Suggestions for analgesia were to imagine that their right hand was placed on their chest, and that their 'former right hand' was no longer their own but was made of some heavy and completely insensitive material like wood or stone. Sensory and pain threshold measures were then taken. During the evoked potential measurement period they received continuous suggestions of analgesia. They also were told to relax and imagine they were in a pleasant place, ignoring everything except the pleasant, relaxed feelings and imagining pleasant sights, sounds, feelings and the imagined place. They were told that though they would receive stimuli, they probably would be able to ignore the stimuli completely.

Results were as follows.

1. In the hypnotic hyperaesthesia condition, sensory and pain thresholds decreased significantly by 47% and 48%, respectively. Three Ss reacted to laser intensities far below what normally can be perceived in the waking state. [The authors ran a separate small control experiment to make sure that the Subjects were not using any other cues, but mention the possibility of light-sensitive skin reacting to the blue laser light, creating evoked potentials.]
2. In the hypnotic analgesia condition, sensory and pain thresholds increased by 316% and 190%, respectively. 7 of 8 Ss did not even respond to pain threshold when the laser intensity was increased to the noxious level of 3W, which is the level at which tissue damage can occur.
3. Pain-related evoked potentials. Amplitude of the first pain-related potential was increased significantly by 14% in the hyperaesthesia condition and reduced significantly by 31% in the analgesia condition. Changes in the evoked potentials were considered minor however compared to those observed for thresholds, which are subjective response measures. Even in Subjects who reported complete analgesia, the experimenters observed the laser pain evoked responses. There were no differences in latencies of the first pain-related potentials for the three conditions (indicating that peripheral and central afferent conduction velocities were the same).

Discussion. "There has been some dispute concerning the experimental design and the reliability of the data obtained in studies dealing with hypnotic suggested analgesia [Spanos & Chaves, 1970]. In our design 2 'opposite' conditions were induced, and the 2 inductions gave 'opposite' results.

"The experience of pain can be significantly altered by suggestions of analgesia, which is in accordance with a number of other studies (for review see [Barber & Adrian, 1982; Hilgard & Hilgard, 1975]). The finding that suggestions of hyperaesthesia can decrease the sensory and pain thresholds and increase the amplitude of the pain evoked potential is a new observation. Since synchronized auditory and visual stimuli from the laser were blocked, and the stimulus was given at random intervals, the changes might be induced by the hypnotic suggestions" (p. 247).

The authors discuss their results in terms of (1) four pain modulation systems (neural/opiate, hormonal/opiate, neural/non-opiate, and hormonal/non-opiate) and (2) focusing and defocusing attention. Because in their pilot study it was necessary to give suggestions continually in order to affect the laser evoked potentials, they conclude that endogenous substances or hormonal/non-opiates would play a minor role, if any, in hypnotic analgesia. (Price and Barber [25] had also found it important to give suggestions continuously.)

hormonal/opiate, neural/non-opiate, and hormonal/non-opiate) and (2) focusing and defocusing attention. Because in their pilot study it was necessary to give suggestions continually in order to affect the laser evoked potentials, they conclude that endogenous substances or hormonal/non-opiates would play a minor role, if any, in hypnotic analgesia. (Price and Barber [25] had also found it important to give suggestions continuously.)

On the other hand, "event-related potentials [7, 26] and pain-related potentials have, previously, been shown to be sensitive to focused and de-focused attention. Recently, Miltner et al. [23] showed the influence of attention on the late pain-related component of potentials, evoked by painful intracutaneous electrical stimulation. The degree to which the subject paid attention to the painful stimulus had a powerful effect on the pain-related complex. When subjects ignored the pain, it was still possible to record the pain-related complex although all the subjects consistently reported less or no pain. In wakeful subjects where cutaneous pain was abolished by lignocaine infiltration, the pain-related evoked potentials were abolished [4]. In our study, we could also record evoked potentials although the subject subjectively did not feel pain. The reason might be that the S acted as if there was full analgesia to the stimuli, in order to satisfy the hypnotist. During suggested hyperaesthesia the thresholds declined below what normally could be perceived in the wakeful state. The volunteers could, therefore, not act hypersensitive, so something did happen.

"The discrepancy in subjective and objective responses might, however, be useful when investigating levels of the neuroaxis at which hypnosis might work" (pp. 248-249).

The authors note that this laser induced pain and the tooth pulp stimulation pain of Mayer & Barber both use the A-delta fibers. Barber & Mayer found it impossible to elicit pain within the output range of the stimulator (up to 150 microA) and reached maximal intensity for all volunteers during suggested analgesia. Using cutaneous laser stimulation the authors found that the skin damage level (3W) could be reached in 7 of 8 volunteers without any reaction of pain.

During the hyperaesthesia condition the sensory threshold was sometimes lower than can be detected in the waking state. Although some researchers have suggested that red light from a helium-neon laser might activate cutaneous photosensitive receptors and thereby elicit brain potentials, the authors were unable to elicit potentials in waking Subjects using their blue and green argon laser light with below sensory threshold intensity.

The authors also note that previous attempts to use physiological correlates of pain such as heart rate, blood pressure, respiration, and galvanic skin response have yielded confusing results. The physiological indicators are present even when Subjects report analgesia, leading some investigators to conclude that the subjective reports are due to illusion [Sutcliffe, 1961], compliance [Wagstaff, 1986], or a placebo induced by the hypnosis context [Wagstaff, 1986]. "These confusing results lead to the conclusion that both the traditional methods used for induction of pain and the monitored physiological responses have been unsatisfactory. The present study has sought to eliminate some of the methodological difficulties by (1) using brief well-defined argon laser stimuli which in awake volunteers induce very stable perceptions between trials [Arendt-Nielsen & Bjerring, 1988], and (2) recording psychophysical thresholds and objective parameters quantitatively related to the intensity of the pain perceived (1, 3)" (p. 249).

Barabasz, Arreed F.; Barabasz, Marianne (1989). Effects of restricted environmental stimulation: Enhancement of hypnotizability for experimental and chronic pain control. International Journal of Clinical and Experimental Hypnosis, 37, 217-231.

Enhancement of hypnotizability and pain tolerance has been demonstrated using restricted environmental stimulation therapy (REST) with university students as Ss (A. F. Barabasz, 1982). The purpose of the present study was to determine whether or not similar results could be obtained with chronic pain patients. Ss consisted of outpatients in treatment for conditions in which pain is prominent who also demonstrated low hypnotizability after repeated hypnosis plateau sessions. 2 groups of Ss were exposed to REST. Situational demand characteristics (Orne, 1962) favored an increase in hypnotizability for REST Group 1 (high demand). REST Group 2 (low demand) was exposed to situational demand characteristics designed to disguise the experimental hypothesis. 2 groups of control Ss were exposed to the same alternative demand characteristic manipulations as the experimental groups, but environmental stimulation was maintained. The Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) of Weitzenhoffer and E. R. Hilgard (1962), including a posthypnotic suggestion for an anesthetic reaction, and an ischemic pain test were administered prior to treatment and again immediately following treatment. After 6 hours of REST, significant increases in SHSS:C scores were found for high-demand and low-demand experimental Ss, as well as for high-demand control Ss. No such increase was found for low-demand controls. Significant decreases in pain scores were found for both high- and low-demand experimental groups. No significant pain score decreases were found for either control group, suggesting a relatively weak effect of demand characteristics. An independent postexperimental inquiry suggested all Ss believed they received active

treatments. The inquiry, conducted 10-15 days after the experiment, also revealed a majority of experimental Ss were using hypnosis on a daily basis to reduce pain with a substantial decrease in pain medication. Only 2 control Ss (highest in hypnotizability) reported similar success. Anecdotal reports of pain reduction experiences using hypnosis after REST intervention were supportive of E. R. Hilgard's (1977) neodissociation theory.

Outpatients getting treatments for conditions involving significant pain, who also were low in hypnotizability (and had reached a plateau level through repeated inductions), had REST (restricted environmental stimulation). Experimental Group 1 = high demand, Experimental Group 2 = low demand (disguised experimental hypothesis). Control groups had pseudo-REST conditions. All Subject spent 6 hrs in the REST chamber (controls read, listened to radio, played computer games, were not stimulus deprived).

The two control groups had the same demand characteristic manipulations as the Experimental groups, but Control Group 1 was cued to the hypnotic focus of the study and given instructions favoring an increase in hypnotizability, while Control Group 2 (low- demand/disguised hypothesis) emphasized the "important psychophysiological measures."

In both high-demand control and experimental groups, E wore a lab coat, maintained an aura of seriousness, and had a medical tray. In low-demand conditions Es dressed in regular clothes.

The Stanford-C was administered, also including a posthypnotic suggestion for an anesthetic reaction,. An ischemic pain test was administered prior to treatment and again immediately following treatment. After 6 hours of REST, significant increases in SHSS:C scores were found for high-demand and low-demand experimental Subjects, as well as for high-demand control Subjects. No such increase was found for low-demand controls.

Significant decreases in pain scores were found for both high- and low-demand experimental groups. No significant pain score decreases were found for either control group, suggesting a relatively weak effect of demand characteristics.

