significant decrease in factor usage noted an average monthly savings of \$850. For the entire treatment group (including those few Ss whose factor usage increased), the training resulted in savings of \$1240 per month over the follow-up period" (p. 81).

## 1985

Jeffrey, Timothy B.; Jeffrey, Louise K.; Greuling, Jacquelin W.; Gentry, William R. (1985). Evaluation of a brief group treatment package including hypnotic induction for maintenance of smoking cessation: A brief communication. International Journal of Clinical and Experimental Hypnosis, 33 (2), 95-98.

Hypnotic, cognitive, and behavioral interventions were used in a 5-session treatment program to assist 35 Ss with maintenance of smoking cessation. 63% of the treated Ss discontinued smoking, and 31% maintained abstinence for 3 months ( $p < .005$ ). These results include 13 dropouts, all of whom were smoking at 3 months follow-up. No S in the waiting-list-control group quit smoking. The results demonstrate that a brief, group treatment program, including hypnotic techniques, can be effective for smoking cessation.

## 1984

Funch, Donna P.; Gale, Elliot N. (1984). Biofeedback and relaxation therapy for chronic temporomandibular joint pain: Predicting successful outcomes. Journal of Consulting and Clinical Psychology, 52 (6), 928-935.

Fifty-seven patients with chronic temporomandibular joint (TMJ) pain were randomly assigned to receive either relaxation or biofeedback therapy. Therapy efficacy was assessed (immediate posttreatment and 2-year follow-up), and pretherapy factors (demographic, clinical, personality) were used to predict successful outcomes for each therapy group. Although there were no significant differences in outcomes,

characteristics of patients with successful outcomes were not similar for the two therapies. Successful patients in the relaxation condition tended to be younger, had experienced TMJ pain for a shorter period of time, and had reported problems with other psychophysiological disorders. Successful patients in the biofeedback group tended to be older, married, had experienced TMJ pain for a longer period of time, and had not received prior equilibration treatment. Only two of these factors, equilibration and presence of other disorders, were related to both short- and long-term outcomes, suggesting that they may be particularly useful as predictors of outcome. These findings do suggest that knowledge of pretherapy factors, particularly clinical, may allow for more optimal assignment to therapy conditions.

Manganiello, Aaron J. (1984). A comparative study of hypnotherapy and psychotherapy in the treatment of methadone addicts. *American Journal of Clinical Hypnosis*, 26, 273-279.

This study sought to examine the effects of hypnotherapy on the ability of methadone-maintained patients to reduce and/or eliminate their drug-taking behavior. Seventy adult volunteers at a methadone maintenance program were randomly assigned to experimental and control groups. The experimental group received hypnotherapy for 6 months in addition to the psychotherapy offered as standard clinic treatment. The control group received only psychotherapy. After treatment a 6-month follow-up was conducted by interviews. Groups were compared to determine significant differences in the number of successful withdrawals, the mean change in methadone dose level, incidence of illicit drug use, and degree of discomfort. Significant differences were found on all measures. The experimental group had significantly less discomfort and illicit drug use, and a significantly greater number of withdrawals. At six-month follow-up, 94% of the Ss in the experimental group who had achieved withdrawal remained narcotic-free. determine significant differences in the number of successful withdrawals, the mean change in methadone dose level, incidence of illicit drug use, and degree of discomfort. Significant differences were found on all measures. The experimental group had significantly less discomfort and illicit drug use, and a significantly greater number of withdrawals. At six-month follow-up, 94% of the Ss in the experimental group who had achieved withdrawal remained narcotic-free.

Murphy, Joseph K.; Fuller, A. Kenneth (1984). Hypnosis and biofeedback as adjunctive therapy in blepharospasm: A case report. *American Journal of Clinical Hypnosis*, 27, 31-37.

The efficacy of ophthalmologic, hypnotic, and biofeedback treatment procedures in a case of blepharospasm was evaluated. Manual eye rubbing and eye opening served as dependent measures which were assessed by the patient during treatment and a three month follow-up. Results indicated that ophthalmologic treatment had a limited effect. In contrast, brief hypnosis had a dramatic but short-lived effect and biofeedback had a moderate but sustained effect. Results are discussed in terms of the efficacy of psychological intervention, the limitations of the report, and the need for future research.

Whorwell, P. J.; Prior, Alison; Faragher, E. B. (1984, December 1). Controlled trial of hypnotherapy in the treatment of severe refractory irritable-bowel syndrome. Lancet, 1232-1234.

30 patients with severe refractory irritable-bowel syndrome were randomly allocated to treatment with either hypnotherapy or psychotherapy and placebo. The psychotherapy patients showed a small but significant improvement in abdominal pain, abdominal distension, and general well-being but not in bowel habit. The hypnotherapy patients showed a dramatic improvement in all features, the difference between the two groups being highly significant. In the hypnotherapy group no relapses were recorded during the 3-month follow-up period, and no substitution symptoms were observed.

### **1983**

Classen, Wilhelm; Feingold, Ernest; Netter, Petra (1983). Influence of sensory suggestibility on treatment outcome in headache patients. Neuropsychobiology, 10, 44-47.

In 45 headache patients the relationship between sensory suggestibility and three measures of treatment effect-ratings on (1) intensity of headaches; (2) efficacy of drugs, and (3) physician's competence - was investigated in a double-blind long-term crossover study. Subjects scoring high on sensory suggestibility clearly showed more relief of headaches upon the analgesic as well as upon the placebo. The physician's competence was rated higher by high-suggestible patients, whereas ratings on drug efficacy were low in all patients. The seemingly controversial behavior of high-suggestible patients was interpreted as a call for continuation of the physician's efforts in spite of the relief the patients already achieved.

Flatt, Jennifer R. (1983). What makes therapy work? Thoughts provoked by a case study. Australian Journal of Clinical and Experimental Hypnosis, 11 (2), 63-72.

The case described is offered as illustrating the doubt common to introspective therapists: what did cure the patient? "Francesca's" presenting problem and the object of the short-term psychological intervention described here, was a

-chological intervention described here, was a fairly circumscribed set of fears related to enclosed spaces. The therapeutic approach adopted was primarily hypnobehavioural, with hypnotically-assisted systematic desensitization and "in vivo" exposure being the main components of the planned programme. However, at the client's suggestion, one hypnotic session with content planned by the therapist as age regression produced rather dramatic and unexpected results claimed by the patient to effect complete cure.

The therapist suggested that "her mind would take her back to a time that was important in understanding her fears and that she would be able to stay calm and relaxed while this past event was revealed to her" (p. 69). She subsequently imagined being in a cave, peaceful and calm. "On being roused from hypnosis, Francesca eagerly described her

cave image. She was enthusiastic about the significance of this experience, claiming that it was evidence that in a \_previous life\_ she had died from being locked into a cave as some sort of punishment and that this experience made her fear of enclosed places rational and comprehensible to her" (p. 69).

## 1981

Frankel, Fred H. (1981). Reporting hypnosis in the medical context: A brief communication. [International Journal of Clinical and Experimental Hypnosis, 29 \(1\), 10-14.](#)

Data relating to hypnosis in medicine fall into 3 categories: studies of efficacy, surveys, and reports of rare cases. Studies of the comparative efficacy of hypnosis pose special problems; surveys focused on the possible association between hypnotic responsivity and the nature of a clinical situation or its treatment are encouraged; and the presentation of unique or rare cases is considered.

Goldstein, Y. (1981). The effect of demonstrating to a subject that she is in a hypnotic trance as a variable in hypnotic interventions with obese women. [International Journal of Clinical and Experimental Hypnosis, 29 \(1\), 15-23.](#)

In order to investigate the question of whether or not Ss experiencing a phenomenon during trance which would be very unlikely to occur outside of trance improves the efficacy of hypnotic treatment for obesity, a S pool of obese women was divided into 3 groups: a non-hypnotic behavior modification group, a hypnosis group without any special phenomenon structured into it, and a hypnosis group with such a phenomenon (hand levitation). Weight-loss data were collected 4 weeks and 6 months after the start of treatment. All treatments resulted in at least moderate weight loss. Statistically significant differences were found between the hypnosis-with-hand-levitation treatment effect and the other treatment effects. Possible reasons for the treatment effects and the differences obtained are discussed.

Gruenewald, Doris (1981). Failures in hypnotherapy. [International Journal of Clinical and Experimental Hypnosis, 29 \(4\), 345-350.](#)

Failures in hypnotherapy are discussed in the context of considerations applying to treatment in general. Emphasis is given to the principle that hypnotherapy must be structured according to patients' personality and needs. When treatment fails, therapists should examine carefully what may have led to an unsatisfactory outcome.

Wilson, John F. (1981). Behavioral preparation for surgery: Benefit or harm?. [Journal of Behavioral Medicine, 4, 79-102.](#)

Elective surgery patients were prepared for surgery with training in muscle relaxation or with information about sensations they would experience. Relaxation reduced hospital stay, pain, and medication for pain and increased strength, energy, and postoperative

epinephrine levels. Information reduced hospital stay. Personality variables (denial, fear, aggressiveness) were associated with recovery and influenced patients' responses to preparation. Less frightened patients benefitted more from relaxation than did very frightened patients. Nonaggressive patients reacted to information with decreased hospital stay along with increased pain, medication, and epinephrine. Aggressive patients responded to information with decreased hospital stay along with decreased pain, medication, and epinephrine. Patients using denial were not harmed by preparation. A catharsis/moderation model is proposed to explain how information benefits patients. An active coping model is proposed to explain the benefits of relaxation. This study suggests that behavioral preparation benefits even frightened, aggressive, or denying elective surgical patients.

## **1980**

Bornstein, Philip H.; Devine, David A. (1980). Covert modeling-hypnosis in the treatment of obesity. [Psychotherapy: Theory, Research and Practice, 17 \(3\), 272-276.](#)

Investigated the efficacy of a covert modeling/hypnosis treatment package in the control of obesity. 48 overweight female volunteers (who had been administered the Harvard Group Scale of Hypnotic Susceptibility, Eating Patterns Questionnaire, and Rotter's Internal-External Locus of Control Scale) were randomly assigned to 1 of the following groups: (a) covert modeling/hypnosis, (b) covert modeling, (c) no-model scene control, and (d) minimal treatment (where Ss received a shortened version of the covert modeling/hypnosis procedure following an 8-wk no-treatment period.) Results indicate a significant effect for weight loss from pretreatment to follow-up across all groups combined. Proportion weight loss measures indicated significantly greater weight loss only for the covert modeling/hypnosis group as compared to the no-model controls. Implications for combining behavior therapy and hypnotic techniques are discussed. (30 ref).

## **1980**

Deyoub, P. L.; Wilkie, R. (1980). Suggestion with and without hypnotic induction in a weight reduction program. [International Journal of Clinical and Experimental Hypnosis, 28 \(4\), 333-340.](#)

Identical suggestions for the control of obesity were administered to a group receiving hypnotic induction and a group receiving task-motivational instructions. A no-treatment control group was also included. The only significant finding was greater weight loss by Ss in the task-motivational group than Ss in the control group. Much of the difference was attributed to weight gain of Ss in the control group. Within groups, highly suggestible Ss lost more weight in the hypnotic group, while suggestibility was unrelated to weight loss in the task-motivational group. The possibility that task-motivational and hypnotic Ss approached treatment with different mental sets and expectations was discussed. The role of hypnotizability in the hypnotic treatment of obesity was discussed.

Subjects approached treatment with different mental sets and expectations was discussed. The role of hypnotizability in the hypnotic treatment of obesity was discussed.

Lundy, Richard M.; Heide, Frederick J.; Wadlington, W. L. (1980). Hypnotic responsiveness as a predictor of outcome in meditation. International Journal of Clinical and Experimental Hypnosis, 28 (4), 358-366.

TM reportedly diminishes Trait Anxiety (not State Anxiety). Spielberger's Anxiety Scale was administered. Non-analytical attention is increased in TM. Spanos, et al. found a relationship between sustained attention in a meditation task and hypnotizability. Both load on the same factor.

Used Control and Experimental groups pretested on a scale of hypnotizability (Harvard Scale?): Lows = 1-4; Mediums = 5-7; Highs = 8-12.

Subjects were given instructions for modified TM, including a lecture on physiological benefits. "Let the sound 'OM' repeat itself; let that sound pass through and return to the mantra." Subjects logged practice on their 20 minute meditation twice a day, for 7 days. They were given pre- and posthypnotic tests of State and Trait anxiety.

**RESULTS.** Meditators decreased Trait anxiety but not State anxiety. But anxiety was reduced more for high hypnotizables than for other levels. There was greater change in anxiety for High hypnotizables who practiced meditation. No difference in pre- and posthypnotic test on Harvard, confirming Spanos, et al.

**CONCLUSIONS.** This provides more evidence that the skill of hypnotizability has more utility than we had thought, in therapy. Spanos, et al. also found that improvement in meditation was correlated with hypnotizability (in terms of number of intrusions) and Benson, Frankel, et al., found Lows benefit less in blood pressure change with either meditation or hypnosis

## 1979

Frankel, Fred H.; Apfel, R. J.; Kelly, S. F.; Benson, H.; Quinn, T.; Newmark, J.; Malmaud, R. (1979). The use of hypnotizability scales in the clinic: A review after six years. International Journal of Clinical and Experimental Hypnosis, 27 (2), 63-73.

This is a review of the use, after 6 years, of the Stanford Hypnotic Susceptibility Scale, Forms A and B (Weitzenhoffer & E. R. Hilgard, 1959); the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962); the Hypnotic Induction Profile (Spiegel & Bridger, 1970); and the Stanford Hypnotic Clinical Scale (Morgan & J. R. Hilgard, 1975) in the clinical situation. The great majority of over 300 patients found their experience with the scale to be a positive one, despite the authors' initial hesitancy about exposing them to the probability of failure on at least some of the items. The standardized scales were administered as specific tests, not as part of therapy.

The data on responsiveness has not only contributed to clinical strategy in individual cases, but has also added to our understanding of hypnosis, of psychopathology, and of therapeutic outcome.

Horowitz, Mardi J. (1979). States of mind: Analysis of change in psychotherapy. New York NY: Plenum Medical Book Company. (Also published in London, England)

Provides a configurational analysis approach to describe problems, resources, and processes of change in psychotherapy. Uses psychoanalytic (ego psychology) model "that emphasizes information processing and the structural aspects of self and object representations" (p. ix). The book provides methods for evaluating treatment outcome using increasingly precise ways of observing clinical material. As an example of how the author writes about states of mind, consider that "One could subject Hamlet to a description of his recurrent states of ambivalence, paralysis of action, deadly decisiveness, and pretense of gaiety or of madness; one could describe his various self-images and core models of role relationship, and explain his changes in state by the ways in which he processed information. Similarly, in a psycho-history one could plot the states, images, and information-processing styles of a person whose decisions interacted with important events" (pp. x-xi).

Pederson, Linda L.; Scrimgeour, William G.; Lefcoe, Neville M. (1979). Variables of hypnosis which are related to success in a smoking withdrawal program. [International Journal of Clinical and Experimental Hypnosis](#), 27 (1), 14-20.

65 habitual smokers were randomly assigned to one of 4 groups: live-hypnosis plus counseling, videotape-hypnosis plus counseling, relaxation-hypnosis plus counseling, and counseling alone. The content and mode of presentation of the hypnosis session varied among the first 3 groups. At 6 months posttreatment, the live-hypnosis plus counseling group contained significantly more abstainers than the other 3 groups. The importance of the specific content of the hypnosis session and the presence of the hypnotherapist for the effectiveness of the procedure is discussed.

Perry, Campbell; Gelfand, Robert; Marcovitch, Phillip (1979). The relevance of hypnotic susceptibility in the clinical context. [Journal of Abnormal Psychology](#), 88 (5), 592-603.

Despite experimental evidence that hypnotic susceptibility is a relatively stable characteristic of the individual, and one that is very difficult to modify, clinical investigators tend to see susceptibility as irrelevant to therapeutic outcome. Such investigators view motivational and interpersonal variables as more essential to the therapeutic change. The evidence for the clinical relevance of hypnotizability is sparse and contradictory. Most existing studies stem from medical hypnosis and indicate that susceptibility plays an important role in the successful treatment of such conditions as clinical pain, warts, and asthma. Two studies are reported that seek to pursue a contrary finding reported by Perry and Mullen, who found that susceptibility was unrelated to the successful treatment of a socially learned behavior (cigarette smoking). Both studies confirmed the earlier finding of a lack of relation. In Study 1, however, stepwise multiple regression analysis located three inventory items concerning the motivation of cigarette smokers. The combination of items was found to predict outcome for 67.39% of 46 clients treated either by hypnosis or by rapid smoking. The finding was replicated in Study 2, which utilized a combined hypnosis - rapid smoking technique and employed a different therapist. The outcome for 9 of the 13 quitters and 37 of the 62 nonquitters

across the two studies could be predicted by the three motivational questionnaire variables.

### **1978**

Benson, Herbert; Frankel, Fred H.; Apfel, Roberta; Daniels, Michael D.; Schniewind, Henry E.; Nemiah, John C.; Sifneos, Peter E.; Crassweller, Karen D.; Greenwood, Martha M.; Kotch, Jamie B.; Arns, Patricia A.; Rosner, Bernard (1978). Treatment of anxiety: A comparison of the usefulness of self-hypnosis and a meditational relaxation technique. [Psychotherapy and Psychosomatics, 30, 229-242.](#)

We have investigated prospectively the efficacy of two nonpharmacologic relaxation techniques in the therapy of anxiety. A simple, meditational relaxation technique (MT) that elicits the changes of decreased sympathetic nervous system activity was compared to a self-hypnosis technique (HT) in which relaxation, with or without altered perceptions, was suggested. 32 patients with anxiety neurosis were divided into 2 groups on the basis of their responsivity to hypnosis: moderate-high and low responsivity. The NIT or HT was then randomly assigned separately to each member of the two responsivity groups. Thus, 4 treatment groups were studied: moderate-high responsivity MT; low responsivity MT; moderate-high responsivity HT; and low responsivity HT. The low responsivity HT group, by definition largely incapable of achieving the altered perceptions essential to hypnosis, was designed as the control group. Patients were instructed to practice the assigned technique daily for 8 weeks. Change in anxiety was determined by three types of evaluation: psychiatric assessment; physiologic testing; and self-assessment. There was essentially no difference between the two techniques in therapeutic efficacy according to these evaluations. Psychiatric assessment revealed overall improvement in 34% of the patients and the self-rating assessment indicated improvement in 63% of the population. Patients who had moderate- high hypnotic responsivity, independent of the technique used, significantly improved on psychiatric assessment ( $p = 0.05$ ) and decreased average systolic blood pressure from 126.1 to 122.5 mm Hg over the 8-week period ( $p = 0.048$ ). The responsivity scores at the higher end of the hypnotic responsivity spectrum were proportionately correlated to greater decreases in systolic blood pressure ( $p = 0.075$ ) and to improvement by psychiatric assessment ( $p = 0.003$ ). There was, however, no consistent relation between hypnotic responsivity and the other assessments made, such as diastolic blood pressure, oxygen consumption, heart rate and the self-rating questionnaires. The meditational and self- hypnosis techniques employed in this investigation are simple to use and effective in the therapy of anxiety.