Significant decreases in pain scores were found for both high- and low-demand experimental groups. No significant pain score decreases were found for either control group, suggesting a relatively weak effect of demand characteristics.

Postexperimental inquiry was conducted by an independent interviewer 10-15 days after the experiment. All 20 Subjects believed they received active treatments. This belief seemed to be strong due to the "extensive efforts in the hypnosis plateauing sessions" (p. 225). Also, a majority of experimental Subject were using hypnosis on a daily basis to reduce pain, with a substantial decrease in pain medication. These were Ss who had the highest post-REST SHSS:C scores (9-12 range). Only 2 control Subjects (highest in hypnotizability) reported similar success. Anecdotal reports of pain reduction experiences using hypnosis after REST intervention were supportive of E. R. Hilgard's (1977) neodissociation theory.

"[In an earlier study] instructional demand cues for compliance (A. F. Barabasz, 1982) raised Ss' subjective reports of hypnotic depth in a control condition but failed to significantly raise SHCS scores" (p. 225). The present study "indicate(s)

that chamber REST by itself increases hypnotizability and ischemic pain tolerance, and that experimental demand characteristics do not further potentiate this effect" (p. 225).

The authors note that because they used the posthypnotic suggestion of anesthesia for all Subjects, "it is not possible to determine whether the lowered pain reports of REST Ss were due to the posthypnotic suggestion because of enhanced hypnotizability or whether the lowered pain sensitivity was a nonsuggested collateral consequence of REST" (p. 226).

The data support the conclusion that REST enhances hypnotizability and concomitantly decreases ischemic pain reports after a posthypnotic suggestion. This effect, of course, may or may not be mediated by a response to hypnotic suggestion. "It is important to recognize the quality of the anecdotal pain control reports as remarkably consistent with E. R. Hilgard's (1977) neodissociation theory of hypnosis. Successful pain controllers did not anesthetize their clinical pains, as asked to do for the ischemic pain, but rather dissociated their pain to other parts of their bodies or outside their bodies" (p. 227).

**Bierman, Steven F. (1989). Hypnosis in the emergency department. American Journal of Emergency Medicine, 7, 238-242.**

Five cases are presented wherein hypnosis was used by the emergency physician either as the primary mode of treatment or as an adjuvant to standard medical care. Common hypnotic phenomena (e.g. anesthesia, analgesia), as well as novel effects, are reported. The technique used for trance induction and utilization is briefly outlined, and criteria are set forth for the bedside recognition of hypnotic trance.

**Edelson, Jeffrey; Fitzpatrick, Jody L. (1989). A comparison of cognitive-behavioral and hypnotic treatments of chronic pain. Journal of Clinical Psychology, 45, 316-323.**

27 male chronic pain patients were assigned to 1 of 3 treatment groups: hypnosis, cognitive-behavioral, and attention control. Hypnosis and cognitive-behavioral treatments were identical, with the exception of the hypnotic induction. Scores on the McGill Pain Questionnaire (MPQ) and a measure of the overt motor behavior element of chronic pain were collected at pretreatment, posttreatment, and follow-up intervals. Analyses showed significant increases in activity and decreases in pain intensity for the cognitive-behavioral treatment.

Changes for the hypnosis treatment were noted only on the MPQ. Changes for both groups were sustained on the 1-mo follow-up. Findings generally support the superiority of the cognitive-behavioral treatment on behavior measures and its equivalence to hypnosis on subjective measures.

**1988**

**Barabasz, Arreed F. (1988, November). Cold pressor pain and spontaneous hypnosis in flotation restricted environmental stimulation. [Paper] Presented at the**

annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

6 hours of REST (reclined on bed in sound attenuated chamber) led to 100% increase in hypnotizability. They didn't get changes with flotation that are obtained with awake bed rest. Chamber method is very good in cigarette smoking (11 replications) but not flotation rest - despite the demand characteristics of a flotation tank. Subjects must remain awake (sleepfree) if meaningful hypnotizability is achieved.

Davies, Peter (1988). Some considerations of the physiological effects of hypnosis. In Heap, Michael (Ed.), Hypnosis: Current clinical, experimental and forensic practices (pp. 61-67). London: Croom Helm Ltd.

This chapter reviews literature on physiological correlates of hypnosis, but these notes are limited to only one fact reported in the review. The author writes, 'A recently completed, and as yet unpublished study by C. Gillett and H. D. Griffiths at Bradford University investigated the relation between hypnosis and classical conditioning of psychophysiological responses. In a complex design involving both normal conditioning and normal test trials and a repetition of both acquisition and test trials under hypnosis, they found not only suppression of the conditioned response but also suppression of skin conductance responses to the half-second bursts of a 115-dB tone used as the unconditioned stimulus. Not to produce a significant autonomic response to such an intrinsically aversive stimulus is a remarkable feat which is probably outside the repertoire of simulators. However, even such results are not conclusive as the design did not include simulator control groups nor even neutrally instructed non-hypnotized group' (pp. 64-65 ).

Van der Does, A. J.; Van Dyck, R.; Spijker, R. E. (1988). Hypnosis and pain in patients with severe burns: A pilot study. Burns Including Thermal Injuries, 14, 399-404.

Presents a pilot study on the effectiveness of hypnosis in the control of pain during dressing changes of burn patients. Eight patients were treated, and all evaluated the interventions as beneficial. The treatment of four patients was more closely analyzed by obtaining pain and anxiety ratings daily. Results show a 50%-64% decrease in reported pain level for three patients and a 52% increase of pain for one patient. The mean decrease for these four patients was 30% (for overall as well as worst pain during dressing changes). A 30% reduction of anxiety level and a modest reduction of medication use were achieved concurrently. It is concluded that hypnosis is of potential value during dressing changes of burn patients. Comparison of global evaluations and daily pain ratings shows that systematic research in some cases leads to conclusions opposite from clinical observations. Follow-up recommendations for future studies are given.

Elton, D.; Boggi-Cavallo, P.; Stanley, G. V. (1988). Group hypnosis and instructions of personal control in the reduction of ischaemic pain. Australian Journal of Clinical and Experimental Hypnosis, 16, 31-37.

Three groups of students were tested on ischemic pain threshold and pain tolerance. The control group of 95 subjects received a single pain test. The hypnosis group of 42 subjects received a single session of hypnotic induction prior to the pain test. The hypnosis and personal control group of 32 subjects received hypnotic induction and suggestions of personal control prior to the pain test. The hypnotic procedure included the use of a pendulum, coupled with suggestions of arm elevation and lip analgesia. It was found that hypnotic induction resulted in lower [sic] pain threshold and pain tolerance. Suggestions of personal control and hypnosis further lowered [sic] the pain measures.

The ABSTRACT appears to have mis-statements, for the word should be "higher" or "raised." In the article the results are stated as, "The hypnosis conditions with suggestion of personal control produced the higher pain threshold (mm/Hg) and longer tolerance (seconds) than the hypnosis only group and both hypnotic inductions produced higher threshold and longer tolerance than the control condition" (p. 35)

"The results suggest that a single brief group session of hypnosis can produce a significant change in response to ischaemic pain. The added instruction of increased personal control produced a greater effect and reinforces the importance of the self concept in the reaction to pain" (p. 36).

Evans, C.; Richardson, P. H. (1988). Improved recovery and reduced postoperative stay after therapeutic suggestions during general anesthesia. Lancet, 2 (8609), 491-493.

The clinical value of suggestions during general anesthesia was assessed in a double-blind randomized placebo-controlled study. 39 unselected patients were allocated to suggestion (N = 19) or control (N = 20) groups who were played either recorded suggestions or a blank tape, respectively, during hysterectomy. The patients in the suggestion group spent significantly less time in the hospital after surgery, suffered from a significantly shorter period of pyrexia, and were generally rated by nurses as having made a better-than-expected recovery. Patients in the suggestion group, unlike the control group, guessed accurately that they had been played an instruction tape.

Bandura, A.; O'Leary, A.; Taylor, C. B.; Gauthier, J.; Gossard, D. (1987). Perceived self-efficacy and pain control: Opioid and non-opioid mechanisms. Journal of Personality and Social Psychology, 53, 563-571.

Subjects who were trained to use psychological coping strategies (e.g. imagery, distraction, dissociation, sensation transformation) had both better pain tolerance

on a cold pressor test and higher self efficacy ratings. Those subjects who were given naloxone (which blocks pain reduction effects of beta endorphins) showed more pain tolerance than subjects not given the cognitive training experiences. They attributed much of the pain tolerance increase associated with cognitive interventions to opiate release, suggesting that cognitive interventions may have physiological mediating effects on pain perception.

Evans, Frederick J.; McGlashan, Thomas H. (1987). Specific and non-specific factors in hypnotic analgesia: A reply to Wagstaff. British Journal of Experimental and Clinical Hypnosis, 4, 141-147. (Comment in response to Wagstaff, G. (1987). Is hypnotherapy a placebo? Hypnosis, 4, 135-140.)

This article is a reply to Wagstaff's (1984) critique of the McGlashan, Evans & Orne (1969) article which was entitled "The nature of hypnotic analgesia and the placebo response to experimental pain," published in Psychosomatic Medicine, 31, 227-246. The paper to which the authors are replying is Wagstaff, G. F. (1984). Is hypnotherapy a placebo? Paper given at the First Annual Conference of the British Society of Experimental and Clinical Hypnosis, University College, London. An abridged version appeared in the British Journal of Experimental and Clinical Hypnosis, 1987, 4, 135-140.