### **1978**

Frankel, Fred H. (1978). Scales measuring hypnotic responsivity: A clinical perspective. [American Journal of Clinical Hypnosis, 21, 208-218.](#)

Differences in the experiences of clinicians and laboratory investigators regarding the distribution of hypnotizability are addressed. The use of various rating scales in the clinical context is reviewed, and the importance of the scales in defining the difference, conceptually, between hypnosis and other procedures capable of achieving similar results is emphasized. The use of the scales in determining the treatment strategy is compared

with the customary practice of the experienced clinician, and with the importance of the characteristics of the total clinical situation. An illustrative case report is included.

Kaplan, Jerold Z.; Wakeman, John (1978). An experimental study of hypnosis in painful burns. [American Journal of Clinical Hypnosis, 21, 3-12.](#)

The present study examines the usefulness of hypnosis in the control of acute pain in thermal and electrically burned patients as an adjunctive analgesic during the routine care of burn wounds. It was hypothesized that the use of hypnosis would lead to significant reductions in the amount of drugs needed as compared to patients using medication only. Anxiety and discomfort associated with daily tanking, debridement, and dressing changes were expected to be reduced because of the introduction of hypnotic procedures. The experimental study also examined the variables of age and percent of burns. Two studies were conducted including patients with 0-20% total body burns and 31-60% burns. A variety of hypnotic techniques were used. Both studies revealed significantly lower percentages of medication used ( $p < .01$ ) by the hypnotic groups than control groups. The 7-18-year-old patients used significantly less medication ( $p < .05$ ) than the adult groups. The implications of the findings, and usefulness of hypnosis and ego strengthening techniques for improvement of self-confidence and improved body image were considered.

Parker, Jerry C.; Gilbert, Gary S.; Thoreson, Richard W. (1978). Reduction of autonomic arousal in alcoholics: A comparison of relaxation and meditation techniques. [Journal of Consulting and Clinical Psychology, 46 \(5\), 879-886.](#)

To investigate and compare the effects of progressive relaxation training and meditation training on autonomic arousal in alcoholics, 30 subjects were selected from a population of alcoholics in a Veterans Administration hospital substance-abuse program. The subjects were randomly assigned to one of the following three experimental conditions: (a) progressive relaxation training group, (b) meditation training group, or (c) quiet rest control group. All groups met for 3 weeks during which state anxiety, blood pressure, heart rate, and spontaneous galvanic skin responses were measured. The measures were designed to assess the treatment effects following the first training session and at the end of the total training period. The results indicate that both progressive relaxation training and meditation training are useful for reducing blood pressure in alcoholics. In addition, significant differences between the groups in the effectiveness of the relaxation procedures were found. Meditation training induced blood pressure decreases at an earlier point in the 3-week training period and affected decreases in systolic blood pressure that progressive relaxation training did not. These results support the idea of considerable specificity of response to relaxation techniques.

**1977**

Albornoz-Ruiz, Jose M. (1977). Suggestibility as a factor in medical treatment. [Maryland State Medical Journal, 26, 66-68.](#)

This paper presents the view that a physician must be aware of the great influence, direct and indirect, s/he has with the patient as a result of their relationship. "Here it should be remembered that the power of a suggestion, without the benefit of formalized hypnosis, is directly related to the intensity and nature of the emotional bond between the patient and the doctor, often colored by a marked transferential unconscious component, where the doctor stands 'in loco parentis' vis-a-vis the patient, regardless of the age, education or intellectual sophistication of the latter.

Whatever the nature of the perception that is eventually presented by the patient as a symptom or identified by the doctor as a sign of illness, such perception will be elaborated upon by the patient's fancy, in lonely reveries where he defines for himself causes, nature and possible course of his disorder, not always in keeping with those established by the doctor as he exposes the same set of phenomena to his learned medical judgment" (p. 68).

Barkley, R. A.; Hastings, J. E.; Jackson, T. L., Jr. (1977). The effects of rapid smoking and hypnosis in the treatment of smoking behavior. [International Journal of Clinical and Experimental Hypnosis, 25 \(1\), 7-17.](#)

29 Ss were assigned to one of 3 treatment conditions and treated for their cigarette smoking over a 2-week period. These conditions were: group rapid smoking, group hypnosis, and an attention-placebo control group. All treatments produced significant reductions in average daily smoking rates during the treatment phase but all Ss returned to near baseline levels of smoking by the 6-week follow-up. The rapid smoking and hypnosis groups did not differ from the control group in smoking rates at treatment termination or at the 6-week follow-up. They also did not differ from the control group in the number of Ss abstaining from smoking by treatment termination but did differ at follow-up. Eventually, at the 9-month follow-up, only Ss from the group rapid smoking condition had significantly more abstainers than the control group. The results suggested that rapid smoking can work as effectively in group procedures as previous individualized approaches had demonstrated. Group hypnosis, while less effective than some previous individualized approaches had indicated, was nevertheless only marginally less effective than the group rapid smoking procedure. The use of abstinence rates as opposed to average rates of smoking was strongly recommended as the best measure of treatment effectiveness for future research in this area.

Stern, John A.; Brown, M.; Ulett, George A.; Sletten, Ivan (1977). A comparison of hypnosis, acupuncture, morphine, Valium, aspirin, and placebo in the management of experimentally induced pain. [Annals of the New York Academy of Sciences, 296, 175-193.](#)

"What general conclusions can we come to on the basis of these investigations? We conclude that hypnosis and suggestions of analgesia, morphine, and acupuncture stimulation (of LI 4, 14, and 15 on the arm exposed to painful stimulation) are effective in reducing experimentally induced pain. This is true for both a cold pressor pain-induction procedure and an ischemic pain-induction procedure. Hypnotic suggestibility does not account for the effectiveness of acupuncture stimulation, though good hypnotic Ss show better protection against pain with hypnotic suggestion and morphine.

"Good hypnotic Ss experience more pain than is true for Poor hypnotic Ss when exposed to the same pain-induction procedure. The effect is more marked for the cold-pressor than the ischemic pain procedure. Good hypnotic Ss are more responsive -- i.e., show greater reduction in pain perception -- to drugs and intervention procedures that produce significant subjective sensations (morphine and diazepam) than is true of Poor hypnotic Ss. This is not true for aspirin and placebo. Last, but not least, Ss low in hypnotic susceptibility tend to perceive painful stimuli as more painful when under the influence of diazepam as compared to the nondrug condition" (p. 192).

**1976**

Moore, Mary E.; Berk, Stephen N. (1976). Acupuncture for chronic shoulder pain: An experimental study with attention to the role of placebo and hypnotic susceptibility. *Annals of Internal Medicine*, 84 (4), 381-384.

One half of 42 Ss treated for painful shoulders received classic acupuncture, and one half received a placebo in which the needles did not penetrate the skin. Half of each of these groups was treated in a positive setting to encourage the subject, and half in a negative setting designed to keep encouragement at a minimum. All patients were independently rated for susceptibility to hypnosis. Although range of motion did not improve, the majority of patients reported significant improvement in shoulder discomfort to a blind evaluator after treatment; placebo and acupuncture groups did not differ in this respect, however. The positive and negative settings did not affect treatment outcome. In all groups, those who were not rated as highly susceptible to hypnosis tended to fail to achieve the highest levels of relief, but such differences were not statistically significant.

There were 42 subjects, and they were tested with the Spiegel Hypnotic Induction Profile. "Both acupuncture and placebo proved to be effective in relieving shoulder discomfort. 69% of the total group made lower assessments of discomfort on the post-treatment rating than on the pretreatment rating" (p. 382).

"Acupuncture was not more effective than placebo in relieving discomfort, however. The average percentage of improvement among those who had acupuncture was not, statistically, significantly different from those who had placebo. Indeed, what little difference there was actually was in the opposite direction, the placebo group improving on the average somewhat more than the acupuncture group" (pp. 382-383).

"In the negative setting, however, where the subject was required to suffer in silence, acupuncture seemed to be less effective than the placebo in relieving discomfort" (p. 383).

"Although the subjects perceived that the treatment relieved their shoulder discomfort, there was no objective evidence of improvement in the shoulder as measured by change in the range of motion scores before and after treatment" (p. 383).

(The placebo was needle pricked against the skin at true site, then rapidly and lightly tapped against the surface of the skin without penetration.)

"Those who were not susceptible to hypnosis failed to experience as much relief from discomfort as those who were" (p. 383).

"The fact that acupuncture was not more successful in relieving shoulder discomfort than a sham procedure suggests that its much publicized success may be merely a powerful placebo effect" (p. 383).

Katz, Kao, Spiegel et al (1974) also found that low hypnotizables did not benefit much in terms of pain relief with acupuncture.

## 1975

Andreychuk, Theodore; Skriver, Christian (1975). Hypnosis and biofeedback in the treatment of migraine headache. [International Journal of Clinical and Experimental Hypnosis](#), 23 (3), 172-183.

A study was made to explore the effects of subject hypnotizability in response to 3 treatment procedures applied to 33 migraine headache sufferers. These treatment procedures included biofeedback training for hand-warming, biofeedback training for alpha enhancement and training for self-hypnosis. The Hypnotic Induction Profile (HIP) of Spiegel & Bridger (1970) was given to each S to determine degree of hypnotizability and the MMPI was administered to all Ss. All 3 treatment groups showed significant reductions in headache rates and there were no significant differences between groups. Cutting across treatment groups, high hypnotizable Ss (N - 15) showed significant reductions in headache rates when compared with low hypnotizable Ss (N - 13). There was no correlation between HIP scores and the hysteria scale of the MMPI.

This research investigated the relationship between hypnotizability and treatment outcome.

Collison, David R. (1975). Which asthmatic- patients should be treated by hypnotherapy?. [Medical Journal of Australia](#), 1 (25), 776-781.

Retrospective analysis of 121 asthmatic patients who were treated by hypnotherapy. Subjects were first broken down into one of three possible groups: "light," "medium," or "deep," according to the depth of trance typically achieved. Hypnoidal states were included in the light trance group and somnambulistic state in the deep trance. All sessions concentrated on suggesting physical and mental relaxation since we know this is one of the causes of the appearance of the "asthma attack." The actual wording varied however, and this involved discussion under hypnosis, of the main personalities of the environment, fears, failures, aims, hopes and frustrations. Post-hypnotic suggestions of

continued relaxation and ability to cope with the various situations of life were given in all the cases. Auto-hypnosis was taught to enable the patient to reinforce the above suggestions and to remain in or selectively achieve a relaxed state. Results were classified into four different categories: "excellent," "good," "poor," and "nil." It was found that those patients who experienced a "high" trance depth were more likely to show excellent improvement than those who were measured as "medium" or "low" trance subjects.

Mullen, G.; Perry, C. (1975). The effects of hypnotic susceptibility on reducing smoking behavior treated by a hypnotic technique. [Journal of Clinical Psychology, 31, 498-505.](#)

In order to examine the relationship between hypnotizability and treatment outcome in which hypnosis is used, 54 people ages 19-47 who undertook to stop smoking were studied. Although it is logical that there should be a relationship, clinical anecdotal material published by people who used hypnosis (Freud, Weitzenhoffer, Lazarus, Sheehan, Orne) suggests that may not be the case. Hypnotic susceptibility was evaluated with a clinical procedure developed by Orne and O'Connell (the DRP). Patients were taught self hypnosis using a brief procedure developed by Herbert Spiegel. Baseline smoking rate and three-month follow-up with postcards mailed every week were employed as measures. Success in the treatment program was defined as a 50% reduction in smoking behavior. After 3 months, 7 people were abstinent, 10 had reduced smoking to criterion level (50%), 16 people had discontinued the investigation, and 21 did not change. Considering only the 15 most and 15 least hypnotizable, 12 of the 15 high susceptibles had reduced smoking by at least 50%, as compared to 5 of the 15 of the low susceptibles. (chi square = 4.88, df = 1,  $p < .05$ ).

Samko, Michael R.; Schoenfeld, Lawrence S. (1975). Hypnotic susceptibility and the Lamaze childbirth experience. [American Journal of Obstetrics and Gynecology, 121, 631-6.](#)

This study explored the relationship between childbirth training and hypnotic susceptibility. A multiple linear regression analysis was performed on the various medical and attitudinal variables related to the subjects' Lamaze childbirth experience and these were tested against hypnotic susceptibility. The results of the analysis indicate that hypnotic susceptibility is not significantly related to Lamaze training, nor is it significantly related to the type of childbirth experience that a Lamaze trained woman has.

Subjects used in this experiment (N = 55) were women who had received Lamaze training within the last two years, and had delivered only one child. The HIP was administered to find a score of hypnotizability and the women were given two questionnaires. The first of the questionnaires sought demographic and medical information, the second was an attitude questionnaire about her childbirth. A third questionnaire was given to the attending physician. "The correlations between hypnotic susceptibility and the physician's rating of how successful he felt the subject's use of the Lamaze technique ( $r = 0.12$ ) and the physician's rating of how helpful he found the mother's use of the Lamaze technique was to delivery ( $r = 0.17$ ) were both nonsignificant" p. 634).

### **1973**

McReynolds, William T.; Barnes, Allan R.; Brooks, Samuel; Rehgagen, Nicholas (1973). The role of attention-placebo influences in the efficacy of systematic desensitization. Journal of Consulting and Clinical Psychology, 41 (1), 86-92.

Systematic desensitization was compared with two attention- placebo control treatments - one taken from Paul and one currently devised as an elaborate, highly impressive "therapeutic" experience - and no treatment. It was hypothesized that (a) fear reductions following desensitization would be no greater than those associated with an equally compelling placebo treatment and (b) fear and control measure changes following the previously used attention-placebo treatment would be less than those following desensitization and the present placebo control manipulations. Both hypotheses were supported, although support for the first was more consistent than for the second.

### **1970**

Maher-Loughnan, G. P. (1970). Hypnosis and auto-hypnosis for the treatment of asthma. International Journal of Clinical and Experimental Hypnosis, 18 (1), 1-14.

Conducted 2 controlled studies into the use of hypnosis in 252 asthma patients. Several different control procedures were used. Methods and results were summarized, and the same conclusion was reached: That hypnosis supplemented by autohypnosis was significantly more effective than control procedures. An outline is given of details of treatment methods. A current analysis of Ss involving up to 6 yr. of follow-up, is presented to provide a working guide to the regime in regular practice. To be fully effective hypnosis should be employed before steroids are started. Steroid-dependent asthma is rarely totally relieved by hypnotherapy. (Spanish & German summaries) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

### **1969**

Rock, Nicholas; Shipley, Thomas; Campbell, Colin (1969). Hypnosis with untrained, nonvolunteer patients in labor. International Journal of Clinical and Experimental Hypnosis, 17, 25-36.

20 nonvolunteer, untrained Ss were individually hypnotized during active labor and compared with 18 controls selected by the same criteria and receiving the same obstetrical treatment. Hypnotized Ss required less medication and obtained greater relief of pain than the controls. The time involved in induction of hypnosis was only 20 min., and the total time added by hypnotic procedures was only 45 min. longer than the regular care of the control group. It was concluded that hypnosis can be used easily on nonvolunteer, untrained patients in active labor, even in a noisy environment, without any serious sequelae. (Spanish & German summaries) (16 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

### **1968**

Faw, Volney; Sellers, David J.; Wilcox, Warren W. (1968). Psychopathological effects of hypnosis. International Journal of Clinical and Experimental Hypnosis, 16, 26-37.

The probability that hypnotic induction produces psychopathological effects has not been experimentally determined. The present study hypothesizes various negative effects following hypnosis such as increased signs of personality disturbances, increased need for medical attention, greater tendencies toward suicide, and negative effects among the more maladjusted persons of the population sample. 107 college students were assigned at random to experimental and control groups. The experimental group was hypnotized 3 times in successive weeks. A comparison between control and experimental groups in respect to pre- and post-MMPI score differences plus a follow-up with the college counseling center and infirmary for a 90-day period following induction led to the rejection of the hypotheses. A comparison of measures yielded some significant differences in favor of the experimental group. It is concluded that there are nondetrimental effects when hypnosis is used with a normal college population.

### 1964

Leckie, F. H. (1964). Hypnotherapy in gynecological disorders. [International Journal of Clinical and Experimental Hypnosis](#), 12 (3), 121-146.

The attitude and position of a gynecologist employing hypnotherapy in clinical practice is emphasized. Particular consideration is given to dysmenorrhea (25 cases), dyspareunia (30 cases), vaginismus (15 cases), frigidity (12 cases), and anxiety states encountered in gynecological practice (26 cases). An indication is given of the general method and of the specific pattern of treatment, which initially is directed to symptom removal by direct suggestion. When this method proves ineffective, special techniques are employed to carry out therapy at a deeper level. Details of clinical data of all cases are presented together with evaluation of the percentage of success achieved. Results have proved encouraging. Several illustrative cases are described.

### 1962

Kolouch, Fred T. (1962). Role of suggestion in surgical convalescence. [Archives of Surgery](#), 85, 144-155.

The author is a surgeon who has offered hypnosis to many patients in his practice. His inductions were usually rapid (30 seconds to 10 minutes), stressing optimistic expectations. The procedure is described as follows: "Suggestion is then utilized in a purposeful manner to communicate a reality image of the entire surgical procedure to the patient. A frank but optimistic discussion of morbidity and mortality is made. An estimate of the pain to be experienced is offered with the emphasis that this can be controlled in part and it will be temporary. The patients are told that they may use opiates or sedatives if they feel a need for chemical pain relief. Any subconscious fears of surgery are investigated using ideomotor questioning. These are ventilated by the patient and put in the proper perspective in relationship to the realities of the forthcoming surgical procedure. If the patient is capable, he is taught glove anesthesia of the hand and given a posthypnotic suggestion for the transference of this to his operative site. He is asked to visualize himself at the conclusion of his convalescence, free of his pathology, alive and well and rehabilitated to normal productivity. It is emphasized to him that by judicious application of his subconscious thoughts to relaxation, pain control, normal

respiratory, gastrointestinal, and urinary functions, he may rapidly accomplish his own preconceived notion of his convalescence.

"He is given a posthypnotic suggestion that he will never respond to hypnosis without his consent. ...

"A posthypnotic suggestion is given to establish a simple signal as a trance inducer for future hypnosis or to enable him to use autohypnosis.

"The patient who is to have a general anesthetic is given the suggestion that while asleep he will not listen to any conversation in the operating room except that which is directed toward him by name.

"In the patients undergoing minor outpatient surgery, hypnosis is frequently induced in the operating room during the scrub time.

"Patients undergoing general or regional anesthesia are frequently placed in a trance before the anesthetic period. ...

"During the surgery care is taken to keep discussion at a level unrelated to the surgical procedure. ...

"At the conclusion, consistent with an honest appraisal of the situation, optimistic, purposeful suggestions are offered the patient while he is still asleep or in hypnosis" (p. 305).

The author evaluated the outcome for 100 surgical patients who had received this procedure, using subjective measures (confidence, well-being, freedom from fear and anxiety) and two objective measures (needs for postoperative pain-relieving drugs, and postoperative hospitalization). Seventy-five patients aged 6-80 had 81 different procedures (breast biopsies, tenorrhaphies, orchiopexies, herniorrhaphies, thyroidectomies, a radical neck dissection, radical mastectomies, cholecystectomies, gastrectomies, rectal surgery, etc.); the remaining 25 patients had minor outpatient procedures under local or hypnoanesthesia.

The author compared the dosage of medications needed by patients he judged to have benefitted from hypnosis and those who didn't benefit. He did the same analysis for length of stay. Based on his own observations, he judged that 75% of the hospitalized patients and nearly all of the OPD patients benefitted and experienced a simplified convalescence. Laparotomy patients required more medications than the other patients. The author compared the hospitalized patients who received hypnotic suggestion to a similar group who were not subjected to such suggestion, on needs for opiates and postoperative hospitalization. There was a reduction in drug needs in most categories of cases, but equal needs in the biliary cases.

in the biliary cases. Patients subjected to thyroidectomy or herniorrhaphy left the hospital sooner if they had been given hypnosis, but the patients undergoing biliary and gastric surgery still required the usual hospital care.

Herniorrhaphy patients benefitted in terms of catheterization: only was catheterized in the hypnosis group compared to 7 in the nonhypnosis group. The author attributed this outcome to a combination of suggestion and local anesthesia. Postoperative complications were rare in the patients utilizing hypnosis.

The economic advantages of suggestion are illustrated in a comparison of the costs of hospitalization of the series of patients undergoing herniorrhaphy and thyroidectomy with and without hypnosis: average cost of thyroidectomy with hypnosis used effectively (\$196) and without hypnosis (\$311); of herniorrhaphies with hypnosis used effectively (\$125) and without hypnosis (\$181). N.B. These costs are presumably from the time period of approximately 1959-60, inasmuch as the paper was read at the Annual Session of the Western Surgical Association on December 1, 1961.

"Probably the most pleasure for the surgeon results from the observation of the responses of children to suggestion in hypnosis. A degree of cooperation and freedom from fear is exhibited that is nearly unbelievable. With hypnosis in children one may utilize local anesthesia in situations which previously required general anesthetics" (p. 310).

## 1962

Weitzenhoffer, Andre M. (1962). The significance of hypnotic depth in therapy. [International Journal of Clinical and Experimental Hypnosis, 10 \(2\), 75-78.](#)

It is a common assumption that hypnosis has a quality of degree. While clinicians often state that success is unrelated to depth, the author maintains that depth determines the techniques one can successfully use in hypnotherapy. At the same time he believes that hypnotic behavior is multidimensional and that the major determinant of hypnotherapeutic success is the therapist's ability to establish a meaningful interpersonal relationship. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

## 1961

Pearson, R. E. (1961). Response to suggestion given under general anesthesia. [American Journal of Clinical Hypnosis, 4, 106-114](#)

Employed a double-blind design with placebo control. Audio tapes containing therapeutic suggestions were played to 43 experimental patients during anesthesia. The main theme of the suggestions was that the patient would cope better and recover faster if he could become relaxed. Placebo tapes (music or blank tapes) were played to the 38 control patients. Only E, who had no contact with the patients, knew which tape was played to a given patient. Three postoperative variables were studied: (a) number of doses of narcotics in the first 5 postoperative days; (b) a numerical rating by the surgeon of the postoperative course; and (c) number of postoperative days until release. Although no significant differences were found between the suggestion group and placebo group on need for narcotics or rated course of recovery, patients receiving suggestions were discharged an average of 2.42 days sooner ( $p < .05$ ).

## 1955

Hart, Hornell (1955). Measuring some results of autohypnosis. [Journal of Clinical and Experimental Hypnosis, 3 \(4\), 229-242.](#)

The author developed self ratings for mood (euphoria-dysphoria) and alertness-fatigue, which were administered to college students in neutral conditions and after self-hypnosis conditions. The self hypnosis, or "auto-conditioning" usually involved deep relaxation

self suggestions followed by other suggestions. The suggestions involved using the word 'you' to be able to re-instate the autoconditioning more and more effectively; suggestions for attitude change (e.g. that 'No matter what comes, we will grapple with it courageously'); and euphoria auto-suggestions (e.g. that 'you will come out of this deep relaxation, feeling rested, alert, cheerful and courageous').

In both single session experiments, as with a class of nurses who experienced an 8 minute auto-conditioning procedure, and in experiments extending over time, depression decreased. He noted that "for various reasons, the students who participated in autoconditioning experiments between February and May, 1955, were in many respects less successful than some of the previous experimental groups had been" (p. 235).

Increased alertness and diminished fatigue was also observed.

Many students chose to give themselves suggestions to correct the habit of procrastination. Two-thirds of the participants reported complete success, up to the level specified, and only one of 43 experiments on correcting procrastination was a "flat failure."

## **P RESEARCH**

### **PAIN MANAGEMENT**

**GOW, MICHAEL (2002). Treating dental needle phobia using hypnosis. [Paper] Presented at IFDAS/SAAD 10th International Dental Congress on Modern Pain Control, Edinburgh, June 2003, also at BSMDH (Scot) meeting December 2003.**

**"This case illustrates the effectiveness of short-term hypnosis treatment for a dental needle phobia. What is significant is the dental history of the patient and the longstanding effect of her dental phobias and how quickly hypnosis was able to remove this problem.**

**Aim: To manage dental needle phobia using hypnosis integrated into an anxiety management treatment plan."**

**Case History: Female, 48, had traumatic and painful experience at the dentist when 5, developed phobia of dental injections and treatment. Has had a dozen General Anaesthetics for dental treatment. Experiences psychosomatic pain prior to treatment.**

**Methods: Medical, dental and phobia history explored. Pre-treatment questionnaire assessed dental anxiety, reasons for anxiety, and ascertained management options. Post-treatment questionnaire assessed changes in dental anxiety and attitudes.**

**Anxiety management techniques: Needle Desensitisation, Relaxation, and Hypnosis (Regression, Progressive Muscular Relaxation, Glove Anaesthesia, Future Rehearsal etc.).**

**Results: Pre-treatment questionnaire revealed high level anxiety (26 out of high of 30 modified Corah score; and high anticipation of future pain during dental treatment (10 out of high of 10 on a Visual Analogue Scale. Post-treatment**

questionnaire revealed low level anxiety (12/30) and low anticipation of future pain (4/10).

**Conclusion:** Hypnosis was an effective adjunct to anxiety management in this case, demonstrating how a non pharmacological approach can find long term solutions by addressing the causes of the anxiety. Previous pharmacological approach had only addressed the symptoms of the immediate anxiety. Successful completion of prescribed dental treatment plan and changes in patient's attitudes highlight positive outcome

**Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)**

This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

**Horton-Hausknecht J.; Mitzdorf U.; Melchart D. (2000). The effect of hypnosis therapy on the symptoms and disease activity in rheumatoid arthritis . Psychology and Health, 14 (6), 1089-1104..**

from: [http://www.imp-muenchen.de/The\\_effect\\_of\\_hypnos.698.1.html](http://www.imp-muenchen.de/The_effect_of_hypnos.698.1.html)

In this study we aimed to assess the effectiveness of clinical hypnosis on the symptoms and disease activity of rheumatoid arthritis (RA). 66 RA patients participated in a controlled group design. 26 patients learnt the hypnosis intervention, 20 patients were in a relaxation control group, and 20 patients were in a waiting-list control group. During hypnosis, patients developed individual visual imagery aimed at reducing the autoimmune activity underlying the RA and at reducing the symptoms of joint pain, swelling, and stiffness. Subjective assessments of symptom severity and body and joint function, using standardized questionnaires and visual analogue scales, were obtained. Objective measures of disease activity via multiple blood samples during the therapy period and at the two follow-ups were also taken. These measurements were of erythrocyte sedimentation rate, C-reactive protein, hemoglobin, and leukocyte total numbers. Results indicate that the hypnosis therapy produced more significant improvements in both the subjective and objective measurements, above relaxation and medication. Improvements were also found to be of clinical significance and became even more significant when patients practiced the hypnosis regularly during the follow-up periods.

Willmarth, Eric K. (2000, August). Modification of experienced pain with hypnotically induced positive mood. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, D. C..

This study investigated the relationship between chronic pain and depressed mood within the context of Associative Network Theory and the High Risk Model of Threat Perception. A bi-directional relationship was hypothesized and tested by comparing pain ratings before and after the hypnotic induction of positive mood by suggestion of positive memories. These results were compared to the pain ratings of two control groups: participants who received hypnotic suggestion for relaxation only and participants who received non-hypnotic suggestion for relaxation and enhanced mood. Participants were 96 patients of a hospital-based Pain Management Center. Following assessment of hypnotic ability using the Harvard Group Scale of Hypnotic Susceptibility: Form A, and the Subjective Experiences Scale, participants recorded levels of depressed mood, sensory pain, affective pain, global pain and self control of pain before and after listening to an audio-taped treatment session. Results show that the induction of a positive mood did influence a decrease in self-reports of pain. In addition, the level of the participants' hypnotic ability was also found to be a significant factor, suggesting that screening for predisposing factors, such as hypnotic ability, and the clinical use of hypnosis for mood enhancement are warranted in a chronic pain population. - Abstract taken from Psychological Hypnosis: A Bulletin of [Amer Psychol Assn] Division 30, Fall 2000.

Capafons, A. (1999). Applications of emotional self-regulation therapy. In Kirsch, I.; Capafons, A.; Cardega, E.; Amigs, S. (Ed.), Clinical hypnosis and self-regulation: Cognitive-behavioral perspectives (pp. 331-349). Washington, D.C.: American Psychological Association.

This chapter reviews the main applications of emotional self-regulation therapy, which have received empirical support: smoking reduction, obesity, fear of flying, drug addictions, and premenstrual distress and dysmenorrhea. The logic of each treatment and main empirical results are summarized.

Lioffi, Christina; Hatira, Popi (1999). Clinical hypnosis versus cognitive behavioural training for pain management with pediatric patients undergoing bone marrow aspirations. International Journal of Clinical and Experimental Hypnosis, 47 (2), 104-116.

A randomized controlled trial was conducted to compare the efficacy of clinical hypnosis versus cognitive behavioral (CB) coping skills training in alleviating the pain and distress of 30 pediatric cancer patients (age 5 to 15 years) undergoing bone marrow aspirations. Patients were randomized to one of three groups: hypnosis, a package of CB coping skills, and no intervention. Patients who received either hypnosis or CB reported less pain and pain-related anxiety than did control patients and less pain and anxiety than at their own baseline. Hypnosis and CB were similarly effective in the relief of pain. Results also indicated that children reported more anxiety and exhibited more behavioral distress in the CB group than in the hypnosis group. It is concluded that hypnosis and CB coping skills are effective in preparing pediatric oncology patients for bone marrow aspiration

**1998**

Alden, Phyllis; Heap, Michael (1998). Hypnotic pain control: Some theoretical and practical issues. International Journal of Clinical and Experimental Hypnosis, 46 (1), 62-76.

Pain management programs assist patients to use their behavioral and cognitive skills for the purpose of rendering their experience of pain as more tolerable in some way. Hypnotic procedures may be included in this perspective. Thus, hypnosis may be best conceived as a set of skills to be deployed by the individual rather than as a state. The authors contend that such an emphasis is more compatible with the approaches of some pain management practitioners who have been generally slow to acknowledge the value of hypnosis and to incorporate hypnosis in their range of treatment skills. In this article, the authors present a minimal and atheoretical definition of hypnosis, and they list the basic properties of hypnosis that may be used in the treatment of pain. For a number of reasons, it is suggested that

undertaking hypnosis as though the individual were indeed being placed into a special trance state may in some cases promote an effective outcome. However, it should be acknowledged that there may be instances when the relevant skills may be more effectively engaged at the expense of a strict special trance state by targeting the specific skills that are to be used for therapeutic benefit.

treatment of pain. For a number of reasons, it is suggested that undertaking hypnosis as though the individual were indeed being placed into a special trance state may in some cases promote an effective outcome. However, it should be acknowledged that there may be instances when the relevant skills may be more effectively engaged at the expense of a strict special trance state by targeting the specific skills that are to be used for therapeutic benefit.

Crawford, Helen J.; Knebel, Timothy; Kaplan, Lyla; Vendemia, Jennifer M. C.; Xie, Min; Jamison, Scott; Pribram, Karl H. (1998). Hypnotic analgesia: 1. Somatosensory event-related potential changes to noxious stimuli and 2. Transfer learning to reduce chronic low back pain. International Journal of Clinical and Experimental Hypnosis, 46 (1), 92-132.

Fifteen adults with chronic low back pain (M = 4 years), age 18 to 43 years (M = 29 years), participated. All but one were moderately to highly hypnotizable (M = 7.87; modified 11-point Stanford Hypnotic Susceptibility Scale, Form C [Weitzenhoffer & Hilgard, 1962]), and significantly reduced pain perception following hypnotic analgesia instructions during cold-pressor pain training. In Part 1, somatosensory event-related potential correlates of noxious electrical stimulation were evaluated during attend and hypnotic analgesia (HA) conditions at anterior frontal (Fp1, Fp2), midfrontal (Fe, F4), central (C3, C4), and parietal (P3, P4) regions. During HA, hypothesized inhibitory processing was evidenced by enhanced N140 in the anterior frontal region and by a prestimulus positive-ongoing contingent cortical potential at Fp1 only. During HA, decreased spatiotemporal perception was evidenced by reduced amplitudes of P200 (bilateral midfrontal and central, and left parietal) and P300 (right midfrontal and central). HA led to highly significant mean reductions in perceived sensory pain and distress. HA is an active process that requires inhibitory effort, dissociated from conscious awareness, where the anterior frontal cortex participates in a topographically specific inhibitory feedback circuit that cooperates in the allocation of thalamocortical activities. In Part 2, the authors document the development of self-efficacy through the successful transfer by participants of newly learned skills of experimental pain reduction to reduction of their own chronic pain. Over three experimental sessions, participants reported chronic pain reduction, increased psychological well-being, and increased sleep quality. The development of "neurosignatures of pain" can influence subsequent pain experiences (Coderre, Katz, Vaccarino, & Malzack, 1993; Melzack, 1993) and may be expanded in size and easily reactivated (Flor & Birbaumer, 1994; Melzack, 1991, 1993). Therefore, hypnosis and other psychological interventions need to be introduced early as adjuncts in medical treatments for onset pain before the development of chronic pain.

The authors suggest that "the anterior frontal region deals with the active allocation of attention and disattention, whereas spatiotemporal aspects of the somatosensory perceptions involve the posterior cortical systems" (p. 113) They acknowledge that "other inhibitory pain systems are actively interacting with the frontal attentional system, including the limbic and thalamic systems" and mention evidence that the inhibitory processing "may extend as far as spinal cord antinociceptive mechanisms as evidenced by reductions in brief latency (Hagbarth & Finer, 1963) and R-III amplitude (Kiernan, Dane, Phillips, & Price, 1995) of spinal reflexes" (p. 113). Both pain perception and strategies of pain control may involve the anterior cingulate cortex (Kropotov et al. 1997), which has many connections with anterior frontal cortex "and is thought to be an area that organizes responses to noxious stimuli" (p. 113).

For the chronic low back pain Ss there were reductions in reported low back pain during the experimental sessions, and significant improvements in psychological well-being and sleep quality across the three sessions. "The importance of developing self-efficacy through learning to control experimental pain and the understanding of one's own attentional and disattentional abilities was demonstrated as being a significant intervention in the modulation and control of chronic pain" (p. 123).

**Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..**

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm,

accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

Weisenberg, Matisyohu (1998). Cognitive aspects of pain and pain control. International Journal of Clinical and Experimental Hypnosis, 46 (1), 44-61.

The cognitive and cognitive-behavioral approaches have been shown to be very effective in controlling pain and its sequelae both in the laboratory and in the clinical setting. As used in most research and treatment, cognitive approaches are concerned with the way the person perceives, interprets, and relates to his or her pain rather than with the elimination of the pain per se. This article reviews some of the origins of cognitive theory and pain theory, as well as examples of the techniques used and the research support for the approach. Special emphasis is given to self-efficacy, perceived control, and stress inoculation therapy. There is also discussion of some of the limitations of the cognitive approach. The overall conclusion is that the cognitive approach is a powerful and effective one for pain control despite its limitations.

of some of the limitations of the cognitive approach. The overall conclusion is that the cognitive approach is a powerful and effective one for pain control despite its limitations.