The closing comments of this Evans & McGlashan 1987 paper read as follows: "The strategy in this study [i.e. McGlashan, Evans & Orne, 1969] was quite different from the usual experimental design. Our goal was to maximize all of those non-specific factors that we could build into the experimental procedure. Only by attempting to maximize non-specific effects is it possible to see whether hypnosis in appropriately responsive subjects can exceed that degree of pain control which occurs due to the maximal operation of these non-specific effects. These non-specific components of the hypnotic situation may account for a great deal of clinical change. ... The critical finding was that hypnosis did add a level of pain control that occurred after maximizing clinically related non-specific factors contributing to change in pain tolerance, and that this increased tolerance occurred only in subjects markedly responsive to hypnosis, in contrast to the significant non-specific effects which were uncorrelated with measured hypnotizability" (pp. 143-144).

The principal findings of the McGlashan, Evans & Orne (1969) study were: "(a) The improved ability to tolerate pain following the ingestion of placebo was roughly the same for high hypnotizable and low hypnotizable subjects. (b) The response to the non-specific aspects of taking a 'drug' among low hypnotizable subjects was identical to, and highly correlated (.76) with, their response to the legitimized expectation that change would occur under hypnosis for low hypnotizable subjects. The placebo component of a believe-in 'drug' ingestion was the same as the placebo component of a believed-in hypnotic experience for these low hypnotizable subjects. (c) The performance of the highly hypnotizable subjects was significantly greater under hypnotic analgesia conditions than it was under placebo conditions.

"This last finding is important conceptually, though of less clinical relevance. It should be noted that not all high hypnotizable subjects showed this result. Even among highly hypnotizable subjects, not all of them had the experience that profound analgesia had occurred! Thus, based on their subjective experience of the relatively small degree of analgesia, 6 of the 12 highly hypnotizable subjects behaved exactly as the low hypnotizable subjects had -- their placebo and hypnotic responses were small, significant, but equal. Only 6 out of 12 carefully screened hypnotizable subjects who subjectively experienced marked analgesia showed dramatic objective changes in pain endurance. Dr. Wagstaff might consider the physiological implications of the observation that we became somewhat frightened about the possibility of tissue damage with two of these six subjects. We had to stop their performance at a point where physiologists had assured us that tissue damage could be expected. They had also assured us, wrongly for these subjects, that we did not have to worry about such a critical point because nobody could endure such a degree of occlusion with this procedure. In fact, for these two subjects, anoxia and muscle cramping were not even apparent!" ( p. 144).

assured us that tissue damage could be expected. They had also assured us, wrongly for these subjects, that we did not have to worry about such a critical point because nobody could endure such a degree of occlusion with this procedure. In fact, for these two subjects, anoxia and muscle cramping were not even apparent!" ( p. 144).

Farthing, G. William; Venturino, Michael; Brown, Scott W.; Lazar, Joel D. (1986, April). Internal vs. external distraction in the control of pain as a function of hypnotic susceptibility. [Paper] Presented at the annual meeting of the Eastern Psychological Association, New York.

This study tested the prediction, derived from their 1984 study: for highly hypnotizable subjects, pain reduction methods involving either attention to external distracting stimuli or attention to internally generated distracting images will be effective in reducing pain. However, for low hypnotizables only external stimulus distraction will be effective, and internal images will not be effective distractors for reducing pain.

Used independent groups of college students, with 1/3 highs, 1/3 mediums, and 1/3 lows. Used five conditions: (n=12 per subgroup 3H x 5T) 1. Suggestion - Subjects told "to image as vividly as you can that your hand is numb and insensitive, as if it were made of rubber." (No hypnotic induction was used.) 2. Guided imagery - Subjects told to listen to a story that would be read to them, and to try to imagine the scenes as vividly as possible. (Story included scenes where the s was the main character.) 3. Word memory - Subjects told to listen to a list of words that would be read to them and try to remember them for later recall test (30 abstract nouns, at rate of 1 every 2 seconds. 4. Pursuit rotor - which subjects did during the ice water immersion. 5. Placebo control - included suggestion, "For this test you will find that you can succeed in not being disturbed by the cold water if you carefully follow the following instructions. While your hand is in the water you should not try to control your thoughts. Just let your mind wander freely to whatever feelings or thoughts or ideas happen to come to you."

Domangue, Barbara B.; Margolis, Clorinda; Lieberman, D.; Kaji, H. (1985). Biochemical correlates of hypnoanalgesia in arthritic pain patients. Journal of Clinical Psychiatry, 46, 235-238.

Self-reported levels of pain, anxiety, and depression, and plasma levels of beta-endorphin, epinephrine, nor-epinephrine, dopamine, and serotonin were measured in 19 arthritic pain patients before and after hypnosis designed to produce pain reduction. Correlations were found between levels of pain, anxiety, and depression. Anxiety and depression were negatively related to plasma norepinephrine levels. Dopamine levels were positively correlated with both depression and epinephrine levels and negatively correlated with levels of serotonin. Serotonin levels were positively correlated with levels of beta-endorphin and negatively correlated to epinephrine. Following hypnotherapy, there were clinically and statistically significant decreases in pain, anxiety, and depression and increases in beta-endorphin-like immunoreactive material

Finer, B. (1985, August). Altered substance P concentrations in CSF during hypnotic analgesia. [Paper] Presented at the 10th International Congress of Hypnosis and Psychosomatic Medicine, Toronto, Canada.

These notes are not a complete record of the presentation.

Substance P is present at many sites of endorphins or enkephalons. Sometimes a strange sleepiness follows triggerpoint stimulation. Acupuncture also may lead to similar changes (e.g. feeling groggy; having difficulty standing - lasts 1-4 hours). If you inject 4 mgms (10 times the ordinary dose) of Naloxone into Ss it leads to groggy sleepiness, for Naloxone-reversed hypnotic analgesia.

1984

D'Eon, Joyce Lillian (1984). Response to pressure pain as moderated by hypnotic susceptibility, type of suggestion strategy, and choice (Dissertation, Concordia University, Canada). Dissertation Abstracts International, 45 (n4-B), 1313-1314.

"The present study examined the relationship between hypnotic susceptibility and ability to control pain, by comparing high and low susceptible subjects' response to pressure pain when these subjects employed either an imagery or a distraction pain attenuating strategy. The effect of providing subjects with a choice of which strategy to employ was investigated. In addition, the subjects' imagery ability and the types of cognitive strategies they engaged in were assessed. Subjects who scored either 9 or above or 4 and below on the Harvard Group Scale of Hypnotic Susceptibility: Form A, were asked to participate in a pain study. All 84 subjects first received a baseline trial on a modified version of the Forgione-Barber Strain Gauge Pain Stimulator, within susceptibility levels. Subjects who were able to keep their finger in the apparatus for 60 seconds were randomly assigned to a Choice, a No Choice, or a Control condition. The 36 high and low susceptible subjects in the Choice condition were given the option of using either an imagery suggestion strategy or a

low distraction strategy on the second trial. The 32 high and low susceptible subjects in the No Choice condition were told about both strategies but were assigned randomly to either the imagery or the distraction strategy group. The 16 subjects in the Control group did not receive a strategy. Both pain intensity and pain tolerance were measured. Results indicated that an equivalent number of high and low susceptible subjects, given a choice of strategy, chose the imagery and distraction strategies. There were no differences in either pain intensity or pain tolerance between high and low susceptible subjects in the Choice conditions. The Choice condition subjects exhibited significant pain reductions from the first to the second trial. No Choice and Control subjects did not reduce pain significantly. In addition, high and low susceptible subjects who chose the imagery strategy did not have higher imagery scores than those subjects who chose the distraction strategy. Subjects in the No Choice condition used fewer coping strategies than subjects in the Choice condition, on the second trial. The implication of these results and directions for future research are discussed" (p. ).

Elkins, Gary R. (1984). Hypnosis in the treatment of myofibrositis and anxiety: A case report. American Journal of Clinical Hypnosis, 27, 26-30.

A 38-year-old woman with chronic myofibrositis pain was treated by the use of hypnosis and psychotherapy. Hypnotherapeutic techniques, including symptom alteration, relaxation, and insight, are described. This regimen resulted in reduction in pain and emotional distress, which was maintained at three months and one year after treatment.

Farthing, G. William; Venturino, Michael; Brown, Scott W. (1984). Suggestion and distraction in the control of pain: Test of two hypotheses. Journal of Abnormal Psychology, 93, 266-276

96 18-30 yr old undergraduates, preselected for high or for low hypnotic susceptibility on the Harvard Group Scale of Hypnotic Susceptibility - Form A, reported their level of perceived pain during a 50-sec baseline immersion of their hand in ice water. In a second immersion, independent groups of high and low hypnotizables (n = 12) were tested (without hypnosis) under 4 conditions: analgesia suggestion alone, verbal- distraction task alone, a combination of suggestion plus distraction, and control. Among high hypnotizables, as compared to the control group, all 3 experimental treatments were effective in reducing pain. The combination of suggestion plus distraction was no more effective than was either of the single treatments alone in reducing pain. Among low hypnotizables, only the distraction treatment was effective. Results support an attentional- diversion explanation of the effect of waking analgesia suggestions rather than a special resources hypothesis. It appears that both high and low hypnotizables can divert attention toward external stimuli, but only high hypnotizables can successfully divert attention inward to control pain.

Information about this study presented at the annual meeting of the Society for Clinical and Experimental Hypnosis indicates that for the waking suggestion group,

the analgesia suggestion was given without any prior hypnotic induction; it involved telling the subjects to imagine that their hand and forearm were numb and insensitive, like a piece of rubber.

[The fact that distraction did not reduce pain ratios more among high hypnotizables than among lows (whereas suggestion did) is similar to Blum & Nash's (1982) finding that positive heightened alert attention to a stimulus did not interfere with an illusion, but inhibiting awareness did.]

Fogel, Barry S. (1984). The 'sympathetic ear': Case reports of a self-hypnotic approach to chronic pain. American Journal of Clinical Hypnosis, 27 (2), 103-106.

Secondary gain issues may limit the success of hypnotherapeutic approaches to chronic pain. A self-hypnotic suggestion that promotes patients' awareness of the interpersonal aspects of their pain complaints was used in the treatment of two patients with chronic headache. Hypnotic suggestions that help make secondary gains conscious may be a useful addition to hypnotic techniques of pain management.

1983

Bassman, S. (1983). The effects of indirect hypnosis, relaxation and homework on the primary and secondary psychological symptoms of women with muscle contraction headache (Dissertation). Dissertation Abstracts International, 44, 1950-B.

Compared the effects of indirect hypnosis (e.g., metaphors, stories, vague suggestions, and implied directives) on muscle contraction headaches with a relaxation and a no-treatment control condition. Both hypnosis and relaxation conditions reduced symptoms more than did the no-treatment condition. Unlike relaxation, indirect hypnosis did not reduce the intensity and duration of headaches, although it did reduce the amount of medication and also benefitted sleep.

1981

Chen, Andrew C.; Dworkin, Samuel F.; Bloomquist, Dale S. (1981). Cortical power spectrum analysis of hypnotic pain control in surgery. International Journal of Neuroscience, 13, 127-136.

Cortical power spectrum (CPS) of brain potentials was recorded from the scalp between prefrontal and parietal regions in both right hemisphere (RH) and left hemisphere (LH). A pattern of laterality shift in CPS occurred at different stages during an extensive oral surgery, performed under hypnosis, in a young female patient. Video and audio recordings as well as psychophysiological recordings were obtained through the following 6 stages: Baseline, Hypnosis, Surgery (1 hr, no cortical recording), Immediate Postsurgery Procedure, Hypnotic Re-experience, Hypnotic Rest, and Posthypnotic Baseline. Indications of anxiety and pain scores were reported in writing by the patient through verbal command by the hypnotist. In each stage, 10 min of CPS (10 spectrum/stage, 8 epochs/spectrum, 6

seconds/epoch) were analyzed by a PDP-11 computer. The results of CPS analysis demonstrated significant large total power reduction at different stages. There was significant correlation between both hemispheres at baseline, but dissociation of hemispheric power output occurred during hypnosis stages. LH was more dominant than RH during baseline and presurgery hypnosis, but both were leveled-off immediately following the surgery procedure. However, RH became more dominant during all postsurgery hypnosis stages. Interestingly, this pattern shifted back to the original relationship during the posthypnotic baseline stage. Specific changes of spectral power in theta and alpha of EEG activities in both hemispheres also occurred in conjunction with hypnosis.

Subject was a 25 year old woman, described as only medium in hypnotizability. She scored 3 on the 5-point Stanford Hypnotic Clinical Scale, 7 on the 12-point Stanford Hypnotic Susceptibility Scale, and 3 on up-gaze, between 2 and 3 on eye roll, on the Spiegel eye roll test.

The principal hypnotic approach was a suggestion of dissociation, i.e. that the patient "experience herself swimming freely and powerfully, in a deep cold mountain lake, pre-occupied with the intensity of the blue-black color of the water, the shimmering of light from above, and the possibilities of exploration of rock formations, caves, etc. It was suggested that while she was experiencing the exhilaration and strenuous stimulation of the cold water and the vigorous exercise, an 'observing-self' would remain on the shore, watching and ensuring that no harm would come to the person. The suggestion was reinforced that any stimulation experienced was experienced in the body, not in the person" (p. 129).

The patient was trained in inductions and dissociation first in the therapist's office, then with two sessions in the research laboratory (where tooth pulp stimulation pain thresholds were measured), and then two sessions in the hospital dental operatory.

The results of the computerized CPS were analyzed by hemispheres. "Large reductions in total power occurred at different stages associated with hypnosis and these reductions in power output of the CPS showed significant left-right differences" (p. 130).

"The total energy output of LH [left hemisphere] continued to diminish as hypnosis continued by as much as 80% of baseline value, while RH [right hemisphere] power output tended to be stabilized from the initial hypnosis recording stage until the awake baseline stage" (p. 130).

"Those stages involving hypnosis were characterized by dominant RH energy output in the alpha spectrum. ...

"Alpha output for the LH decreased an average of 65% between awake baseline levels and postsurgery hypnosis stages, while RH alpha only decreased approximately 50% of resting levels. This resulted in a relative shift of alpha output which was approximately equal in both hemispheres prior to surgery, to a 2:1 shift in favor of RH alpha output as hypnosis progressed. This differential shift in laterality of alpha was reversed when the subject awakened from hypnosis.

"Of interest was the observation that total power reductions and laterality shifts associated with hypnosis were not altered by the profound instrumentation of surgery and postoperative pain, nor were observed laterality shifts affected by hypnotic suggestions aimed at recreating the surgical experience (see Stage 5)" (p. 130).

During the experiment when the investigators used hypnotic suggestion to recreate the surgical experience, LH output continued to diminish while RH output did not change, making the LH-RH contrast highly significant. "This suggests that the RH is active during deep stages of hypnosis and can remain so despite hypnotic suggestions which are presumed to be intensely aversive" (p. 131).

In their Discussion, the authors reinforced the conclusion that overall cortical functioning is reduced during hypnosis, and that the left cerebral hemisphere shows a greater reduction than the right. They discuss the increased theta density in RH and LH during the postsurgery hypnosis stage in terms of reports that theta is associated with altered states of consciousness (Tebecis et al., 1975; Ulett et al., 1972; Anad, China, & Singh, 1961; Banquet, 1973; Kasamatsu & Hirai, 1966; Wallace, 1970) and with cognitive tasks like mental arithmetic (Dolce et al., 1974).

The authors note that their results are congruent with Hilgard's neodissociation theory of hypnosis, and add that since their suggestions were dissociative in nature rather than of local anesthesia, the EEG may reflect the brain physiology of dissociation.

Finally, they comment on the implications for pain neurophysiology. "The total power changes and shifting patterns in laterality of cortical functioning observed more closely tracked the hypnosis experience than the pain experience; this is, in fact, a very puzzling issue. It appears on the face of it that the EEG measurements recorded are not reflective of EEG-related pain phenomenology despite the strenuous and invasive surgical procedures used. The observations that overall power output continued to decrease during the several hypnosis stages after strenuous surgery and then increased as the patient came out of hypnosis makes reasonable the possibility that hypnosis has some functional brain correlates; we cannot conclude from the present cortical power spectrum analysis that any brain correlates of surgical pain were revealed. We are well aware that EEG recordings were not available during actual surgery itself, because of artifacts resulting from head movements, etc. Nevertheless, it can be fairly claimed that recordings obtained immediately after such oral surgery of one hour duration, could reasonably be expected to be associated with a person in pain. But, both by verbal report and available objective data, any surgically induced traumatic pain was of brief duration under hypnosis" (p. 135).

Claghorn, James L.; Mathew, Roy J.; Largen, John W.; Meyer, John S. (1981). Directional effects of skin temperature self-regulation on regional cerebral blood flow in normal subjects and migraine patients. American Journal of Psychiatry, 138, 1182-1187.

Vascular headache of the migraine type is associated with vasomotor changes in cerebral arteries. The authors studied whether skin temperature training (biofeedback) reduced the frequency, severity, and duration of these headaches by

measuring the regional cerebral blood flow (CBF) in 11 female migraine patients (27-52 years) and 9 female volunteers (22-37 years), using the noninvasive 133 Xe inhalation technique. Half of each group was randomly assigned to a hand-warming or a hand-cooling group. CBF increased in several regions of the left hemisphere to a significant degree only for the migraineurs who were in the hand-warming group. The pattern of vasomotor regulation apparently differed between migraine and normal Ss. The migraineurs' headache symptoms were affected by both warming and cooling, but warming produced more salutary effects.

1980

Adams, Henry E.; Feuerstein, Michael; Fowler, Joanne L. (1980). Migraine headache: Review of parameters, etiology, and intervention. Psychological Bulletin, 87 (2), 217-237.