Dinges, David F.; Whitehouse, Wayne G.; Orne, Emily Carota; Bloom, Peter B.; Carlin, Michele M.; Bauer, Nancy K.; Gillen, Kelly A.; Shapiro, Barbara S.; Ohene-Frempong, Kwaku; Dampier, Carlton; Orne, Martin T. (1997). Self-hypnosis training as an adjunctive treatment in the management of pain associated with sickle cell disease. International Journal of Clinical and Experimental Hypnosis, 45 (4), 417-432.

A cohort of patients with sickle cell disease, consisting of children, adolescents, and adults, who reported experiencing three or more episodes of vaso-occlusive pain the preceding year, were enrolled in a prospective two-period treatment protocol. Following a 4-month conventional treatment baseline phase, a supplemental cognitive-behavioral pain management program that centered on self-hypnosis was implemented over the next 18 months. Frequency of self-hypnosis group training sessions began at once per week for the first 6 months, became biweekly for the next 6 months, and finally occurred once every third week for the next 6 months, and finally occurred once every third week for the remaining 6 months. Results indicate that the self-hypnosis intervention was associated with a significant reduction in pain days. Both the proportion of "bad sleep" nights and the use of pain medications also decreased significantly during the self-hypnosis treatment phase. However, participants continued to report disturbed sleep and to require

medications on those days during which they did experience pain. Findings further suggest that the overall reduction in pain frequency was due to the elimination of less severe episodes of pain. Non-specific factors may have contributed to the efficacy of treatment. Nevertheless, the program clearly demonstrates that an adjunctive behavioral treatment for sickle cell pain, involving patient self-management and regular contact with a medical self-hypnosis team, can be beneficial in reducing recurrent, unpredictable episodes of pain in a patient population for whom few safe, cost-effective medical alternatives exist.

**Tan, Siang-Yang; Leucht, Christopher A. (1997). Cognitive-behavioral therapy for clinical pain control: A 15-year update and its relationship to hypnosis. International Journal of Clinical and Experimental Hypnosis, 45 (4), 396-416**

Since Tan's (1982) review of cognitive and cognitive-behavioral methods for pain control was published 15 years ago, significant advances have been made in cognitive-behavioral therapy for pain. The scientific evidence for its efficacy for clinical pain attenuation is now much more substantial and is briefly reviewed. In particular, cognitive-behavioral therapy for chronic pain was recently listed as one of 25 empirically validated or supported psychological treatments available for various disorders. A number of emerging issues are further discussed in light of recent developments and research findings. The relationship of cognitive-behavioral therapy to hypnosis for pain control is briefly addressed, with suggestions for integrating hypnotic and cognitive-behavioral techniques.

**Dane, Joseph R. (1996). Hypnosis for pain and neuromuscular rehabilitation with multiple sclerosis: Case summary, literature review, and analysis of outcomes. International Journal of Clinical and Experimental Hypnosis, 44 (3), 208-231.**

Videotaped treatment sessions in conjunction with 1-month, 1-year, and 8-year follow-up allow a unique level of analysis in a case study of hypnotic treatment for pain and neuromuscular rehabilitation with multiple sclerosis (MS). Preparatory psychotherapy was necessary to reduce the patient's massive denial before she could actively participate in hypnosis. Subsequent hypnotic imagery and posthypnotic suggestion were accompanied by significantly improved control of pain, sitting balance, and diplopia (double vision), and a return to ambulatory capacity within 2 weeks of beginning treatment with hypnosis. Evidence regarding efficacy of

hypnotic strategies included (a) direct temporal correlations between varying levels of pain relief and ambulatory capacity and the use versus nonuse of hypnotic strategies, (b) the absence of pharmacological explanations, and (c) the ongoing presence of other MS-related symptoms that remained unaltered. In conjunction with existing literature on hypnosis and neuromuscular conditions, results of this case study strongly suggest the need for more detailed and more physiologically based studies of the phenomena involved. - Journal Abstract

LaClave, Linda J.; Blix, Susanne (1989). Hypnosis in the management of symptoms in a young girl with malignant astrocytoma: A challenge to the therapist. International Journal of Clinical and Experimental Hypnosis, 37 (1), 6-14.

This paper presents the case of a 6.5-year-old girl with malignant astrocytoma of the left brain hemisphere. During the course of her chemotherapy treatment, severe vomiting developed to the degree that on several occasions she became dehydrated. Discontinuation of chemotherapy was being considered when she was referred for hypnotherapy. Despite severe neurological impairments which excluded many traditional techniques, hypnosis was successful in eliminating emesis. Hypnosis was also utilized to decrease pain and to improve sleep patterns. Drawings are presented to help show how this child resolved anxiety associated with treatment and fears surrounding the knowledge of her impending death.

From: Psychology and Health, 2000, vol 14, p. 1089.

Horton-Hausknecht J, Mitzdorf U, Melchart D: The effect of hypnosis therapy on the symptoms and disease activity in rheumatoid arthritis .

In this study we aimed to assess the effectiveness of clinical hypnosis on the symptoms and disease activity of rheumatoid arthritis (RA). 66 RA patients participated in a controlled group design. 26 patients learnt the hypnosis

intervention, 20 patients were in a relaxation control group, and 20 patients were in a waiting-list control group. During hypnosis, patients developed individual visual imagery aimed at reducing the autoimmune activity underlying the RA and at reducing the symptoms of joint pain, swelling, and stiffness. Subjective assessments of symptom severity and body and joint function, using standardized questionnaires and visual analogue scales, were obtained. Objective measures of disease activity via multiple blood samples during the therapy period and at the two follow-ups were also taken. These measurements were of erythrocyte sedimentation rate, C-reactive protein, hemoglobin, and leukocyte total numbers. Results indicate that the hypnosis therapy produced more significant improvements in both the subjective and objective measurements, above relaxation and medication. Improvements were also found to be of clinical significance and became even more significant when patients practiced the hypnosis regularly during the follow-up periods.

"The effect of hypnotic suggestion on pain and mobility of joints was remarkable. On the fifth session there was hardly any pain, and shoulder movements were almost normal" (p. 179).

1987

Chaves, John; Brown, Jude (1987). Spontaneous cognitive strategies for the control of clinical pain and stress. Journal of Behavioral Medicine, 10 (3), 263-276.

The spontaneous cognitive strategies employed by 75 patients undergoing dental extractions or mandibular block injections were elicited using a structured interview. Interest focused on the relationship between these strategies and several personality variables, including state and trait anxiety, locus of control, and absorption. In addition, the effect of strategy utilization on perceived pain and stress was assessed. Forty-four percent of the patients employed cognitive strategies designed to minimize pain and stress, while 37% catastrophized, engaging in cognitive activity which exaggerated the fearful aspects of their experience. Only 19% of the patients denied any cognitive activity during the clinical procedure, and many of these used noncognitive coping strategies. Discriminant analysis revealed that situational anxiety was associated with the use of cognitive coping strategies. Catastrophizing was associated with increasing age, past dental stress, and higher levels of stress vulnerability (high trait anxiety and external locus of control). Copers reported less stress than catastrophizers but not less pain.

1986

Williams, David A.; Thorn, Beverly E. (1986). Can research methodology affect treatment outcome? A comparison of two cold pressor test paradigms. Cognitive Therapy and Research, 10 (5), 539-545.

Examined the effect of fixed or open latency instructions on subjective pain report for the cold pressor test using a single cognitive training strategy with 80 undergraduates. The fixed latency paradigm instructed Ss to leave their hand in the cold water for a fixed amount of time (e.g., 3 min), whereas the tolerance paradigm

asked Ss to endure pain for as long as possible. Results suggest that the fixed latency paradigm is associated with lower subjective pain ratings especially when a cognitive strategy is used. The tolerance groups failed to decrease their subjective perception of pain but evidenced longer latencies when a cognitive strategy was used. It is concluded that while other research has used these paradigms interchangeably to assess efficacy, these 2 paradigms apparently pose different challenges to Ss. (15 ref).

**Kabat-Zinn, Jon; Lipworth, Leslie; Burney, Robert (1985). The clinical use of mindfulness meditation for the self-regulation of chronic pain. Journal of Behavioral Medicine, 8 (2), 163-190.**

90 chronic pain patients were trained in mindfulness meditation in a 10-wk stress reduction and relaxation program. Self-report indices, including the McGill Pain Questionnaire, the Profile of Mood States, and the Hopkins Symptom Checklist, were administered to the Ss to assess multiple aspects of pain and certain pain-related behaviors. Results show statistically significant reductions in measures of present-moment pain, negative body image, inhibition of activity by pain, symptoms, mood disturbance, and psychological symptomatology, including anxiety and depression. Pain-related drug utilization decreased, and activity levels and feelings of self-esteem increased. Improvement appeared to be independent of gender, source of referral, and type of pain. A comparison group of 21 pain patients did not show significant improvement on these measures after traditional treatment protocols. At follow-up, the improvements observed during the meditation training were maintained up to 15 months postmeditation training for all measures except present-moment pain. The majority of Ss reported continued high compliance with the meditation practice as part of their daily lives.

**Smith, Shirley J.; Balaban, Alvin B. (1983). A multidimensional approach to pain relief: Case report of a patient with systemic lupus erythematosus. International Journal of Clinical and Experimental Hypnosis, 31 (2), 72-81.**

A multidimensional approach to the relief of intense pain associated with a chronic, debilitating disease (Systemic Lupus Erythematosus) is illustrated in this case report. Techniques associated with behavioral therapy (deep muscle relaxation, systematic desensitization); hypnosis (trance states, guided imagery, age regression, anesthetic induction and transfer and auto-hypnosis); and psychodynamic psychotherapy (dyadic interchange, suggestion, encouragement, interpretation of resistance and the transference/countertransference relationship) were utilized in obtaining virtual freedom from disabling pain and the necessity for analgesic and tranquilizing medications. Follow-up over a 3-year period demonstrated the utility of the approach.

**1979**

Johnson, L. S.; Wiese, K. F. (1979). Live versus tape-recorded assessments of hypnotic responsiveness in pain control patients. International Journal of Clinical and Experimental Hypnosis, 27 (2), 74-84.

This study compared the effectiveness of live versus tape-recorded hypnotic procedures in producing general hypnotic responsiveness in hospitalized pain patients. 30 patients individually received in counterbalanced order both a live and an audiotaped presentation of the Stanford Hypnotic Clinical Scale (Hilgard & Hilgard, 1975), which contains an induction and a 5-item test of hypnotic susceptibility suitable for bed-ridden patients. The live presentation produced a significantly higher total score than the taped procedure ( $p < .05$ ), with no significant order effects. The correlation between modes of presentation was .66. Order effects were not significant but a trend in that direction was discussed. The differences were found to hold for the high and medium ranges of susceptibility. Tentative conclusions were drawn that one cannot assume taped procedures to be equivalent to live in hypnotic analgesia research with clinical populations. The non-equivalence of live and taped procedures need not invalidate the clinical use of the latter, should they prove empirically effective. A case study of low back pain is added to illustrate effective tape-induced analgesia for patients unsuccessful with self-hypnosis.

1978

Schafer, Donald W.; Hernandez, A. (1978). Hypnosis, pain and the context of therapy. International Journal of Clinical and Experimental Hypnosis, 26 (3), 143-153.

The therapeutic use of hypnosis in pain syndromes assumes that organic pain can be brought under control through hypnotic techniques. Although it might be inferred from laboratory experiments that the hypnotic control of pain is in direct proportion to the individual's hypnotizability, clinical work would indicate that most motivated patients can achieve sufficient levels of hypnosis to alleviate pain. The psychological state of the patient -- regardless of whether the pain was initially organic or psychogenic -- modifies the patient's response to therapeutic hypnosis. This paper presents an approach to the patient that helps insure that the context of hypnotherapy will be optimal. Many patients who might otherwise be classified as un hypnotizable can in the appropriate context be helped to utilize hypnosis for the control of their pain.

1966

Zane, M. D. (1966). The hypnotic situation and changes in ulcer pain. International Journal of Clinical and Experimental Hypnosis, 14 (4), 292-304.

This is a study of internal and external hypnotic conditions associated with changes in pain developed during 5 hypnosis sessions in a patient with an acute duodenal ulcer. The 12 increases and 8 decreases in pain studied were found to be related to the interaction of coexisting reactions directed toward shifting social and private goals. Pain was associated with conflict among these reactions; intensification of

**pain occurred as a train of self-propagating internal events increased the conflict; relief of pain accompanied a reduction in the conflict. Increasing bodily disorganization resulted as shifts in focus of attention among social and private goals resulted in the rapid growth of conflicting mental and physical processes. An external stimulus, in the form of a highly individualized hypnotic suggestion, was often required to stop the disorganizing processes.**

processes.

Cangello, V. W. (1961). The use of hypnotic suggestion for pain relief in malignant disease. International Journal of Clinical and Experimental Hypnosis, 9, 17-22.

Using hypnotic suggestion, pain relief was attempted in 22 cases. 13 of these patients showed a decrease in narcotic requirements. Duration of effectiveness was from 1 week to 4 1/2 months. It is concluded that this method should be tried before resorting to either chemical or surgical procedures since it is relatively simple to perform, has no harmful complications, and is not unduly time consuming. Wallace, G. (1959). Hypnosis in anesthesiology. International Journal of Clinical and Experimental Hypnosis, 7 (3), 129-138.

The author states that reassurance of surgical patients in a preoperative visit may be enhanced with "the truly interpersonal relationship that hypnosis has as its foundation" (p. 131). He does not use the word "hypnosis" per se with these patients. Suggestions may be given that the patient will tolerate required procedures comfortably. Hypnosis supplements but usually does not replace anesthesia for an entire surgical procedure, but can be used in conjunction with regional techniques such as a nerve block, or in minor procedures on its own. A period of conditioning is necessary for producing true anesthesia, and that often is too time consuming for many anesthesiologists. Hypnosis can be used postoperatively for hiccoughs, for motivating the patient to become suitably active, etc. It is especially useful in a pediatric setting and in obstetrical procedures. He describes specific techniques used for conditioning obstetrical patients. The author also discusses pain management applications of hypnosis.

Stokvis, B. (1956). The application of hypnosis in organic diseases. Journal of Clinical and Experimental Hypnosis, 4 (2), 79-82.

"SUMMARY. Hypnotherapy, applied as a symptomatic treatment, is especially indicated in those cases of organic diseases in which the patient has neurotically elaborated his physical suffering. In cases presenting neither etiological nor secondary psychic factors one may try to improve the patient's condition by hypnotic treatment. Description of a case (hypnotherapy in a woman with carcinoma mammae)[sic]. The writer's lack of appreciation of hypnotherapy in organic diseases does not include the treatment of diseases which are definitely psychosomatically determined" (pp. 81-82).

**Danziger, N.; Fournier, E.; Bouhassira, D.; Michaud, D.; De Broucker, T.; Santarcangelo, E.; Carli, G.; Chertock, L.; Willer, J. C. (1998). Different strategies of modulation can be operative during hypnotic analgesia: A neurophysiological study. Pain, 75 (1), 85-92.**

**Nociceptive electrical stimuli were applied to the sural nerve during hypnotically-suggested analgesia in the left lower limb of 18 highly susceptible subjects. During this procedure, the verbally reported pain threshold, the nociceptive flexion (RIII) reflex and late somatosensory evoked potentials were investigated in parallel with autonomic responses and the spontaneous electroencephalogram (EEG). The hypnotic suggestion of analgesia induced a significant increase in pain threshold in all the selected subjects. All the subjects showed large changes (i.e., by 20% or more) in the amplitudes of their RIII reflexes during hypnotic analgesia by comparison with control conditions. Although the extent of the increase in pain threshold was similar in all the subjects, two distinct patterns of modulation of the RIII reflex were observed during the hypnotic analgesia: in 11 subjects (subgroup 1), a strong inhibition of the reflex was observed whereas in the other seven subjects (subgroup 2) there was a strong facilitation of the reflex. All the subjects in both subgroups displayed similar decreases in the amplitude of late somatosensory evoked cerebral potentials during the hypnotic analgesia. No modification in the autonomic parameters or the EEG was observed. These data suggest that different strategies of modulation can be operative during effective hypnotic analgesia and that these are subject-dependent. Although all subjects may shift their attention away from the painful stimulus (which could explain the decrease of the late somatosensory evoked potentials), some of them inhibit their motor reaction to the stimulus at the spinal level, while in others, in contrast, this reaction is facilitated.**

**Chaves, John F.; Dworkin, Samuel F. (1997). Hypnotic control of pain: Historical perspectives and future prospects. International Journal of Clinical and Experimental Hypnosis, 45 (4), 356-376.**

**Hypnotic analgesia has occupied a pivotal place in experimental and clinical hypnosis. It emerged early in the 19th century when effective clinical techniques for pain management had not yet developed, and the relief of pain and suffering had not even become a well-defined social goal. Its acceptance was further complicated by political struggles surrounding the humanitarian transformation of medicine during this era as well as a redefinition of the physician-patient relationship that wrested control from the patient. The initial struggle for professional acceptance was won only when the debate became almost entirely localized within the professional community. Acceptance of hypnosis by professional organizations has been followed by alternating periods of interest and indifference. While the evidence**

for the powerful effects of suggestion and related variables has often been observed and reported in nonhypnotic contexts, their relationship to hypnotic phenomena has often not been appreciated. Since the mid-20th century, scientific information about hypnotic analgesia has grown substantially and has had significant influence on strategies for acute and chronic pain management. If recent calls for its wider application in pain management are to succeed, it will require additional data from clinical populations and a balanced and scientifically prudent approach by its advocates. [Journal Abstract]

Zachariae, Robert; Bjerring, Peter (1994). Laser-induced pain-related brain potentials and sensory pain ratings in high and low hypnotizable subjects during hypnotic suggestions of relaxation, dissociated imagery, focused analgesia, and placebo. International Journal of Clinical and Experimental Hypnosis, 42 (1), 56-80.

Pain reports and amplitudes of painful argon laser-induced brain potentials were obtained for 10 high and 10 low hypnotizable volunteers following placebo and a randomized sequence of four hypnotically induced conditions of (a) neutral hypnosis, (b) deep relaxation, (c) pleasant dissociated "out of body" imagery, and (d) focused analgesia of the hand. Both high and low hypnotizable subjects exhibited significant reductions of reported pain during conditions of neutral hypnosis, relaxation, dissociated imagery, and focused analgesia. High hypnotizable subjects displayed significantly greater reductions than low hypnotizables in all conditions except placebo. Both high and low hypnotizables exhibited significant reductions of reported pain in all five conditions as well as in the posthypnotic condition, when amplitudes of evoked potentials were compared to the prehypnotic baseline. Only the high hypnotizable group showed significant reductions in amplitudes when the data were recalculated to reflect relative changes compared to the average amplitude of the pre- and postconditions to compensate for a possible habituation effect indicated by the significantly lowered amplitudes in the posthypnotic condition. The results are discussed in light of a number of hypotheses concerning mechanisms of hypnotic analgesia.

**1990**

Arendt-Nielsen, Lars; Zachariae, Robert; Bjerring, Peter (1990). Quantitative evaluation of hypnotically suggested hyperaesthesia and analgesia by painful laser stimulation. Pain, 42, 243-251.

Sensory and pain thresholds to laser stimulation were determined, and the laser-pain evoked brain potentials were measured for 8 highly hypnotizable (Harvard Scores 10-11) student volunteers in 3 conditions: (1) waking, (2) suggestion of hyperaesthesia during hypnosis, (3) suggestion of analgesia during hypnosis.

The investigators used a laser beam 3 mm in diameter, with a 200 msec stimulus duration; the same area (but different points within the area) was used for consecutive stimulations. Ss were otherwise maintained in low stimulus conditions so they would not have visual or auditory cues about laser beam onset; they wore goggles, had eyes shut, and had earphones on. Sensory threshold was defined as warmth; pain threshold was defined as a distinct sharp pin prick.

The laser intensity used for stimulation corresponded to strong pain. Interstimulus intervals averaged 15 sec (but were randomly varied between 10-20 sec). Sensory and pain thresholds as well as two evoked potential measurements were taken during waking, hypnotized hyperaesthesia, and hypnotized analgesia conditions in a single 1 1/2 hour session.

The evoked potential component of interest was the negative complex N1 with latency of 300 msec; amplitude (P1=N1-P2) and latency of this complex (N1) were measured. EEG epochs contaminated by eye movement were omitted from analysis. The standardized induction and deepening of hypnosis required 15-20 minutes; then the suggestion was given that Ss could alter their perception of stimuli such as pain. Hyperaesthesia suggestions were to imagine the right hand was in very hot water, then taken out but still very red, hot, sensitive so that even the vaguest stimulus would be detectable and unpleasant. They were told that they would receive a series of painful but tolerable stimuli, and to raise the left index finger if they could just perceive a laser pulse (sensory threshold), and again if they felt pricking pain (pain threshold).

Suggestions for analgesia were to imagine that their right hand was placed on their chest, and that their 'former right hand' was no longer their own but was made of some heavy and completely insensitive material like wood or stone. Sensory and pain threshold measures were then taken. During the evoked potential measurement period they received continuous suggestions of analgesia. They also were told to relax and imagine they were in a pleasant place, ignoring everything except the pleasant, relaxed feelings and imagining pleasant sights, sounds, feelings and the imagined place. They were told that though they would receive stimuli, they probably would be able to ignore the stimuli completely.

Results were as follows.

1. In the hypnotic hyperaesthesia condition, sensory and pain thresholds decreased significantly by 47% and 48%, respectively. Three Ss reacted to laser intensities far below what normally can be perceived in the waking state. [The authors ran a separate small control experiment to make sure that the Subjects were not using any other cues, but mention the possibility of light-sensitive skin reacting to the blue laser light, creating evoked potentials.]
2. In the hypnotic analgesia condition, sensory and pain thresholds increased by 316% and 190%, respectively. 7 of 8 Ss did not even respond to pain threshold when the laser intensity was increased to the noxious level of 3W, which is the level at which tissue damage can occur.
3. Pain-related evoked potentials. Amplitude of the first pain-related potential was increased significantly by 14% in the hyperaesthesia condition and reduced significantly by 31% in the analgesia condition. Changes in the evoked potentials

were considered minor however compared to those observed for thresholds, which are subjective response measures. Even in Subjects who reported complete analgesia, the experimenters observed the laser pain evoked responses. There were no differences in latencies of the first pain-related potentials for the three conditions (indicating that peripheral and central afferent conduction velocities were the same).

**Discussion.** "There has been some dispute concerning the experimental design and the reliability of the data obtained in studies dealing with hypnotic suggested analgesia [Spanos & Chaves, 1970]. In our design 2 'opposite' conditions were induced, and the 2 inductions gave 'opposite' results.

"The experience of pain can be significantly altered by suggestions of analgesia, which is in accordance with a number of other studies (for review see [Barber & Adrian, 1982; Hilgard & Hilgard, 1975]). The finding that suggestions of hyperaesthesia can decrease the sensory and pain thresholds and increase the amplitude of the pain evoked potential is a new observation. Since synchronized auditory and visual stimuli from the laser were blocked, and the stimulus was given at random intervals, the changes might be induced by the hypnotic suggestions" (p. 247).

The authors discuss their results in terms of (1) four pain modulation systems (neural/opiate, hormonal/opiate, neural/non-opiate, and hormonal/non-opiate) and (2) focusing and defocusing attention. Because in their pilot study it was necessary to give suggestions continually in order to affect the laser evoked potentials, they conclude that endogenous substances or hormonal/non-opiates would play a minor role, if any, in hypnotic analgesia. (Price and Barber [25] had also found it important to give suggestions continuously.)

On the other hand, "event-related potentials [7, 26] and pain-related potentials have, previously, been shown to be sensitive to focused and de-focused attention. Recently, Miltner et al. [23] showed the influence of attention on the late pain-related component of potentials, evoked by painful intracutaneous electrical stimulation. The degree to which the subject paid attention to the painful stimulus had a powerful effect on the pain-related complex. When subjects ignored the pain, it was still possible to record the pain-related complex although all the subjects consistently reported less or no pain. In wakeful subjects where cutaneous pain was abolished by lignocaine infiltration, the pain-related evoked potentials were abolished [4]. In our study, we could also record evoked potentials although the subject subjectively did not feel pain. The reason might be that the S acted as if there was full analgesia to the stimuli, in order to satisfy the hypnotist. During suggested hyperaesthesia the thresholds declined below what normally could be perceived in the wakeful state. The volunteers could, therefore, not act hypersensitive, so something did happen.

In wakeful subjects where cutaneous pain was abolished by lignocaine infiltration, the pain-related evoked potentials were abolished [4]. In our study, we could also record evoked potentials although the subject subjectively did not feel pain. The reason might be that the S acted as if there was full analgesia to the stimuli, in order to satisfy the hypnotist. During suggested hyperaesthesia the thresholds declined below what normally could be perceived in the wakeful state. The volunteers could, therefore, not act hypersensitive, so something did happen.

"The discrepancy in subjective and objective responses might, however, be useful when investigating levels of the neuroaxis at which hypnosis might work" (pp. 248-249).

The authors note that this laser induced pain and the tooth pulp stimulation pain of Mayer & Barber both use the A-delta fibers. Barber & Mayer found it impossible to elicit pain within the output range of the stimulator (up to 150 microA) and reached maximal intensity for all volunteers during suggested analgesia. Using cutaneous laser stimulation the authors found that the skin damage level (3W) could be reached in 7 of 8 volunteers without any reaction of pain.

During the hyperaesthesia condition the sensory threshold was sometimes lower than can be detected in the waking state. Although some researchers have suggested that red light from a helium-neon laser might activate cutaneous photosensitive receptors and thereby elicit brain potentials, the authors were unable to elicit potentials in waking Subjects using their blue and green argon laser light with below sensory threshold intensity.

The authors also note that previous attempts to use physiological correlates of pain such as heart rate, blood pressure, respiration, and galvanic skin response have yielded confusing results. The physiological indicators are present even when Subjects report analgesia, leading some investigators to conclude that the subjective reports are due to illusion [Sutcliffe, 1961], compliance [Wagstaff, 1986], or a placebo induced by the hypnosis context [Wagstaff, 1986]. "These confusing results lead to the conclusion that both the traditional methods used for induction of pain and the monitored physiological responses have been unsatisfactory. The present study has sought to eliminate some of the methodological difficulties by (1) using brief well-defined argon laser stimuli which in awake volunteers induce very stable perceptions between trials [Arendt-Nielsen & Bjerring, 1988], and (2) recording psychophysical thresholds and objective parameters quantitatively related to the intensity of the pain perceived (1, 3)" (p. 249).

Hajek, P.; Jakoubek, B.; Radil, T. (1990). Gradual increase in cutaneous threshold induced by repeated hypnosis of healthy individuals and patients with atopic eczema. Perceptual and Motor Skills, 70, 549-550.

Gradual increase in cutaneous pain threshold was found in healthy subjects and patients with atopic eczema during repeated hypnotic sessions with specific suggestions. This increase was less in the former than in the latter group. Repeated threshold measurements did not influence the threshold. The analgesic effect outlasted the hypnotic sessions by several months. It could be, however, suddenly reduced by appropriate hypnotic suggestion.

Cutaneous pain threshold was measured in "time in seconds from onset of heat source of defined size, distance from skin, and temperature, to subjective threshold percept of pain" (p. 549). Used two symmetrical locations on both forearms, at healthy areas of the skin. Ten hypnotic sessions were induced in each S three times weekly, each lasting one hour.

Suggestions were the following type: "The "conduction of switch to the brain is interrupted." Your "immunologic system will digest the damaged skin cells like a shark."

Subjects were 14 healthy subjects and 13 patients with atopic eczema treated for years with the usual medications, unsuccessfully or with complications.

There was gradual increase in cutaneous pain threshold across the 10 sessions, especially for the patient group. Control experiments with repeated threshold measurements in repeated sessions without hypnosis showed no changes.

"Time of increases in cutaneous pain threshold was associated with improvement of atopic eczema. Both effects correlated significantly ( $r = 0.8$ ) with hypnotizability as measured by the Stanford scale" (pp. 549-550).

"In 9 patients without further hypnotic sessions a slow spontaneous decay of the cutaneous pain threshold was observed during a 17-mo. period. Special experiments performed with six repeatedly hypnotized healthy subjects showing increased thresholds did prove, however, that the cumulative analgesic effect could be reduced to control values immediately by using the hypnotic suggestion that the 'skin sensitivity returns to normal values.'

"These results suggest a close association between hypnosis and activation and/or deactivation of endogenous analgesic systems (irrespectively whether they are of opioid or nonopioid nature)" (p.550)

Chaves, John; Brown, Jude (1987). Spontaneous cognitive strategies for the control of clinical pain and stress. Journal of Behavioral Medicine, 10 (3), 263-276.

The spontaneous cognitive strategies employed by 75 patients undergoing dental extractions or mandibular block injections were elicited using a structured interview. Interest focused on the relationship between these strategies and several personality variables, including state and trait anxiety, locus of control, and absorption. In addition, the effect of strategy utilization on perceived pain and stress

was assessed. Forty-four percent of the patients employed cognitive strategies designed to minimize pain and stress, while 37% catastrophized, engaging in cognitive activity which exaggerated the fearful aspects of their experience. Only 19% of the patients denied any cognitive activity during the clinical procedure, and many of these used noncognitive coping strategies. Discriminant analysis revealed that situational anxiety was associated with the use of cognitive coping strategies. Catastrophizing was associated with increasing age, past dental stress, and higher levels of stress vulnerability (high trait anxiety and external locus of control). Copers reported less stress than catastrophizers but not less pain.

with the use of cognitive coping strategies. Catastrophizing was associated with increasing age, past dental stress, and higher levels of stress vulnerability (high trait anxiety and external locus of control). Copers reported less stress than catastrophizers but not less pain

Evans, Frederick J.; McGlashan, Thomas H. (1987). Specific and non-specific factors in hypnotic analgesia: A reply to Wagstaff. British Journal of Experimental and Clinical Hypnosis, 4, 141-147. (Comment in response to Wagstaff, G. (1987). Is hypnotherapy a placebo? Hypnosis, 4, 135-140.)

This article is a reply to Wagstaff's (1984) critique of the McGlashan, Evans & Orne (1969) article which was entitled "The nature of hypnotic analgesia and the placebo response to experimental pain," published in Psychosomatic Medicine, 31, 227-246. The paper to which the authors are replying is Wagstaff, G. F. (1984). Is hypnotherapy a placebo? Paper given at the First Annual Conference of the British Society of Experimental and Clinical Hypnosis, University College, London. An abridged version appeared in the British Journal of Experimental and Clinical Hypnosis, 1987, 4, 135-140.

The closing comments of this Evans & McGlashan 1987 paper read as follows: "The strategy in this study [i.e. McGlashan, Evans & Orne, 1969] was quite different from the usual experimental design. Our goal was to maximize all of those non-specific factors that we could build into the experimental procedure. Only by attempting to maximize non-specific effects is it possible to see whether hypnosis in appropriately responsive subjects can exceed that degree of pain control which occurs due to the maximal operation of these non-specific effects. These non-specific components of the hypnotic situation may account for a great deal of clinical change. ... The critical finding was that hypnosis did add a level of pain control that occurred after maximizing clinically related non-specific factors contributing to change in pain tolerance, and that this increased tolerance occurred only in subjects markedly responsive to hypnosis, in contrast to the significant non-specific effects which were uncorrelated with measured hypnotizability" (pp. 143-144).

The principal findings of the McGlashan, Evans & Orne (1969) study were: "(a) The improved ability to tolerate pain following the ingestion of placebo was roughly the same for high hypnotizable and low hypnotizable subjects. (b) The response to the non-specific aspects of taking a 'drug' among low hypnotizable subjects was identical to, and highly correlated (.76) with, their response to the legitimized expectation that change would occur under hypnosis for low hypnotizable subjects.

The placebo component of a believe-in 'drug' ingestion was the same as the placebo component of a believed-in hypnotic experience for these low hypnotizable subjects. (c) The performance of the highly hypnotizable subjects was significantly greater under hypnotic analgesia conditions than it was under placebo conditions.

"This last finding is important conceptually, though of less clinical relevance. It should be noted that not all high hypnotizable subjects showed this result. Even among highly hypnotizable subjects, not all of them had the experience that profound analgesia had occurred! Thus, based on their subjective experience of the relatively small degree of analgesia, 6 of the 12 highly hypnotizable subjects behaved exactly as the low hypnotizable subjects had -- their placebo and hypnotic responses were small, significant, but equal. Only 6 out of 12 carefully screened hypnotizable subjects who subjectively experienced marked analgesia showed dramatic objective changes in pain endurance. Dr. Wagstaff might consider the physiological implications of the observation that we became somewhat frightened about the possibility of tissue damage with two of these six subjects. We had to stop their performance at a point where physiologists had assured us that tissue damage could be expected. They had also assured us, wrongly for these subjects, that we did not have to worry about such a critical point because nobody could endure such a degree of occlusion with this procedure. In fact, for these two subjects, anoxia and muscle cramping were not even apparent!" ( p. 144).

two of these six subjects. We had to stop their performance at a point where physiologists had assured us that tissue damage could be expected. They had also assured us, wrongly for these subjects, that we did not have to worry about such a critical point because nobody could endure such a degree of occlusion with this procedure. In fact, for these two subjects, anoxia and muscle cramping were not even apparent!" ( p. 144).

1981

Houston, Rodney Earl (1981). The effects of autohypnosis, imagery, or single suggestion on pain threshold and tolerance (Dissertation, University of Cincinnati). Dissertation Abstracts International, 42 (5), 1961-A.

Pain threshold, pain tolerance, and subject's subjective opinion of the pain were studied in 94 volunteer subjects (75 female, 19 male), who had been randomly assigned to three treatment groups (self hypnosis, in-vivo imagery, single suggestion) and a control group. (The original randomized sample included 124 Ss, but 30 were lost to the study-- 22 because of initial baseline scores being above maximum, 2 after reading the consent form, and 6 not returning for post-testing.) Mean age was 25; age range was 18-59 years.

The pain stimulus was 33 degree F. ice water in which the dominant hand was submerged for as long as the subjects were able. Subjects were told to nod when pain was first felt (threshold), and remove their hand when the pain was more than they could tolerate (tolerance). They were then asked to rate the pain on a 7-point scale, from 'none' to 'extreme.' Thus the three outcome measures were threshold time, tolerance time, and degree of perceived pain.

During the week between pretesting and posttesting, the self hypnosis group was to listen to a tape training them in self hypnosis at least twice; the imagery group was to listen to their imagery training tape at least twice; the simple suggestion group received no training. Posttesting was the same as pretesting, except that the simple suggestion group was given the single waking suggestion, "You will be able to withstand the pain much longer this time."

The experimental predictions were that treatment groups would increase in threshold levels and tolerance levels more than the control group; and that the treatment groups would decrease more than the control group in reported pain level. Multivariate analysis of variance of difference scores (pre- to posttest) demonstrated significant differences on the three dependent measures when comparing the three treatment groups to the control group. " Significant differences were also found when comparing treatment groups, autohypnosis and imagery to those given the single suggestion. No significant differences were found when comparing the autohypnosis to the imagery treatment.

"The results indicate that training in autohypnosis and in-vivo imagery has an effect on threshold, tolerance and pain levels. The results also indicate that the use of a single suggestion may not have an effect on threshold, tolerance, and pain levels" (p. 1961).

Ahlberg, D.; Lansdell, H.; Gravitz, M. A.; Chen, T. C.; Ting, C. Y.; Bak, A. F.; Blessing, D. (1975). Acupuncture and hypnosis: Effects on induced pain. Experimental Neurology, 49, 272-280.

The reactions of 14 volunteers to electrical stimulation near the supra- orbital nerve were studied under acupuncture, placebo-acupuncture, and hypnosis. As the intensity of stimulation increased, a minimum sensation, a minimum pain, and then a maximum or intolerable pain sensation were produced. Under hypnosis the average intensity of the stimulus for producing these sensations was higher than before the trance induction. Under acupuncture and placebo-acupuncture no clear increase in current intensity was observed. Acupuncture, as well as hypnosis, did not consistently change the blood, blood pressure, pulse rate, EKG, respiratory rate, or EEG.