The migraine headache is a disorder of much interest to clinicians and researchers in the areas of psychology and medicine. Research that has investigated various characteristics of this disorder and the factors contributing to its etiology and a variety of treatment techniques have appeared in both the medical and the psychological literature. The present article provides a comprehensive critical appraisal of this literature, with particular emphasis on psychological intervention. Theoretical issues involving biological and psychological factors in migraine etiology are discussed, and a psychobiological model for the migraine disorder is proposed. Areas requiring further basic and clinical research are identified. Major conclusions include (a) that etiological factors of migraine remain unclear; (b) that pharmacological intervention does not constitute an adequate treatment method in terms of headache elimination; (c) that although a number of psychological treatment approaches have been reported in the literature, there are few well-controlled evaluations, and definitive conclusions regarding differential effectiveness of the various techniques are difficult; and (d) that a biofeedback approach directed at modifying the peripheral pain mechanism in migraine appears to be a promising treatment technique for this disorder.

Crowley, R. (1980). Effects of indirect hypnosis (Rapid Induction Analgesia) for relief of acute pain associated with minor podiatric surgery (Dissertation). Dissertation Abstracts International, 40, 45-49.

Lynn et al. (1993) cited this dissertation. They noted that all 30 volunteer subjects responded painfully when stimulated by a needle administered by a podiatrist and that the Rapid Induction Analgesia of Joseph Barber (RIA) was not as effective as local chemical analgesia. Furthermore, according to Lynn et al., RIA patients did not report a reduction in their anxiety following podiatric surgery comparable to that reported by patients who received chemical analgesia. The author also found that hypnotizability was related to multiple chronic pain indices.

Edwards, William Henry (1980). Direct versus indirect hypnosis for the relief of chronic pain in spinal cord injured patients (Dissertation, United States International University). Dissertation Abstracts International, 40 (10-B), 4996

This study compared effectiveness of direct hypnosis and indirect hypnosis (Rapid Induction Analgesia, developed by Joseph Barber) in reducing experimental and clinical pain in spinal cord injured patients. The 30 male paraplegic patients who had chronic benign pain volunteered for the study. They were administered three tests: the Pain Estimate Scale (Sternbach, 1974), Ischemic Muscle Pain Test (IMPT), and the Stanford Profile Hypnotic Susceptibility Scale, Form II -- SPHSS -- (Weitzenhoffer and Hilgard, 1967). Each patient experienced three sessions: (1) Baseline Control, (2) Direct Hypnosis, and (3) Indirect Hypnosis. Patients were randomly assigned to Sessions (2) and (3). The results indicated no significant statistical difference in the effectiveness of direct versus indirect hypnotic analgesia in these chronic pain patients. Direct and indirect hypnosis were equally effective; hypnotizability was not associated with outcome. Furthermore, there was no interaction between treatment effects and pretreatment pain level. The results were similar for both clinical and experimental pain.

1979

Barber, Joseph; Donaldson, David; Ramras, Susan; Allen, Gerald D. (1979). The relationship between nitrous oxide conscious sedation and the hypnotic state. Journal of the American Dental Association, 99, 624-626.

Nitrous oxide-oxygen produces a state of consciousness in the patient that is reported to be similar to the hypnotic state. In this investigation, the authors test the hypothesis that nitrous oxide-oxygen heightens a patient's responsiveness.

This study apparently did not have a control group receiving nitrous oxide but no suggestions, to evaluate the amnesia and analgesic effects of the drug alone.

Beers, Thomas M.; Karoly, Paul (1979). Cognitive strategies, expectancy, and coping style in the control of pain. Journal of Consulting and Clinical Psychology, 47, 179-180.

Measures of tolerance, self-reported pain threshold, and overall discomfort of cold-pressor pain were obtained from 114 male subjects in a pretest-training-posttest experiment. Training consisted of brief practice in one of four cognitive strategies: rational thinking, compatible imagery, incompatible imagery, and task-irrelevant cognition. Analyses of covariance indicated (a) that cognitive-imaginal strategies facilitated endurance of pain and raised self-reported threshold, (b) that rational thinking and compatible imagery were generally the most effective treatments, (c) that expectancy alone was not a significant pain-attenuating factor, (d) that treatments did not affect discomfort ratings, and (e) that individual differences in imaginal ability and coping style did not correlation with changes in any of the dependent measures.

**Bennett, Henry L.; Giannini, Jeffrey A.; Kline, Mark D. (1979, September). Consequences of hearing during general anesthesia. [Paper] Presented at the annual meeting of the American Psychological Association, New York.**

**A double blind 2X2 study exposed 23 herniorrhaphy and cholecystectomy patients to either a 45 minute suggestion tape or to the actual sounds of the operation. Structured interviews conducted postoperatively assessed hypnotic susceptibility and regressed patients under hypnosis to operative events. Ten patients accurately recalled significant events from surgery but only under hypnosis. Recall was greater and more accurate in patients scoring high on the Stanford Clinical Hypnosis Scale. Fewest number of pain medications were given postoperatively to patients receiving the suggestion tape. Hernia patients showed better recall than gallbladder patients.**

**1978**

**Barber, Joseph (1978, August). Hypnosis: A suggestion for pain relief. Pain Topics, 7.**

**He lists 3 misconceptions that prevent hypnosis being used more widely for pain control: 1. Hypnosis renders a patient helplessly under the control of the hypnotist. 2. Hypnosis can only relieve psychogenic pain, not pain of a clearly somatic origin. 3. Hypnosis is effective only in 'susceptible' individual (the most damaging misconception). He also gives examples of indirect suggestions of pain relief (i.e. increased comfort, etc.)**

**1977**

**Barber, Joseph (1977). Rapid induction analgesia: A clinical report. American Journal of Clinical Hypnosis, 19, 138-149.**

**This is a report of clinical dental experience using a newly developed, hypnotic pain control procedure. Characteristics of the procedure are outlined, an explanation for its success is suggested, and the broader implications of this success are discussed. The unusually high incidence of clinical analgesia rapidly obtained with this procedure leads the author to question the meaning and relevance of the concept of 'hypnotic susceptibility' for the practical clinical application of hypnosis.**

**Berk, Stephen N.; Moore, Mary E.; Resnick, Jerome H. (1977). Psychosocial factors as mediators of acupuncture therapy. Journal of Consulting and Clinical Psychology, 45 (4), 612-619.**

**This study investigated a number of psychosocial variables that have been suggested as possible mediating factors in acupuncture therapy. Forty-two volunteers with bursitis and/or tendonitis of the shoulder served as subjects. All were randomly assigned to one of four treatment groups: acupuncture - positive milieu, acupuncture - negative milieu, placebo acupuncture - positive milieu, and placebo acupuncture - negative milieu. Pretreatment and posttreatment subjective pain**

reports and shoulder motion studies, as well as pretreatment assessments of hypnotic susceptibility and suggestibility, were determined for each subject. Results indicated that (a) acupuncture and placebo acupuncture were equally effective in producing highly significant ( $p < .001$ ) reductions in subjective pain reports; (b) neither treatment effectively improved objective shoulder motion; (c) subjects treated in the positive milieu reported more improvement than those in the negative milieu ( $p < .053$ ); and (d) hypnotic susceptibility, suggestibility, belief in the treatment, and the satisfaction of expectations showed no relationship to treatment outcome. It is concluded that acupuncture therapy provides a powerful placebo. Treatment milieu variables warrant future study in the attempt to understand the acupuncture phenomena.

Chertok, Leon; Michaux, D.; Droin, M. C. (1977). Dynamics of hypnotic analgesia: Some new data. Journal of Nervous and Mental Disease, 164, 88-96.

Following two surgical operations under hypnotic anesthesia, it was possible, during subsequent recall under hypnosis, to elicit a representation of the past operative experience. It would seem that under hypnosis there is a persistence that under hypnosis there is a persistence of the perception of nociceptive information and of its recognition as such by the subject. From an analysis of these two experiments in recall, it is possible to formulate several hypotheses concerning the psychological processes involved in hypnotic analgesia. In consequence of an affective relationship, in which the hypnotist's word assumes a special importance for the subject, the latter has recourse to two kinds of mechanism: a) internal (assimilation to an analogous sensation, not, however, registered as dangerous--rationalization); and b) external (total compliance with the interpretations proposed by the hypnotist), which lead to a qualitative transformation of nociceptive information, as also the inhibition of the behavioral manifestations normally associated with a painful stimulus.

1976

Chaves, John F.; Barber, Theodore Xenophon (1976). Hypnotic procedures and surgery: A critical analysis with applications to 'acupuncture analgesia'. American Journal of Clinical Hypnosis, 18 (4), 217-236.

Although hypnotic procedures are useful for reducing the anxiety of surgery and helping patients tolerate surgery, they do not consistently eliminate pain. Six factors that are part of or associated with hypnotic procedures help patients tolerate surgery. These factors pertain to patient selection, the patient-physician relationship, the preoperative 'education' of the patient, the adjunctive use of drugs, and the use of suggestions of analgesia and distraction. It appears that the same factors account for the apparent successes of 'acupuncture analgesia' as well. A frequently-overlooked fact, that most internal tissues and organs of the body do not hurt when they are cut by the surgeon's scalpel, is also important in understanding how surgery can be performed with either 'hypnoanesthesia' or 'acupuncture analgesia.'