Spanos, Nicholas P.; Horton, Carol; Chaves, John F. (1975). The effects of two cognitive strategies on pain threshold. Journal of Abnormal Psychology, 84 (6), 677-681.

Found that goal directed fantasy strategy suggestions were more effective than no goal directed fantasy suggestions in raising pain threshold, even when the suggestions were equated for length.

Stacher, G.; Schuster, P.; Bauer, P.; Lahoda, R.; Schulze, D. (1975). Effects of suggestion of relaxation or analgesia on pain threshold and pain tolerance in the waking and in the hypnotic state. Journal of Psychosomatic Research, 19, 259-265.

The effects of suggestion of analgesia and relaxation respectively under both hypnotic and waking conditions on pain threshold and pain tolerance measured by electrical stimulation of the skin were evaluated. Four healthy female subjects susceptible to hypnosis underwent four experiments each: (A) after two basal 16 min periods hypnotic suggestion of relaxation for 16 min followed by 16 min of hypnotic suggestion of analgesia, (B) as in (A) but suggestion of analgesia in the first and suggestion of relaxation in the second 16 min, (C) as in (A) but suggestions given in the waking state, (D) as in (B) but also suggestions given in the waking state. After all the procedures the experiments were continued for two further 16 min periods. To control for order effects, the experiment was designed as a 4 x 4 Latin square. Pain threshold and tolerance increased in varying degrees under all types of suggestions. Suggestion of relaxation given in the waking or in the hypnotic state was found to be less effective in elevating pain threshold and tolerance than suggestion of analgesia under the same conditions. Suggestion of both relaxation and analgesia resulted in higher increases of threshold and tolerance under hypnotic than under waking conditions.

Each experimental session had 4 periods. During the first 16-minute period pain threshold increased and pain tolerance increased on all experimental days. This may have been due to a habituation effect.

There were "more or less massive elevations of pain threshold and tolerance" in both hypnotic experiments (A and B). The elevations were higher following analgesia suggestions than following relaxation suggestions in all experiments.

"Suggestion of analgesia resulted generally in higher elevations of threshold and tolerance when the period with suggestion of analgesia followed the period with suggestion of relaxation than vice versa" (p. 262). "The analogous comparison for tolerance showed no significant F-values; this, again, might be due to the substitution procedure but also to the higher inhomogeneity of the tolerance values" (p. 263).

the tolerance values" (p. 263).

"The different effects of suggestion of relaxation and of analgesia respectively resulted also in a significant interaction 'treatment x time' (both measures:  $P < 0.1$ ). This result has to be ascribed mainly to the hypnotic experiments: in both treatments A and B the elevations of threshold and tolerance were higher under suggestion of analgesia than under suggestion of relaxation. In the waking conditions (C and D) both measures were, on the average, higher in the second 16-min period of treatment regardless whether relaxation was followed by analgesia or analgesia by relaxation" (p. 263).

"There also seemed to be an influence of the initial values on the treatment effects, as higher initial values led to larger elevations of threshold ( $P < 0.05$ ) and tolerance ( $P < 0.1$ ). Therefore, the above reported results of the contrast between treatments A, C, and B, D respectively has to be regarded with care, since this contrast might be slightly overestimated because of the low initial values under treatment B" (p. 263).

In their discussion, the authors wrote: "The results of the present study show, that suggestion of analgesia caused higher elevations of pain threshold and tolerance than suggestion of relaxation in the hypnotic condition. This is not in favour of the hypothesis, that pain relief under hypnosis is due only to a diminution of anxiety and/or to a placebo effect [2, 3, 5], as both the anxiety relieving and the placebo effect are working in the relaxation as well as in the analgetic condition. The higher threshold and tolerance values in the latter condition seem to result from the specific contents of the suggestion of analgesia and might act via a neocortical or higher central nervous process exerting control over the activity in both the discriminative and motivational systems [18]. Our findings are consistent with those of McGlashan et al. [19], who found higher elevations of pain threshold and tolerance to ischemic muscle pain under hypnotic analgesia than under placebo.

"An interesting point is, that in the experiments with suggestions in the waking state, suggestion of analgesia in all instances resulted in higher elevations of pain threshold and tolerance when relaxation was suggested prior to analgesia than [sic] vice versa. This may be interpreted that subjects already relaxed and relatively free from anxiety respond better to explicit suggestion of analgesia.

"Pain threshold is reported to have more physiological determinants while tolerance is regarded to be relatively more sensitive to psychological factors [22]. In our study, threshold and tolerance, apart from a greater variability of the latter, agreed fairly closely with one another in the treatment periods. There is obviously considerable interdependence between these two measures" (p. 264).

1974

Bloom, Richard F. (1974). Validation of suggestion-induced stress.

Technical Memorandum 23-74 (October 1974), US Army Human Engineering Laboratory, Aberdeen Proving Ground, Maryland 21005, AMCMS Code 5910.21.68629, Contract No. DAAD05-73-C-0243, Dunlap and Associates, Inc. (now Stamford, CT), AD002557.

Sixty college men, divided into three equal groups, each attended two induced stress sessions in which their physiological, psychological and performance reactions were measured. Their responses were compared to determine if valid stress reactions could be induced through suggestion in an altered state (in this case, hypnosis), and also to determine the validity of such reactions if the subject had never before experienced that stress situation. It was demonstrated that valid stress reactions can be induced in an individual with the aid of suggestions, especially if the real stress situation has been experienced before. If no previous experience with that real situation exists, the subject still exhibits stressful reactions; however, the closest resemblance to real stress is found in the subjective or psychological measures, less similarity is found in the physiological measures, and the least similarity is found in the performance measures.

West, Louis Jolyon; Niell, Karleen C.; Hardy, James D. (1952). Effects of hypnotic suggestion on pain perception and galvanic skin response. A. M. A. Archives of Neurology and Psychiatry, 68, 549-560.

A study is reported in which pain perception and galvanic skin responses of seven subjects were measured before and during hypnosis. The depths of hypnotic trance varied from light to deep. Stimuli of measured intensity were administered, and changes in pain threshold were measured. Quantitative estimates of pain intensity were made by the subjects. Alterations in ability to discriminate between pains of differing intensities were noted. Quantitative records of galvanic skin responses were utilized, permitting statistical analysis of data from matched pairs. Data were collected at 45 experimental sessions, during which a total of 478 painful stimuli were administered, the stimuli varying in intensity from threshold to blister-producing levels. At each session, the subject's sensations from and responses to stimuli during a control period were compared with sensations from and responses to identical stimuli administered after hypnotic suggestions of anesthesia. The following observations were made: 1. Hypnotic suggestions of anesthesia influence pain perception by causing elevation of pain threshold, hypalgesia, and analgesia. 2. When hypnotic suggestions of anesthesia caused hypalgesia and elevation of pain threshold, ability to discriminate among stimuli of different intensities was impaired. 3. There was a general correlation between the depth of hypnotic trance and the degree to which pain perception was altered by hypnotic suggestion. 4. The galvanic skin response to noxious stimulation was diminished, and it sometimes disappeared, as a result of hypnotic suggestions of anesthesia. The galvanic skin response was affected even when there was no alteration in pain perception, according to subjective reports.

The authors review literature on the effects of analgesia suggestions on the galvanic skin response and other autonomic nervous system responses. The present study differs from previous studies in the following ways: "1. The subjects were studied in various stages of hypnosis. 2. Quantitatively determined noxious stimuli were used instead of pinching or pinprick. 3. Changes in pain threshold were measured. 4. Quantitative estimates of pain intensity were made by the subject in the hypnotized and the un hypnotized state. 5. Changes in ability to discriminate between pains of differing intensity were noted. 6. Quantitative records of galvanic skin responses in the control and in the hypnotized state were utilized" (p. 552).

Analgesia was defined as "that state in which none of the noxious stimuli administered were reported as painful;" hypalgesia was defined as "a state in which noxious stimuli were reported as less painful than would be expected on the basis of reports of the same subject regarding the same stimuli in control situations" (p. 554).

In their Discussion, the authors state, "As a result of hypnotic suggestions of anesthesia, the following effects on sensation were observed: (1) no alteration in reports of pain intensity; (2) hypalgesia for higher-intensity stimuli without elevation of the pain threshold; (3) definite elevation of pain threshold with hypalgesia; (4) analgesia; (5) disturbances in pain discrimination.

" The third effect was observed in the majority of trials. The threshold elevation in light trances may be similar to that which can be produced by suggestion in the un hypnotized subject, but in deeper trances the effectiveness of hypnotic suggestion is much greater. The progression of effects 1 through 4 appears to be directly related to the depth of trance. The fifth effect was variable and was seen only in conjunction with the third effect. It is described as a separate phenomenon because the disturbance of ability to discriminate relatively between stimuli of differing intensities was only clearly observed when we were remeasuring pain thresholds. In actuality, it may merely represent a facet of altered pain perception, and the variability of its appearance may be related to the variable psychological state of the subject. It must be kept in mind that the hypnotic trance is not a static state" (p. 558). For one Subject, analgesia decreased in successive hypnotic sessions, while for four Subjects analgesia increased; a sixth Subject exhibited overall variability in hypnotic depth and analgesia from session to session.

The authors indicate that their review of the literature found no evidence that hypnosis, absent suggestions for analgesia, affects the galvanic skin response. In the present study, diminishment of the GSR is related to, though not dependent on, the effectiveness of the suggestion of anesthesia. "Thus, in Subject 2, with only moderate hypalgesia, the GSR to noxious stimuli was diminished by 64%; in S 6, with analgesia on nearly all trials, only 57%. It is particularly interesting that S 1 had a reduction in GSR of 26% after hypnotic suggestions which apparently had no effect upon his pain perception, and which seemed even to make him anxious. S 5 showed a direct correlation between depth of trance and decrease of GSR while Subjects 6 and 7 showed no such correlation" (p. 559).

"It is important to realize that on some occasions hypnotic anesthesia apparently led to complete disappearance of the GSR to all stimuli during a given session, such stimuli evoking pain of 6 or 7 dols in the control period. This phenomenon was seen twice with Subject 3, twice with Subject 5, and once with Subject 6. In several trials there was only a very slight GSR to the higher stimuli during hypnosis. In all the control periods there was only one occasion on which a stimulus evoking pain of 6 or 7 dols failed to produce a GSR, while equally intense stimulation failed to produce a GSR on 14 occasions after hypnotic suggestions of anesthesia. This observation is stressed because it suggests a need for caution in the clinical use of the GSR to distinguish organic from hysterical anesthetics" (pp. 559-560).

Willmarth, Eric K. (2000, August). Modification of experienced pain with hypnotically induced positive mood. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, D. C..

This study investigated the relationship between chronic pain and depressed mood within the context of Associative Network Theory and the High Risk Model of Threat Perception. A bi-directional relationship was hypothesized and tested by comparing pain ratings before and after the hypnotic induction of positive mood by suggestion of positive memories. These results were compared to the pain ratings of two control groups: participants who received hypnotic suggestion for relaxation only and participants who received non-hypnotic suggestion for relaxation and enhanced mood. Participants were 96 patients of a hospital-based Pain Management Center. Following assessment of hypnotic ability using the Harvard Group Scale of Hypnotic Susceptibility: Form A, and the Subjective Experiences Scale, participants recorded levels of depressed mood, sensory pain, affective pain, global pain and self control of pain before and after listening to an audio-taped treatment session. Results show that the induction of a positive mood did influence a decrease in self-reports of pain. In addition, the level of the participants' hypnotic ability was also found to be a significant factor, suggesting that screening for predisposing factors, such as hypnotic ability, and the clinical use of hypnosis for mood enhancement are warranted in a chronic pain population. - Abstract taken from *Psychological Hypnosis: A Bulletin of [Amer Psychol Assn] Division 30*, Fall 2000.

Milling, Leonard S.; Kirsch, Irving; Burgess, Cheryl A. (1999). Brief modification of suggestibility and hypnotic analgesia: Too good to be true?. *International Journal of Clinical and Experimental Hypnosis*, 47 (2), 91-103.

A 10-minute training procedure, based on the Carleton Skill Training Program, has previously been reported to produce substantial increments in responsiveness to hypnotic suggestion. The authors attempted to replicate this effect and also assessed the impact of the training procedure on hypnotically suggested analgesia. Ninety-eight students who had been preselected for high, medium, and low levels of initial suggestibility were randomly assigned to experimental and control groups. Training failed to increase overall suggestibility scores or to enhance the effects of a suggestion for pain reduction. Suggested pain reduction was more highly correlated with posttreatment suggestibility scores than with pretreatment suggestibility and, in a regression analysis, only posttreatment suggestibility predicted pain reduction uniquely.

Barber, Joseph (1998). The mysterious persistence of hypnotic analgesia. *International Journal of Clinical and Experimental Hypnosis*, 46 (1), 28-43.

Hypnotic treatment of pain has a long history and, among hypnotic phenomena, pain relief is a relatively commonplace focus for intervention, yet we lack a conceptual explanation for this treatment. Hilgard's neodissociation theory accounts for the phenomenon of acute hypnotic analgesia, but not of persistent pain relief. Perhaps the enduring effect of hypnotic treatment can be explained at either of two levels: a neurophysiological model or a learning model. This explanation leads to the

**further question: How does hypnotic treatment of recurring pain achieve enduring relief? Clinical experience suggests a two-component model. First, the clinician communicates specific ideas that strengthen the patient's ability to derive therapeutic support and to develop a sense of openness to the unexplored possibilities for pain relief within the security of a nurturing therapeutic relationship. Second, the clinician employs posthypnotic suggestions that capitalize on the patient's particular pain experiences, which simultaneously ameliorate the pain experience, and which, in small, repetitive increments, tend to maintain persistent pain relief over increasing periods of time.**

**Author's Summary: "When a patient who suffers from recurring pain is treated with hypnotic methods and then reports substantial relief over time, what is significant is that the relief is so long-lasting, and that it endures through the patient's various daily activities. Although I believe that the initial alteration of consciousness via the hypnotic experience greatly facilitates subsequent analgesia, it is not necessary to believe, nor is it even plausible, that subsequent analgesia is accomplished through re-creation of the hypnotic condition. Rather, it appears that the patient is able to generalize from these initial experiences to achieve this analgesia independent of a hypnotic intervention.**

**"Laboratory research and clinical experience suggest that the persistence of hypnotic analgesia is a function of learning, the therapeutic relationship that fosters that learning, and the neurophysiological changes that subserve that learning. The patient's understanding of the meaning and purpose of the clinician's suggestions is a primary determiner of their efficacy" (pp. 39-40).**

**Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..**

**"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.**

**The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible**

to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

Chaves, John F.; Dworkin, Samuel F. (1997). Hypnotic control of pain: Historical perspectives and future prospects. International Journal of Clinical and Experimental Hypnosis, 45 (4), 356-376

Hypnotic analgesia has occupied a pivotal place in experimental and clinical hypnosis. It emerged early in the 19th century when effective clinical techniques for pain management had not yet developed, and the relief of pain and suffering had not even become a well-defined social goal. Its acceptance was further complicated by political struggles surrounding the humanitarian transformation of medicine during this era as well as a redefinition of the physician-patient relationship that wrested control from the patient. The initial struggle for professional acceptance was won only when the debate became almost entirely localized within the professional community. Acceptance of hypnosis by professional organizations has been followed by alternating periods of interest and indifference. While the evidence for the powerful effects of suggestion and related variables has often been observed and reported in nonhypnotic contexts, their relationship to hypnotic phenomena has often not been appreciated. Since the mid-20th century, scientific information about hypnotic analgesia has grown substantially and has had significant influence on strategies for acute and chronic pain management. If recent calls for its wider

application in pain management are to succeed, it will require additional data from clinical populations and a balanced and scientifically prudent approach by its advocates. [Journal Abstract]

1998

Wakeman, R. J. (1988). Hypnotic desensitization of job-related heat intolerance in recovered burn victims. American Journal of Clinical Hypnosis, 31, 28-32.

The thermally injured patient who suffers extensive third-degree burns usually finds the adaptation to high temperature environments quite difficult. A 7-year study of 50 thermally injured patients with greater than 45% total body surface second- and third-degree burns was conducted to assess the usefulness of hypnosis for improved heat adaptation at the work site. There were 25 subjects in the experimental group who received hypnotic training and 25 in a matched control group. The experimental group achieved a mean of 6.25 hours worked over 16 weeks and 63.5 days worked out of 80. They worked 4.5 to 6.5 hours per day for an average of 221 days per year for up to 3 years from baseline. The control group achieved a mean of 4.5 hours worked over 16 weeks and 54.33 days worked out of 80. The efficacy of hypnosis in heat desensitization is discussed.

worked over 16 weeks and 54.33 days worked out of 80. The efficacy of hypnosis in heat desensitization is discussed.

Mean age was 38 for the hypnosis group, 33 for the control group; both groups had mean educational level of 8 grades. Mean percentage of total body surface burn was 50% for hypnosis and 54% for control groups.

Each patient was seen for 16 weeks, for 2 hours/week. The hypnosis group received hypnosis, were taught self hypnosis, and were given cassette tapes for use at home. The hypnosis training included a variety of techniques (e.g. progressive deep muscle relaxation, eye-fixation, eye-roll, and visual imagery techniques). They were given suggestions for lower skin temperature, lower 'inner body' temperature, less itching, gradual improvement of time spent on the job, as well as ego strengthening suggestions. The control patients received supportive psychotherapy, family consultation, and cognitive behavior therapy for the same amount of contact time with the same therapist.

The hypnosis group was to do self hypnosis every two hours at the worksite, in addition to home practice. Visual imagery suggestions were things like imagery of a cool waterfall flowing over the skin, having a tall cold glass of beer or soft drink, etc. They also had biofeedback of skin temperature during office visits, to reinforce decreases in skin temperature near the burned sites. They had exposure to heat (in a 95 degree sauna) for in gradually increased periods of time (15 to 120 minutes) before returning to the worksite.

Three years after treatment 20 of 25 control patients had quit their jobs or transferred to a cooler worksite, and all 25 had resigned from their original jobs or applied for further disability benefits. In contrast, only 2 of 25 experimental Ss were working in controlled-temperature settings, and none had applied for permanent disability benefits.