1975

Ahlberg, D.; Lansdell, H.; Gravitz, M. A.; Chen, T. C.; Ting, C. Y.; Bak, A. F.; Blessing, D. (1975). Acupuncture and hypnosis: Effects on induced pain. Experimental Neurology, 49, 272-280.

The reactions of 14 volunteers to electrical stimulation near the supra-orbital nerve were studied under acupuncture, placebo-acupuncture, and hypnosis. As the intensity of stimulation increased, a minimum sensation, a minimum pain, and then a maximum or intolerable pain sensation were produced. Under hypnosis the average intensity of the stimulus for producing these sensations was higher than before the trance induction. Under acupuncture and placebo-acupuncture no clear increase in current intensity was observed. Acupuncture, as well as hypnosis, did not consistently change the blood, blood pressure, pulse rate, EKG, respiratory rate, or EEG.

Anderson, J. A. D.; Basker, M. A.; Dalton, R. (1975). Migraine and hypnotherapy. International Journal of Clinical and Experimental Hypnosis, 23 (1), 48-58.

Therapeutic measures for migraine are largely ineffective. Prophylaxis by hypnosis (including autohypnosis) and prochlorperazine is difficult to assess because of the intermittency of the disease and the subjective nature of the disabling symptoms. A method of studying this problem is described in this article. Random allocation of 47 patients was made to one or other prophylactic measure. This was followed by monthly assessments and independent evaluation of 1 year of continuous care. Criteria of improvement were the number of attacks per month, number who had Grade 4 attacks, and complete remission. Results showed that the number of attacks and the number who suffered blinding attacks were significantly lower for the group receiving hypnotherapy than for the group receiving prochlorperazine. For the group on hypnotherapy, these 2 measures were significantly lower when on hypnotherapy than when on previous treatment. Prochlorperazine seemed about as effective as previous treatment. 10 out of 23 patients on hypnotherapy achieved "complete remission" during the last 3 months of the trial as opposed to only 3 out of 24 on prochlorperazine. It is concluded that further trials of hypnotherapy are justified against some other treatment not solely associated with the ingestion of tablets.

Andreychuk, Theodore; Skriver, Christian (1975). Hypnosis and biofeedback in the treatment of migraine headache. International Journal of Clinical and Experimental Hypnosis, 23 (3), 172-183.

A study was made to explore the effects of subject hypnotizability in response to 3 treatment procedures applied to 33 migraine headache sufferers. These treatment procedures included biofeedback training for hand-warming, biofeedback training for alpha enhancement and training for self-hypnosis. The Hypnotic Induction Profile (HIP) of Spiegel & Bridger (1970) was given to each S to determine degree of hypnotizability and the MMPI was administered to all Ss. All 3 treatment groups showed significant reductions in headache rates and there were no significant differences between groups. Cutting across treatment groups, high hypnotizable Ss (N - 15) showed significant reductions in headache rates when compared with low hypnotizable Ss (N - 13). There was no correlation between HIP scores and the hysteria scale of the MMPI.

Carli, G. (1975). Some evidence of analgesia during animal hypnosis [Abstract]. Experimental Brain Research, 23, 35.

The purpose of this study was to investigate the response to painful stimuli during animal hypnosis. The experiments were performed on unanesthetized, free-moving rabbits carrying implanted electrodes for recording the EEG and EMG activity and nerve stimulation. Injection of formaline into the dorsal region of the foot produced long lasting EEG desynchronization and motor pain reactions. In some rabbits a procedure of habituation was used to reduce hypnosis duration below 45 sec. Hypnosis was induced by inversion. The following results were obtained: 1) Polysynaptic reflexes elicited [sic] by electrical stimulation of cutaneous and muscle afferents were depressed during hypnosis. 2) Hypnosis transitorily suppressed all the painful manifestations due to formaline injection and was characterized by high [sic] voltage slow wave activity in the EEG, 3) In habituated rabbits, a significant increase in hypnotic duration and EEG synchronization was observed when hypnosis was preceded by formaline injection. Hypnosis duration was not potentiated by painful stimuli when Naloxone (5mg/Kg i.v.) was injected before hypnosis induction. 4) In habituated rabbits a recovery in hypnotic duration coupled to EEG synchronization was obtained, in absence of painful stimuli, following subanalgesic injection of Morphine (1mg/Kg). It has been previously shown that in the rabbit administration of 5-20 mg/Kg of Morphine produces EEG synchronization and strong reduction of pain reactions. It is suggested that, during animal hypnosis in a condition of continuous nociceptive stimulation, the pain response is blocked by a mechanism which exhibit [sic] similar effects of Morphine both at spinal cord (polysynaptic reflexes) and at cortical levels (EEG synchronization).

Clawson, T. A.; Swade, R. H. (1975). The hypnotic control of blood flow and pain: The cure of warts and the potential for the use of hypnosis in the treatment of cancer. American Journal of Clinical Hypnosis, 17 (3), 160-169.

Case histories show that hypnosis can control massive bleeding and pain, and it can remove warts, probably by stopping blood flow to them. We propose that blood flow to cancerous tumors can likewise be controlled, which could destroy them outright, or which control could be a useful adjunct to chemo- or radio-therapy.

1974

Chaves, John F.; Barber, Theodore Xenophon (1974). Acupuncture analgesia: A six-factor theory. Psychoenergetic Systems, 1, 11-21.

The dramatic successes claimed for acupuncture suggest that Western medicine has failed to identify important factors that pertain to the nature of pain and its control. This may not be the case, as there are at least six factors which are often overlooked by writers describing the absence of pain (i.e., analgesia) during acupuncture: (a) the patients accepted for surgery under acupuncture usually believe that it will work, (b) drugs are frequently used in combination with acupuncture, (c) the pain associated with surgical procedures is less than is generally assumed, (d) the patients are prepared in special ways for surgery under acupuncture, (e) the acupuncture needles distract the patient from the pain of surgery and, (f) suggestions for pain relief are present in acupuncture treatment. It is concluded that more research is needed to determine whether additional factors are needed to help explain the phenomenon of acupuncture analgesia

Chaves, John F.; Barber, Theodore Xenophon (1974). Cognitive strategies, experimenter modeling, and expectation in attenuation of pain. Journal of Abnormal Psychology, 83 (4), 356-363.

Verbal reports of pain were obtained from 120 subjects during a base-level pretest and also during a posttest conducted under one of several experimental treatments. The pain stimulus was a heavy weight applied to a finger for two minutes. During the posttest, subjects who had been asked to utilize cognitive strategies for reducing pain (to imagine pleasant events or to imagine the finger as insensitive) showed a reduction in pain as compared to uninstructed control subjects. Subjects led to expect a reduction in pain, but not provided with cognitive strategies, also showed reduced pain during the posttest as compared to control subjects, but the reduction was smaller than for subjects using cognitive strategies. An experimenter modeling procedure, used with one half of the subjects under each experimental treatment, was effective in reducing verbal reports of pain only for subjects with high pretest levels who were asked to imagine pleasant events.

1972

Cedercreutz, C. (1972). The big mistakes: A note. International Journal of Clinical and Experimental Hypnosis, 20, 15-16.

In his book, *A System of Medical Hypnosis*, Ainslie Meares writes, "Most books on hypnosis, from Bernheim to the present time, devote a great deal of space to the description of successful and dramatic cures. These accounts may be of prestige value to the author, and may do something to inform the profession of the potential value of hypnosis in medicine, but these success stories are really of little help to those who would learn the technique of hypnotherapy because the emphasis is always on the success of the treatment rather than on analysis of the psychodynamic mechanisms which brought it about. As in everything else, we learn most from a study of our failures [p. 3]." These comments remain as true today as they were ten years ago. With the notable exception of Meares, few colleagues have been willing to share their errors, allowing us to profit from their experience. Thus, when Dr. Cedercreutz sent along a note describing his experience with one of his patients, I was struck by his generosity, and it seemed most appropriate for all of us to share his experience by way of the Journal. Hopefully, this may encourage other colleagues to share their failures as well as their successes so that all of us may learn to be more effective therapists and better scientists. M.T.O. [Martin Orne]

The case reported involves a patient who had migraine headache removed with hypnosis, but later developed gastrointestinal symptoms that were operated surgically with absence of positive (physical) pathology noted. Subsequent investigation of the psychological component of the problem with hypnosis revealed an early trauma (seeing a soldier killed with a bayonette) that led to migraine-like pain in the head and vomiting.

1970

Bowers, Kenneth S.; Kelly, P. (1970). Stress, disease, psychotherapy, and hypnosis. Journal of Abnormal Psychology, 490-505.

Presents evidence for the importance of suggestion and hypnotic ability in the healing or amelioration of various somatic disorders. It is argued that even in some treatment interventions that are not explicitly hypnotic, suggestion and hypnotic ability may be hidden factors that help to promote successful healing. Consequently, hypnotic ability may be an individual difference variable that influences treatment outcome in a manner not heretofore recognized by many investigators and clinicians involved in helping the psychologically and physically ill.

Evans, Michael B.; Paul, Gordon L. (1970). Effects of hypnotically suggested analgesia on physiological and subjective responses to cold stress. Journal of Consulting and Clinical Psychology, 35 (3), 362-371.

Relative effects of suggested analgesia and hypnotic induction were evaluated with regard to reduction of stress responses (self-report, heart rate, pulse volume) to the physical application of ice-water stress. Four groups (N = 16 each) of undergraduate female Ss, equated on hypnotic susceptibility, were run individually, receiving (a)

hypnotic induction plus analgesic suggestion, (b) hypnotic induction alone, (c) waking self-relaxation plus analgesic suggestion, or (d) waking self-relaxation alone. The major findings were that suggestion, not hypnotic induction procedures, produced reductions in the self-report of distress, and that the degree of reduction was related to hypnotic susceptibility in both "hypnotic and "waking" conditions. Neither suggestion nor hypnotic induction procedures resulted in reduction of the physiological stress responses monitored in this study. Several methodological issues are discussed. Although findings add to the bulk of evidence supporting the "skeptical" view of hypnotic phenomena, results are related to other literature, suggesting that an adequate evaluation of hypnotic analgesia as used clinically has not yet been undertaken.

the bulk of evidence supporting the "skeptical" view of hypnotic phenomena, results are related to other literature, suggesting that an adequate evaluation of hypnotic analgesia as used clinically has not yet been undertaken.

**1969**

Barber, Theodore Xenophon (1969). An empirically-based formulation of hypnosis. American Journal of Clinical Hypnosis, 12 (2), 100-130.

A formulation is presented which does not invoke a special state of consciousness ("hypnosis" or "trance") to account for the behaviors that have been historically associated with the word hypnotism. Instead, so-called hypnotic behaviors - e.g., "analgesia," "hallucination," "age-regression," and "amnesia" - are conceived to be functionally related to denotable antecedent variables which are similar to those that control performance in a variety of interpersonal test-situations. The antecedent variables which determine behavior in a "hypnotic" situation include Ss' attitudes, expectancies, and motivations with respect to the situation, and the wording and tone of instructions- suggestions and of questions used to elicit subjective reports. The formulation is exemplified by several dozen experimental studies, and prospects for further research are delineated.

**1964**

**Attar, A.; Muftic, M. (1964). Narcohypnosis in abdominal surgery. British Journal of Medical Hypnotism, 16 (1), 29-32**

Effectiveness of a relaxation technique to increase the comfort level of patients in their first postoperative attempt at getting out of bed was tested on 42 patients, aged 18 to 65, who were hospitalized for elective surgery. Study group patients were taught the relaxing technique; control group patients were not taught the technique. Each group had an equal distribution of cholecystectomy, herniorrhaphy, and hemorrhoidectomy patients. Blood pressure, pulse, and respiratory rates of subjects in both groups were compared prior to surgery and after the postoperative attempt to get out of bed. Subjects' reports of incisional pain and bodily distress were measured via a pain and distress scale after their attempt at getting out of bed. Amount of analgesics used in the first 24 hrs following surgery was examined. Mean differences in report of incisional pain and body distress, analgesic consumption, and respiratory rate changes were statistically significant, supporting the hypothesis that use of a relaxation technique to reduce muscular tension will lead to an increased comfort level of postoperative patients.

1961

Cangelo, V. W. (1961). The use of hypnotic suggestion for pain relief in malignant disease. International Journal of Clinical and Experimental Hypnosis, 9, 17-22.

Using hypnotic suggestion, pain relief was attempted in 22 cases. 13 of these patients showed a decrease in narcotic requirements. Duration of effectiveness was from 1 week to 4 1/2 months. It is concluded that this method should be tried before resorting to either chemical or surgical procedures since it is relatively simple to perform, has no harmful complications, and is not unduly time consuming. Ament, Phillip (1955). A psychosomatic approach to the use of anesthesia for a hysterical dental patient: A case history. Journal of Clinical and Experimental Hypnosis, 3, 120-123. (Abstracted in *Psychological Abstracts* 56: 1280)

Author describes a case highly resistant both to anesthesia and dentistry. Although very responsive to hypnosis, she continued moaning and moving from side to side (later determined to be her way of preventing dental work even though anesthetized). Ultimately a combination of hypnosis and multiple anesthetics was needed, including nembutal, sodium pentothal, nitrous oxide and novocain. In the

author's experience, most other patients require only hypnosis or hypnosis plus novocaine.

## **PARALYSIS**

**1988**

**Radil, T.; Snydrova, I.; Hacik, L.; Pfeiffer, J.; Votava, J. (1988). Attempts to influence movement disorders in hemiparetics. Scandinavian Journal of Rehab. Med. Suppl., 17, 157-161.**

Step duration, measured in hemiparetic patients walking on a circular path, showed that step duration of the affected foot is usually longer. Functional electrical stimulation of the peroneal nerve in the swing phase of the step (eliminating foot drop) shortened step duration in the majority of cases. Hypnosis induced by the verbal fixation technique was used in hemiparetic patients (a) to ascertain whether the patients' mobility would increase during hypnosis and to determine (in positive cases) whether this approach might be used to predict the effect of rehabilitation performed by classical methods; (b) to use hypnosis as a method of auxiliary treatment. The general finding was that the extent of movements of the hemiparetic upper extremity considerably improved during and immediately after hypnosis. This effect could be observed both at the level of severe impairment (at the beginning of treatment) and during the later stages when mobility greatly improved due to rehabilitation and recovery.

**LaRiccia, P. J.; Katz, R. H.; Peters, J. W.; Atkinson, G. W.; Weiss, T. (1985). Biofeedback and hypnosis in weaning from mechanical ventilators. Chest, 87, 267-269.**

Weaning patients from mechanical ventilation can be hindered by both physical and psychologic factors. Biofeedback has been used successfully as an adjunct in difficult weaning problems. We have used a combination of hypnosis and biofeedback to wean a patient with neurologic disease who previously failed weaning by standard procedures. A 30-year-old woman with respiratory failure secondary to multiple sclerosis with transverse myelitis was given eight sessions of biofeedback over 12 days in which the movements of her chest wall, as monitored by magnetometers, were displayed on an oscilloscope. The patient was praised for targeted respiratory rate, amplitude, and rhythm. These sessions included hypnosis in which the patient was given suggestions of well-being and that she could breathe as she had five years earlier. In this manner the patient was successfully weaned. Respiratory biofeedback and hypnosis appear to be useful adjuncts in weaning patients from ventilators.

**Pajntar, M.; Roskar, E.; Vodovnik, L. (1985). Some neuromuscular phenomena in hypnosis. In Waxman, D.; Misra, P.C.; Gibson, M.; Basker, M.A. (Ed.), Modern trends in hypnosis (pp. 181-206). New York: Plenum Press.**

The phenomena presented here allow us to conclude that with hypnosis, the functioning of the neuromuscular system may be significantly influenced, either by increasing or decreasing the functioning of voluntary or electrically stimulated contractions, and that the function of movements may be improved. Two suggestions proved to be most efficient: 1) physical and mental relaxation, and 2) age regression. In age regression the patient recalls the ideomotor system, which is likely to result in a reconstruction of the forgotten motor contractions or in a strong intensification of these contractions under additional suggestions. With regard to relaxation, on one hand it intensifies the functioning of the voluntarily stimulated neuro-muscular systems, and on the other hand it prevents an excessive functioning of the involuntarily reflex stimulated antagonistic systems" (pp 202; 204).  
, on one hand it intensifies the functioning of the voluntarily stimulated neuro-muscular systems, and on the other hand it prevents an excessive functioning of the involuntarily reflex stimulated antagonistic systems" (pp 202; 204).

1981

Nardi, T. J. (1981). Treating sleep paralysis with hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (4), 358-365.

The use of hypnosis in the management of sleep paralysis is described and discussed. 2 cases are presented in which autohypnosis was used to desensitize the patients to the anxiety that accompanied their sleep paralysis. The autohypnosis also provided a means of terminating the attacks. Follow-up data suggests that this approach may serve to decrease the frequency of sleep paralysis attacks.

1980

Pajntar, Marjan; Jeglic, Anton; Stefancic, Martin; Vodovnik, Lojze (1980). Improvements of motor response by means of hypnosis in patients with peripheral nerve lesions. International Journal of Clinical and Experimental Hypnosis, 28 (1), 16-26.

In order to accelerate rehabilitation of patients with peripheral nerve lesions, hypnosis was employed to encourage them voluntarily to move those muscles with weak re-innervation and to achieve the best possible activity of the affected muscle groups. By measuring muscle force and endurance and by observing the electrical activity of the affected muscles, it was found that the activity of the affected muscles was much better while patients were in hypnosis than when they were in the waking state. The patients were able to contract even paretic muscles having only weak re-innervation with such strength, that clinically perceptible contraction of the muscles and movement of paretic extremities occurred. Such early and improved activation is very important for prevention of much permanent damage.

1977

Schneck, Jerome M. (1977). Sleep paralysis and microsomatognosia with special reference to hypnotherapy. International Journal of Clinical and Experimental Hypnosis, 25, 72-77.

Sleep paralysis is described in connection with a patient whose episodes incorporated the experience of her entire body feeling extremely small. The psychological implications of the paralysis and her microsomatognosia are discussed. Comparisons are made with other perceptual distortions involving the sense of change in body size. The characteristics of sleep paralysis and associated personality patterns are delineated. This material is discussed with special reference to experiences of patients in hypnosis, especially hypnotherapy and hypnoanalysis.