The authors note that family support was essential for the hypnosis patients to carry out their treatment program, and family consultations were essential for every patient. They also found the 'fade-in' technique using the sauna in the hospital occupational therapy area very useful for bridging the gap between practice in the office and going back to the work setting. "This procedure enabled the subject to practice self- hypnosis under controlled physical conditions while performing a work task that was more realistic than 'imagined heat' in the office setting" (p. 31).

Chaves, John; Brown, Jude (1987). Spontaneous cognitive strategies for the control of clinical pain and stress. Journal of Behavioral Medicine, 10 (3), 263-276

The spontaneous cognitive strategies employed by 75 patients undergoing dental extractions or mandibular block injections were elicited using a structured interview. Interest focused on the relationship between these strategies and several personality variables, including state and trait anxiety, locus of control, and absorption. In addition, the effect of strategy utilization on perceived pain and stress was assessed. Fourty-four percent of the patients employed cognitive strategies designed to minimize pain and stress, while 37% catastrophized, engaging in cognitive activity which exaggerated the fearful aspects of their experience. Only 19% of the patients denied any cognitive activity during the clinical procedure, and many of these used noncognitive coping strategies. Discriminant analysis revealed that situational anxiety was associated with the use of cognitive coping strategies. Catastrophizing was associated with increasing age, past dental stress, and higher levels of stress vulnerability (high trait anxiety and external locus of control). Copers reported less stress than catastrophizers but not less pain.

Slomoff, Daniel A. (1986, March). Hypnotic susceptibility, vividness of imagery and the ability to self-regulate pain in a cold pressor test (Dissertation, Fielding Institute). Dissertation Abstracts International, 46 (9), 3231-B.

"Previous studies suggested that subjects who used more vivid images and who are good hypnotic subjects are more involved in their imagery and therefore have better pain control. In this study, subjects were given the Harvard Group Scale of Hypnotic Susceptibility and the Sheehan-Betts Questionnaire Upon Mental Imagery and then exposed to a cold pressor test for pain. Previous studies had limitations using an imagery scale which only tested for visual imagery, asking subjects to learn a new cognitive strategy, and limiting the study to female subjects. This study used both an objective and subjective multisensory test of imagery, tested for both genders, and allowed subjects to use their inherent cognitive strategies. "It was hypothesized that hypnotically susceptible subjects would demonstrate greater pain tolerance and pain intensity. This was not supported. It was also hypothesized that subjects who scored high on pain intensity control and this was also not supported. It was discussed that the instruments may not be strong enough to measure differences when pain tolerance and pain control are being looked at. "It was

further predicted that there would be an interaction effect between hypnotizability and vividness of imagery for pain tolerance and pain intensity control. The results did not support this hypothesis. the author felt that it might be necessary to compare high and low imagers rather than high and medium imagers in this study. In that case the degree of difference between the groups might be great enough to demonstrate the interaction effects. As was predicted, it was found that highly hypnotizable subjects who were good imagers did use more imagery and rated this imagery as more effective and more vivid. "It is suggested that future research assess the type of imagery associated with a specific kind of pain experience. Pain as the result of temperature, pressure, or electrical stimulation might require different imagery as a cognitive coping strategy. Appropriate assessment tools will then need to be developed in this regard" (p. 3231).

Williams, David A.; Thorn, Beverly E. (1986). Can research methodology affect treatment outcome? A comparison of two cold pressor test paradigms. Cognitive Therapy and Research, 10 (5), 539-545.

Examined the effect of fixed or open latency instructions on subjective pain report for the cold pressor test using a single cognitive training strategy with 80 undergraduates. The fixed latency paradigm instructed Ss to leave their hand in the cold water for a fixed amount of time (e.g., 3 min), whereas the tolerance paradigm asked Ss to endure pain for as long as possible. Results suggest that the fixed latency paradigm is associated with lower subjective pain ratings especially when a cognitive strategy is used. The tolerance groups failed to decrease their subjective perception of pain but evidenced longer latencies when a cognitive strategy was used. It is concluded that while other research has used these paradigms interchangeably to assess efficacy, these 2 paradigms apparently pose different challenges to Ss. (15 ref).

Spanos, Nicholas P.; Ollerhead, Virginia Gail; Gwynn, Maxwell I. (1985-86). The effects of three instructional treatments on pain magnitude and pain tolerance: Implications for theories of hypnotic analgesia. Imagination, Cognition and Personality, 5, 321-337.

Between baseline and posttesting on the cold pressor test, subjects were assigned to four treatments: a) hypnotic analgesia, b) brief instructions to "Do whatever you can to reduce pain," c) stress inoculation, and d) no instruction control. Participants in the three instructional treatments showed significantly greater baseline to posttest decrements in pain magnitude and significantly greater increments in pain tolerance than controls. However, the instructional treatments did not differ significantly from one another in these regards. Pretested hypnotic susceptibility correlated significantly with degree of pain reduction in the hypnotic analgesia treatment but not in the "Do whatever" or stress inoculation treatments. Theoretical implications are discussed.

1983

Braun, Bennett G. (1983). Psychophysiological phenomena in multiple personalities and hypnosis. American Journal of Clinical Hypnosis, 26 (2), 124-137

"Conclusion. As can be seen from the above example, the final common pathway, physiologic expression, which is seen in multiple personality is not bizarre when compared with physiologic changes achieved in non-multiples using hypnosis or, in certain cases, non-multiples without the use of hypnosis. A form of hypnosis/autohypnosis\* may be a common denominator. The neurophysiologic changes shown by Putnam et. al. (1982), but not observed by Coons (1982), may well have a similar explanation. The question of the neurophysiologic effect of hypnotic suggestion has not as yet been studied with appropriate controls or safeguards.

"That multiples do show significant changes in their psychophysiologic response patterns cannot be denied. To consider that the psychophysiologic changes of multiple personality are so rare or different as to make multiples 'freaks' is not only a disservice to them, but to medical science, since it blocks thinking. The study of multiple personality will further our understanding, theorizing, and treatment of mental and physical illness" (p. 134). "\*These terms are being used here in the generic sense" (p. 134).

1981

Houston, Rodney Earl (1981). The effects of autohypnosis, imagery, or single suggestion on pain threshold and tolerance (Dissertation, University of Cincinnati). Dissertation Abstracts International, 42 (5), 1961-A.

Pain threshold, pain tolerance, and subject's subjective opinion of the pain were studied in 94 volunteer subjects (75 female, 19 male), who had been randomly assigned to three treatment groups (self hypnosis, in-vivo imagery, single suggestion) and a control group. (The original randomized sample included 124 Ss, but 30 were lost to the study-- 22 because of initial baseline scores being above maximum, 2 after reading the consent form, and 6 not returning for post-testing.) Mean age was 25; age range was 18-59 years.

The pain stimulus was 33 degree F. ice water in which the dominant hand was submerged for as long as the subjects were able. Subjects were told to nod when pain was first felt (threshold), and remove their hand when the pain was more than they could tolerate (tolerance). They were then asked to rate the pain on a 7-point scale, from 'none' to 'extreme.' Thus the three outcome measures were threshold time, tolerance time, and degree of perceived pain.

During the week between pretesting and posttesting, the self hypnosis group was to listen to a tape training them in self hypnosis at least twice; the imagery group was to listen to their imagery training tape at least twice; the simple suggestion group received no training. Posttesting was the same as pretesting, except that the simple suggestion group was given the single waking suggestion, "You will be able to withstand the pain much longer this time."

The experimental predictions were that treatment groups would increase in threshold levels and tolerance levels more than the control group; and that the treatment groups would decrease more than the control group in reported pain level. Multivariate analysis of variance of difference scores (pre- to posttest) demonstrated significant differences on the three dependent measures when comparing the three treatment groups to the control group. " Significant differences were also found when comparing treatment groups, autohypnosis and imagery to those given the single suggestion. No significant differences were found when comparing the autohypnosis to the imagery treatment.

"The results indicate that training in autohypnosis and in-vivo imagery has an effect on threshold, tolerance and pain levels. The results also indicate that the use of a single suggestion may not have an effect on threshold, tolerance, and pain levels" (p. 1961).

Spanos, Nicholas P.; Brown, Jude M.; Jones, Bill; Horner, Donna (1981). Cognitive activity and suggestions for analgesia in the reduction of reported pain. Journal of Abnormal Psychology, 90, 554-556.

Assessed 38 undergraduates' pain magnitude and pain tolerance for arm immersion in ice water during a baseline and posttest session. Before the posttest, half the Ss received an analgesia suggestion. On the basis of their written testimony, Ss were classified as having either predominately coped (e.g., imagined event inconsistent with pain or made positive self-statements) or predominantly exaggerated (e.g., worried about and exaggerated the noxious aspects of the situation) during each immersion. On both immersions, copers reported less pain and exhibited higher pain tolerance than exaggerators. Moreover, the suggestion was associated with reductions in reported pain only when it transformed baseline exaggerators into posttest copers.

Worthington, Everett L.; Shumate, Michael (1981). Imagery and verbal counseling methods in stress inoculation training for pain control. Journal of Counseling Psychology, 28 (1), 1-6

Investigated 3 elements of stress inoculation training, a therapeutic package for helping clients control anxiety, anger or pain. 96 undergraduate females were tested twice for ice water tolerance. In a 3 design, the independent variables were the presence or absence of (a) pleasant imagery, (b) a conceptualization of pain as a multistage process, and (c) planned, explicit self-instructions. A multivariate analysis of covariance using the (transformed) pretest tolerance rating and 2 self-ratings of pain. Imagery users (Is) controlled their pain better than nonimagery users (NIs). There was a significant interaction of Imagery and Conceptualization. NIs had longer tolerance and less self- reported pain at withdrawal when they heard no conceptualization. The Is did not derive additional benefit from hearing the conceptualization. Self-instruction did not affect pain control. Results suggest that pleasant imagery effectively relieves pain and may account for much of the effectiveness of stress inoculation training. (23 ref)

1975

Stacher, G.; Schuster, P.; Bauer, P.; Lahoda, R.; Schulze, D. (1975). Effects of suggestion of relaxation or analgesia on pain threshold and pain tolerance in the waking and in the hypnotic state. Journal of Psychosomatic Research, 19, 259-265.

The effects of suggestion of analgesia and relaxation respectively under both hypnotic and waking conditions on pain threshold and pain tolerance measured by electrical stimulation of the skin were evaluated. Four healthy female subjects susceptible to hypnosis underwent four experiments each: (A) after two basal 16 min periods hypnotic suggestion of relaxation for 16 min followed by 16 min of hypnotic suggestion of analgesia, (B) as in (A) but suggestion of analgesia in the first and suggestion of relaxation in the second 16 min, (C) as in (A) but suggestions given in the waking state, (D) as in (B) but also suggestions given in the waking state. After all the procedures the experiments were continued for two further 16 min periods. To control for order effects, the experiment was designed as a 4 x 4 Latin square. Pain threshold and tolerance increased in varying degrees under all types of suggestions. Suggestion of relaxation given in the waking or in the hypnotic state was found to be less effective in elevating pain threshold and tolerance than suggestion of analgesia under the same conditions. Suggestion of both relaxation and analgesia resulted in higher increases of threshold and tolerance under hypnotic than under waking conditions.

Each experimental session had 4 periods. During the first 16-minute period pain threshold increased and pain tolerance increased on all experimental days. This may have been due to a habituation effect.

There were "more or less massive elevations of pain threshold and tolerance" in both hypnotic experiments (A and B). The elevations were higher following analgesia suggestions than following relaxation suggestions in all experiments.

"Suggestion of analgesia resulted generally in higher elevations of threshold and tolerance when the period with suggestion of analgesia followed the period with suggestion of relaxation than vice versa" (p. 262). "The analogous comparison for tolerance showed no significant F-values; this, again, might be due to the substitution procedure but also to the higher inhomogeneity of the tolerance values" (p. 263).

"The different effects of suggestion of relaxation and of analgesia respectively resulted also in a significant interaction 'treatment x time' (both measures:  $P < 0.1$ ). This result has to be ascribed mainly to the hypnotic experiments: in both treatments A and B the elevations of threshold and tolerance were higher under suggestion of analgesia than under suggestion of relaxation. In the waking conditions (C and D) both measures were, on the average, higher in the second 16-min period of treatment regardless whether relaxation was followed by analgesia or analgesia by relaxation" (p. 263).

waking conditions (C and D) both measures were, on the average, higher in the second 16-min period of treatment regardless whether relaxation was followed by analgesia or analgesia by relaxation" (p. 263).

"There also seemed to be an influence of the initial values on the treatment effects, as higher initial values led to larger elevations of threshold ( $P < 0.05$ ) and tolerance ( $P < 0.1$ ). Therefore, the above reported results of the contrast between treatments A, C, and B, D respectively has to be regarded with care, since this contrast might be slightly overestimated because of the low initial values under treatment B" (p. 263).

In their discussion, the authors wrote: "The results of the present study show, that suggestion of analgesia caused higher elevations of pain threshold and tolerance than suggestion of relaxation in the hypnotic condition. This is not in favour of the hypothesis, that pain relief under hypnosis is due only to a diminution of anxiety and/or to a placebo effect [2, 3, 5], as both the anxiety relieving and the placebo effect are working in the relaxation as well as in the analgetic condition. The higher threshold and tolerance values in the latter condition seem to result from the specific contents of the suggestion of analgesia and might act via a neocortical or higher central nervous process exerting control over the activity in both the discriminative and motivational systems [18]. Our findings are consistent with those of McGlashan et al. [19], who found higher elevations of pain threshold and tolerance to ischemic muscle pain under hypnotic analgesia than under placebo.

"An interesting point is, that in the experiments with suggestions in the waking state, suggestion of analgesia in all instances resulted in higher elevations of pain threshold and tolerance when relaxation was suggested prior to analgesia then [sic] vice versa. This may be interpreted that subjects already relaxed and relatively free from anxiety respond better to explicit suggestion of analgesia.

"Pain threshold is reported to have more physiological determinants while tolerance is regarded to be relatively more s to psychological factors [22]. In our study, threshold and tolerance, apart form a greater variability of the latter, agreed fairly closely with one another in the treatment periods. There is obviously considerable interdependence between these two measures" (p. 264).

1954

Thaheld, Feri Herndon (1954). Nonconclusive electrostimulation under narcotic hypnosis. Journal of Clinical and Experimental Hypnosis, 2, 175-177.

Hypnosis was used in an attempt to reduce the side effects of nonconvulsive electrostimulation in a single subject. Subject was given 2 gr of nembatal, followed

by hypnotic induction, then repeated suggestions that the "subject could feel no pain and that therefore as a result of this there could not be any physical response at all to this very harmless and quite painless treatment which was being administered" (p. 176).

Subject had 42 treatments (unidirectional, modulated, spiked current averaging 5-9 ma, through electrodes placed above the ears, for usually 3 minutes but sometimes 5-8 minutes) over 3 wk period. Ordinarily in such a situation pain would be experienced, with physiological changes (dilation of pupils, increase in pulse rate, flushing of skin, perspiration, some contraction of muscles) and emotional outbursts observed. In this subject, "none of the usual side reactions were found to be present and the further use of posthypnotic suggestions eliminated any after-effects or complications which might have arisen" (p. 176).

The author discussed the possibility that trance depth was facilitated by the pyramiding action of layering one set of suggestions on top of another, something like Vot's fractionation technique (in which subject is repeatedly hypnotized and de-hypnotized with suggestions of increasing depth).

The author discussed the possibility that trance depth was facilitated by the pyramiding action of layering one set of suggestions on top of another, something like Vot's fractionation technique (in which subject is repeatedly hypnotized and de-hypnotized with suggestions of increasing depth).

## **PAIN**

The author discussed the possibility that trance depth was facilitated by the pyramiding action of layering one set of suggestions on top of another, something like Vot's fractionation technique (in which subject is repeatedly hypnotized and de-hypnotized with suggestions of increasing depth).

Two theories of pain control by hypnosis currently exist: 1. Socio-cognitive model - patient actively copes with noxious stimulus. Hypnotic analgesia should be like cognitive techniques like stress inoculation training. It requires deliberate effort. 2. Dissociative control model - pain reduction requires little cognitive effort.

These 2 theories have different predictions. He explains "ironic effects" theory, in which person must identify pain to reduce pain. Wagner's reflexivity constraint: any process of mental control must be consistent with state we are trying to create.

This investigation involved 25 Highs and 24 Lows who reported pain, produced by strain gauge. Taught either hypnotic analgesia or stress inoculation. Reported every 5 sec (high load) or 45 sec (low load). Subtracted report from baseline to make pain reduction scores. Highs in hypnosis had no difference in pain reduction under high or low mental load. For the other 3 groups (Highs under stress inoculation; Lows under either hypnosis or stress inoculation) the results were different. That is, for Highs in hypnosis the mean of pain reduction scores was the same even when challenged by frequent reports of how much pain was being experienced.

Results are congruent with Miller and Bowers' dissociative control model.

Wagner's ironic process theory is useful. Frequency of pain reporting moderates Ss reports of pain in analgesia. These results challenge the cognitive social model of hypnotic analgesia and support a dissociative control model. Unlike stress inoculation, hypnotic analgesia does not require cognitive effort for high hypnotizable subjects.

## **1994**

Alden, P. A. (1994, October). Hypnotic approaches in pain control with terminally-ill patients. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

( These notes do not cover the entire presentation, which was based on clinical practice experience.) One conclusion reached was that J. Barber's Rapid Induction Analgesia (RIA) is more immediately effective than a direct approach to induction, but that a direct approach improves with time. RIA seems to work better for low hypnotizables. Next she plans to study whether patients would benefit from being given a tape of RIA routinely as an adjunct to pain control.

Crawford, Helen J. (1994). Brain dynamics and hypnosis: Attentional and disattentional processes. International Journal of Clinical and Experimental Hypnosis, 42 (3), 204-232.

This article reviews recent research findings, expanding an evolving neuropsychophysiological model of hypnosis (Crawford, 1989; Crawford & Gruzelier, 1992), that support the view that highly hypnotizable persons (highs) possess stronger attentional filtering abilities than do low hypnotizable persons, and that these differences are reflected in underlying brain dynamics

Behavioral, cognitive, and neurophysiological evidence is reviewed that suggests that highs can both better focus and sustain their attention as well as better ignore irrelevant stimuli in the environment. It is proposed that hypnosis is a state of enhanced attention that activates an interplay between cortical and subcortical brain dynamics during hypnotic phenomena, such as hypnotic analgesia. A body of research is reviewed that suggests that both attentional and disattentional processes, among others, are important in the experiencing of hypnosis and hypnotic phenomena. Findings from studies of electrocortical activity, event-related potentials, and regional cerebral blood flow during waking and hypnosis are presented to suggest that these attentional differences are reflected in underlying neurophysiological differences in the far fronto-limbic attentional system.

Crawford, Helen J. (1994). Brain systems involved in attention and disattention (hypnotic analgesia) to pain. In Pribram, Karl H. (Ed.), Origins: Brain and self organization (pp. 661-679). Hillsdale, NJ: Lawrence Erlbaum Associates.

Data are reviewed from regional cerebral blood flow, EEG, and somatosensory event-related potential (SERP; both scalp and intracranial) studies of attention to and disattention (hypnotic analgesia) of painful stimuli to provide further evidence for two neurophysiological systems of pain involving the cortex: (1) the epicritic, sensory system of pain associated with the parietal, posterior region, and (2) the protocritic, distress, comfort-discomfort system of pain associated with the far fronto- limbic region. Studies of neurophysiological changes accompanying suggested hypnotic analgesia support the hypothesis that the executive controller of the far frontal cortex, via the far fronto-limbic attentional system, acts as a gate against the ascent of painful stimuli into conscious awareness by 'directing' downward the inhibition of incoming somatosensory information coming from the thalamic region. In hypnotically responsive individuals who could eliminate the perception of pain, reviewed studies demonstrated increased regional cerebral blood in the frontal and somatosensory regions, shifts in hemispheric dominance of EEG theta power, differential surface SERP topographical patterns in the anterior and posterior regions of the brain, and reduction of the intracranial SERP P160 waveform in the gyrus cingulus.

Paradoxically, there may be physiological reactivity to pain stimuli while the hypnotized Subject reports they are not consciously aware of pain. Posner's proposal of two different attentional systems may account for why there is

physiological reactivity concurrent with lack of awareness of pain. Posner suggested that the posterior brain is involved with engaging and disengaging attention while the anterior brain is involved in attention for action or effortful attention. "Thus, the posterior region is involved in space and time, the epicritic processes, whereas the anterior region is involved in comfort- discomfort, the protocritic processes (Pribram, 1991)" (p. 665).

In parallel, there appear to be two systems of pain involving the cortex, as revealed in positron emission tomography research. Also relevant is clinical data showing that "removal of the frontal or cingulate cortex in patients with intractable pain leads to the amelioration of distress while not eliminating sensory pain (Bouckoms, 1989)" (p. 665).

The author proposes a neuropsychophysiology of hypnotic analgesia based on Hilgard's (1986) neodissociation theory of hypnosis, together with Pribram and McGuinness' (1975, 1992) attention model. In this view, "Hilgard's executive control system is the far frontal cortex 'directing' the inhibition of incoming painful stimuli" (p. 666) after determining that the somatosensory signal is 'irrelevant.'

"Highly hypnotizable individuals ('highs') have greater attentional and disattentional abilities than low hypnotizable individuals ('lows'). ... Recent neuroimaging techniques (PET, SPECT, CBF) that assess regional brain metabolism have found no differences in waking conditions between low and highly hypnotizable individuals, but have consistently reported that only highs show increased cerebral blood flow during hypnosis, suggestive of enhanced cognitive effort (Crawford, Gur et al., 1993; Halama, 1989; Meyer, Diehl, Ulrich, & Meinig, 1989; Walter, 1992)" (p. 666).

The hippocampus appears to be involved as a gating mechanism in selective attention (Crowne, Konow, Drake & Pribram, 1972; Isaacson, 1982, Isaacson & Pribram, 1986; R. Miller, 1991; Pribram, 1991; Arnolds et al., 1980) This gating function may be promoted "through a cortico-hippocampal relay [that] transmits information by theta wave modulation and Hebbian synaptic modification so that there is selective disattention" (p. 667). The author suggests that hypnotic pain control may involve directing attention away from pain sensory signals.

Highly hypnotizable people generate more EEG theta than low hypnotizables whether they are hypnotized or not, and Crawford (1990) observed marked hemispheric shifts in theta when highs (but not lows) were attempting to control pain with hypnosis.

This paper reports on preliminary results of SERP studies of people given hypnotic analgesia suggestions to reduce electric shock stimulus evoked pain. The results were analyzed individual by individual, because group data obscured pronounced shifts in SERP patterns (e.g. habituation rates differed among Subjects). For highs, the SERP tended to be reduced, and the lower amplitudes were observed as early as the N100-P200 components. This did not occur for low hypnotizables.

Different kinds of mechanisms may be operative for high hypnotizables, however. "In over half of the high hypnotizable subjects the far frontal region (Fp1, Fp2) showed strong arousal during attention to pain, but during hypnotic analgesia there was a flattening out of the SERPs to the point they are hard to measure. By contrast,

the more posterior SERPs (including F3 and F4), while reduced in amplitude, were still evident. The other half of highs showed little SERP activity in the far frontal region in either attend or disattend conditions, but substantial reductions of SERPs at all locations during hypnotic analgesia" (p. 670). Additionally, some of the highs evidenced a contingent negative variation (CNV) or a late 400-500 msec negativity in the far frontal region, which author is inclined to interpret as "a preparation for a response or for an inhibition of a response" (p. 670).

Case studies of two patients with intracranial electrodes and scalp electrodes recording SERPs are presented in support of the experimental data. The two female patients were diagnosed with obsessive compulsive disorder; one was highly hypnotizable and one was not. They received 30 moderately painful stimuli to the left middle finger under sequential conditions: waking attention, hypnosis with analgesia suggestions, and hypnosis with attention instructions. The highly hypnotizable patient reported significantly less pain during suggested analgesia, and that reduction in pain was associated temporally with reduction of SERP at P160 in the gyrus cingulus (and at no other recording sites). The 'unhypnotizable' patient showed no SERP changes. As an aside, the author notes that "Subsequent to the hypnotic analgesia, when the pain was attended to again during waking this patient showed a significant enhancement of the same positivity wave at Fz, as if there was a rebound effect (something we have also observed in some of our SERP subjects at the BRAINS Center)" (p. 674).

aside, the author notes that "Subsequent to the hypnotic analgesia, when the pain was attended to again during waking this patient showed a significant enhancement of the same positivity wave at Fz, as if there was a rebound effect (something we have also observed in some of our SERP subjects at the BRAINS Center)" (p. 674).

Erickson, James C. (1994, October). The metaphors of pain and therapy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Metaphors of Pain may be: 1. Anatomically or physiologically descriptive. 2. Extremely common, especially in chronic pain syndromes. 3. Unrecognized by many therapists. 4. Often pithy, succinct phrases (like puns). "Pain in the neck, pain in the butt" may reflect symbolic meaning of the pain, which if attended to may benefit the patient.

Head and neck pain metaphors include such things as "a headache, a pain in the neck, grit your teeth, and grin and bear it" (related to bruxism and TMJ syndrome). Also pertains to post-rhinoplasty pain in the nose.

Back pains: upper thoracic pain "a load on my shoulders" like Atlas carrying the world. Or "a cross to bear" which implies uncomplaining, but bearing a heavy burden. Low back pain - a "weak spine," or "spineless." With laminectomy, a "yellow streak up the back."

Dermatitis: Pruritis or dermatitis when "something gets under the skin."

Chest pains when "sick at heart."

Nagging, nasty situation is a "thorn in my side."

"A stab in the back" when wronged by society or a person. "Pain in the ass" may be a spouse or a situation. [Other material provided by the speaker is not reported here.]

Kiernan, Brian; Dane, Joseph R. (1994, October). Hypnoanalgesia reduces new physiologic index of pain, the R-III Index, but the role of hypnotic susceptibility remains unclear. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Stimulated by work of Basil Finer, and following upon the Neodissociation theory of Hilgard; pain is registered by the body but dissociation that produces analgesia is a function of higher brain centers.

Could hypnotic analgesia be mediated lower, at the level of the spinal cord? Gate at dorsal horn could be open or shut; subject to descending modulation. Is hypnosis involved in descending modulation of activity in the dorsal horn?

Hypothesis: reduced pain intensity would be associated with reduced activity at dorsal horn. From Price & Barber, we wanted to look at affect and intensity aspects of pain. Polysynaptic reflex, R-III, latency consistent with conduction velocity (when hand touches a hot stove); even with severed spinal cord injury we still demonstrate the reflex. The magnitude of reflex is linearly related to the pain sensation. The stronger the electrical pulse, the greater the magnitude of the reflex. Magnitude of reflex is linearly related to subjective pain. It is an index of nociceptive activity.

Procedure: Evoke reflex with electrical stimulus at ankle; measure signal at muscle with EMG. We anticipated that at dorsal horn, descending modulation would dampen signal.

15 healthy volunteers. Sural nerve was stimulated. R III reflex measured via EMG response. Used the visual analogue scale (VAS) to assess pain.

1993

Bruehl, Stephen; Carlson, Charles R.; McCubbin, James A. (1993). Two brief interventions for acute pain. Pain, 54, 29-36.

This study evaluated two brief (3-5 min) interventions for controlling responses to acute pain. Eighty male subjects were randomly assigned to 1 of 2 intervention groups (Positive Emotion Induction (PEI) or Brief Relaxation (BR)) or to 1 of 2 control groups (No-instruction or Social Demand). The PEI focused on re-creating a pleasant memory, while the BR procedure involved decreasing respiration rate and positioning the body in a relaxed posture. All subjects underwent a 60-sec finger pressure pain trial. Analyses indicated that the PEI subjects reported lower ratings of pain, fear, and anxiety, and experienced greater finger temperature recovery than controls. The BR procedure resulted in greater blood pressure recovery, but did not alter ratings of pain or emotion relative to controls. Further research is needed to explore the clinical use of the PEI for acute pain management.

Covino, Nicholas A.; Frankel, F. M. (1993). Hypnosis and relaxation in the medically ill. Psychotherapy and Psychosomatics, 60, 75-90.

Interest in the application of hypnotic techniques for patients with medical disorders seems to rise and fall over the years. Enthusiasm for this work comes both from patients and from clinicians. Often, however, these techniques are offered without regard to the psychological theories that should inform their operation and the limits that clinical and experimental research suggest. This article offers a brief description of the elements of hypnosis and a review of the history of the use of hypnotic techniques with a variety of medical problems, including asthma, habits, pain, cardiology, surgical preparation, irritable bowel syndrome, persistent nausea and vomiting, trichotillomania, and infection and immunity. Special attention is placed on the psychological and physiological principles that help to establish the valid use of hypnotherapy.

Crawford, Helen J.; Gur, Ruben C.; Skolnick, Brett; Gur, Raquel E.; Benson, Deborah M. (1993). Effects of hypnosis on regional cerebral blood flow during ischemic pain with and without suggested hypnotic analgesia. International Journal of Psychophysiology, 15, 181-195.

Using <sup>133</sup>Xe regional cerebral blood flow (CBF) imaging, two male groups having high and low hypnotic susceptibility were compared in waking and after hypnotic induction, while at rest and while experiencing ischemic pain to both arms under two conditions: attend to pain and suggested analgesia. Differences between low and highly-hypnotizable persons were observed during all hypnosis conditions: only highly-hypnotizable persons showed a significant increase in overall CBF, suggesting that hypnosis requires cognitive effort. As anticipated, ischemic pain produced CBF increases in the somatosensory region. Of major theoretical interest is a highly-significant bilateral CBF activation of the orbito-frontal cortex in the highly-hypnotizable group only during hypnotic analgesia. During hypnotic analgesia, highly-hypnotizable persons showed CBF increase over the somatosensory cortex, while low-hypnotizable persons showed decreases. Research is supportive of a neuropsychophysiological model of hypnosis (Crawford, 1991; Crawford and Gruzelier, 1992) and suggests that hypnotic analgesia involves the supervisory, attentional control system of the far-frontal cortex in a topographically specific inhibitory feedback circuit that cooperates in the regulation of thalamocortical activities.

Don, Norman S. (1993, October). Trance surgery in Brazil. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Showed a videotape of a Brazilian trance surgeon, who cuts without analgesia or asepsis. Patients later report no pain, infections, etc. The healer/surgeon is believed by everyone to be in a trance state, and the body is believed to be taken over by a spiritual doctor. The people involved deny that the patient is in trance.

Everett, John J.; Patterson, David R.; Burns, G. Leonard; Montgomery, Brenda; Heimbach, David (1993). Adjunctive interventions for burn pain control: Comparison of hypnosis and Ativan. Journal of Burn Care and Rehabilitation, 14, 676-683.

Thirty-two patients hospitalized for the care of major burns were randomly assigned to groups that received hypnosis, lorazepam, hypnosis with lorazepam, or placebo controls as adjuncts to opioids for the control of pain during dressing changes. Analysis of scores on the Visual Analogue Scale indicated that although pain during dressing changes decreased over consecutive days, assignment to the various treatment groups did not have a differential effect. This finding was in contrast to those of earlier studies and is likely attributable to the low baseline pain scores of subjects who participated. A larger number of subjects with low baseline pain ratings will likely be necessary to replicate earlier findings. The results are argued to support the analgesic advantages of early, aggressive opioid use via PCA or through careful staff monitoring and titration of pain drugs.

1992

Adams, P. C.; Stenn, P. G. (1992). Liver biopsy under hypnosis. Journal of Clinical Gastroenterology, 15, 122-124.

Two patients underwent outpatient percutaneous liver biopsy under hypnosis without complications. One patient had severe anxiety about the procedure because of a previous adverse experience with liver biopsy, and the other had a history of severe allergy to local anesthesia. Both patients had undergone a session of hypnosis at least once prior to the biopsy. One received no local anesthesia, and the other received 1% lidocaine as a local anesthetic. Both patients were completely cooperative during the procedure with the required respiratory maneuvers. Both patients stated that they were aware of the procedure under hypnosis but described no pain and would be most willing to have the procedure done under hypnosis in the future.

Alden, Phyllis (1992, October). The use of hypnosis in the management of pain on a spinal injuries unit. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

To have a spinal injury is one of the most devastating injuries that can happen, reducing you suddenly from a normal life to situation of loss of control, helplessness, etc.- -with nothing to say about what is being done in surgery or other aspects of treatment.

In UK patients come for acute care and rehabilitation all in one place. Over 2 1/2 yrs we had 46 referrals. 7 refused hypnosis ("witch doctoring"). 30 benefitted

1991

Blankfield, Robert P. (1991). Suggestion, relaxation, and hypnosis as adjuncts in the care of surgery patients: A review of the literature. American Journal of Clinical Hypnosis, 33, 172-186.

He notes that the authors provide little information re complications, and length of stay (LOS) is one of the most sensitive response measures used in these studies. The mean difference in LOS for 5 studies that have randomized assignment is 1.3 days. The N's are 80-100 for 3 of the studies, 39 and 60 for others. For two well controlled studies that did not achieve significance, the N's were 40 and 45. Many studies mixed the diagnosis and types of surgeries, making it difficult to interpret the results.

Clarke, J. H.; Reynolds, P. J. (1991). Suggestive hypnotherapy for nocturnal bruxism: A pilot study. American Journal of Clinical Hypnosis, 33, 248-253.

Although one can find many case reports of hypnotherapy for bruxism, there is a paucity of scientific research on the subject. This study describes the use of suggestive hypnotherapy and looks at its effectiveness in treating bruxism. Eight subjects who reported bruxism with symptoms such as muscle pain and complaints of bruxing noise from sleep partners were accepted into the study. An objective baseline of the bruxing was established using a portable electromyogram (EMG) detector attached over the masseter muscle during sleep. Hypnotherapy was then employed. Both self-reports and posttreatment EMG recordings were used to evaluate the hypnotherapy. Long-term effects were evaluated by self-reports only. The bruxers showed a significant decrease in EMG activity; they also experienced less facial pain and their partners reported less bruxing noise immediately following treatment and after 4 to 36 months.

1990

Arendt-Nielsen, Lars; Zachariae, Robert; Bjerring, Peter (1990). Quantitative evaluation of hypnotically suggested hyperaesthesia and analgesia by painful laser stimulation. Pain, 42, 243-251.

Sensory and pain thresholds to laser stimulation were determined, and the laser-pain evoked brain potentials were measured for 8 highly hypnotizable (Harvard Scores 10-11) student volunteers in 3 conditions: (1) waking, (2) suggestion of hyperaesthesia during hypnosis, (3) suggestion of analgesia during hypnosis.

The investigators used a laser beam 3 mm in diameter, with a 200 msec stimulus duration; the same area (but different points within the area) was used for consecutive stimulations. Ss were otherwise maintained in low stimulus conditions so they would not have visual or auditory cues about laser beam onset; they wore goggles, had eyes shut, and had earphones on. Sensory threshold was defined as warmth; pain threshold was defined as a distinct sharp pin prick.

The laser intensity used for stimulation corresponded to strong pain. Interstimulus intervals averaged 15 sec (but were randomly varied between 10-20 sec). Sensory and pain thresholds as well as two evoked potential measurements were taken

during waking , hypnotized hyperaesthesia, and hypnotized analgesia conditions in a single 1 1/2 hour session.

The evoked potential component of interest was the negative complex N1 with latency of 300 msec; amplitude (P1=N1-P2) and latency of this complex (N1) were measured. EEG epochs contaminated by eye movement were omitted from analysis. The standardized induction and deepening of hypnosis required 15-20 minutes; then the suggestion was given that Ss could alter their perception of stimuli such as pain. Hyperaesthesia suggestions were to imagine the right hand was in very hot water, then taken out but still very red, hot, sensitive so that even the vaguest stimulus would be detectable and unpleasant. They were told that they would receive a series of painful but tolerable stimuli, and to raise the left index finger if they could just perceive a laser pulse (sensory threshold), and again if they felt pricking pain (pain threshold).