1963

Slater, Roger C.; Flores, Louis S. (1963). Hypnosis in organic symptom removal: A temporary removal of an organic paralysis by hypnosis. American Journal of Clinical Hypnosis, 5 (4), 248-255.

**"Summary and Conclusions. A detailed case study is reported on the use of hypnosis with beneficial results in an instance of eventually proved organic brain disease. Three other confirmatory case reports of organic disease definitely benefitted by the use of hypnosis are briefly cited.**

**" The first patient had been adequately studied repeatedly for organic brain disease. Because the studies led to an uncertain indefinite unconfirmed suspicion of psychogenic epilepsy, the patient was returned with a recommendation for continued treatment and observation by the author, a general practitioner. Hence, she was, after still further study for organic disease, treated symptomatically by hypnosis with beneficial results. This led to the erroneous conclusion that the patient's disability was probably functional. A sudden fatal outcome of the actual but unrecognized brain disease led to a correct but post- mortem diagnosis of astrocytoma of the brain, Grade IV.**

**"This report and those given to supplement it raise significant questions about the importance and value of hypnosis in organic disease. These include the challenging question of the extent to which the use of hypnosis can potentiate the natural corrective forces of the body; the need to recognize the value of hypnosis in effecting beneficial results in organic disease; the need to qualify the reliability of hypnosis as a differential diagnostic procedure in relation to psychogenic and organic disability; and the possibility and extent of the amelioration or actual correction of known organic illness" (p. 254).**

## **PARAPSYCHOLOGY**

**2002**

**Gravitz, M.A. (2002). The search for Bridey Murphy: Implications for modern hypnosis.. American Journal of Clinical Hypnosis, 45, 3-10.**

**The 1956 publication of "The Search for Bridey Murphy" was a noteworthy event in the history of hypnosis. This internationally best selling book, written for lay readers, described several recorded sessions of alleged time-regression to a prior life nearly two centuries before 1956. While subsequent investigations disproved that claim, there were a number of important implications for the science and practice of hypnosis. Although it was concluded that the Bridey Murphy interviews were**

products of cryptomnesia, the book was a significant factor associated with a resurgence of public and professional interest in the modality.

The author notes that the hypnotist was a layman who did no mental status evaluation prior to the hypnosis. The author also considers and rejects several alternative hypotheses (reincarnation or regression to past lives; fraud or hoax; monetary motivation on the part of the hypnotist; and development of a dissociated identity, i.e. multiple personality disorder. He concludes, "Tighe's expectancies, her prior hypnotic experiences with Bernstein, her compliance, transference, acquiescence, and heightened suggestibility, could have set the stage for the subsequent behavior of both the hypnotist and subject in a nonconscious interrelationship in which both parties accepted their beliefs as reality" (p. 7).

**1996**

Dixon, Mike; Labelle, Louise; Laurence, Jean-Roch (1996). A multivariate approach to the prediction of hypnotic susceptibility. International Journal of Clinical and Experimental Hypnosis, 44 (3), 250-264.

The present study examined the relation between various self-report measures and two measures of hypnotizability within a multivariate framework. A group of 748 participants was tested on the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A), the Tellegen Absorption Scale (TAS), as well as the Preference for an Imagic Cognitive Style (PICS) questionnaire. One hundred ninety of these participants also completed the Paranormal Experiences Questionnaire (PEQ). Data were analyzed using hierarchical multiple regression equations, and the results of the analyses indicated that both the TAS and PICS accounted for significant amounts of unique variance in each of two 373-member samples of HGSHS:A scores. A further sub-sample of participants (n = 161) was tested on the Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) to see if these results would generalize to another measure of hypnotizability. Hierarchical multiple regression analyses revealed that although the PEQ predicted significant amounts of unique SHSS:C variance over and above that predicted by the TAS, the PICS failed to do so. This inconsistency in results may be due in part to the generally low intercorrelation between the different hypnotizability scales and points to the need to develop new predictor variables that are orthogonal to each other. - Journal Abstract

**1994**

Atkinson, Richard P. (1994). Relationships of hypnotic susceptibility to paranormal beliefs and claimed experiences: Implications for hypnotic absorption. American Journal of Clinical Hypnosis, 37, 34-40.

This study examined the relationship of hypnotic susceptibility level to belief in and claimed experience with paranormal phenomena. The Harvard ... and the Inventory of Paranormal Beliefs and Experiences [developed for this study] were administered on consecutive days to 43 undergraduate students (14 men, 29 women) ... . a

significant multiple correlation was obtained ( $r = .55, p < .001$ ). A partial correlation between hypnotic susceptibility and belief in paranormal phenomena was also significant ( $r = .53, p < .001$ ), while hypnotic susceptibility was not found to be significantly related to claimed paranormal experiences. Implications of these relationships for the role of absorption in hypnosis are discussed.

Discusses relationship to Absorption, and the fact that Labelle, Dixon, Laurence, & Nadon (1990) got correlation of hypnotizability with paranormal experience

Walsh, Roger (1994, August). Transpersonal psychology--the state of the art. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

Twenty-five years ago a group formed that was called transpersonal psychology, following after humanistic psychology (e.g. Maslow). Some of the humanistic psychologists came into transpersonal psychology. Maslow was interested in healthy people, and in peak experiences that were transpersonal in nature--experiences encompassing wider aspects of life, including mystical experiences.

Peak experiences were thought to be positive, but also overwhelming. When psychologists looked Eastward, they found that there were whole families of these types of experiences, and that they could be induced by will and could be stabilized into not only peak but plateau experiences. There was a reservoir of wisdom in the world's religions that could be drawn upon. This wisdom is being integrated with Western science to create the discipline of transpersonal psychology.

There is a broad spectrum of altered states of consciousness. Traditionally, altered states of consciousness were thought to be few in number, and usually pathological. Our society has been resistant toward studying them. For example, Esdaile's use of hypnosis in surgery was not welcomed, even though he was lowering morbidity and mortality because he controlled shock. His paper was turned down for publication. He amputated a leg in front of colleagues in Britain, who commented that he "must have hired a very hard rogue" to have his leg cut off under hypnosis.

Our culture is monophasic, deriving its world view almost exclusively from the waking state; other cultures are polyphasic and also draw their world view from dreams, meditative, or yogic contemplative states, etc. Recently we can apply more sophisticated analyses, to compare states of consciousness and map these out, phenomenologically. There are several key dimensions of experience for mapping the states: 1. Control 2. Awareness of Environment 3. Concentration 4. Mental Energy/Arousal 5. Emotion 6. Identity or Self Sense 7. Out-of-Body Experience 8. Content of Experience

Using these dimensions, we could compare shamanic, yogic, and Buddhist practices. A Nepalese shaman drums himself into a trance state, demonstrating: 1. Ability to enter and leave an altered state of consciousness and partly control experience 2. Decreased awareness of his environment 3. Increased concentration, fluid attention 4. Increased mental energy/arousal 5. Either pleasurable or not [pleasurable] emotion 6. Separate self sense: may be experienced as a non-physical "spirit" or "soul" 7. Controlled ecstasy (Out of Body experience)

A Nepalese shaman drums himself into a trance state, demonstrating: 1. Ability to enter and leave an altered state of consciousness and partly control experience 2. Decreased awareness of his environment 3. Increased concentration, fluid attention 4. Increased mental energy/arousal 5. Either pleasurable or not [pleasurable] emotion 6. Separate self sense: may be experienced as a non-physical "spirit" or "soul" 7. Controlled ecstasy (Out of Body experience)

Buddhist meditation is training awareness to examine experience as minutely as possible, in effect a heightened awareness (Vipassana).

A yogic practitioner engages in concentration, focusing on a fixed stimulus and holding it unwaveringly, till it dissolves a sense of separation into a unity with the object, ultimately with the Self.

[Author showed a slide comparing the three.] All three approaches have increased control and concentration. (The Yogi's is unshakable.) An awareness of the environment is increased for the Buddhist; the Yogi may lose awareness entirely. Others have ecstatic experience; the yogi has enstatic experience. Identity for the shaman is separate (a soul); for the Buddhist awareness is so precise that what was "I" is deconstructed into evanescent flux, into thoughts, images, emotions (like a movie with solitary frames); the yogi dissolves the self sense, but because of fixed concentration the separate self disappears and yogis feel like merging with larger Self.

So now for first time in history we can compare and map both similarities and differences. Now we have new possibilities for understanding and contrasting different practices. We can now differentiate the many states of consciousness that are available. But there are an awful lot of states. Can we find an over-arching framework? For the first time, we can say yes--due to the work of Ken Wilber. This is Developmental Structuralism (looking for common deep structures).

For example, you can identify millions of different faces, and they are surface structures; but they all have a common deep structure. Likewise, if we see that a Hindu creates images of [devas] and a Christian sees saints, they are seeing archetypal images. Likewise, Buddhists experience nirvana in which all phenomena disappear, and so does another group. This [sense of all phenomena disappearing] is common to both, but different from those who see archetypal images. We may be able to come up with a typology of altered states.

Wilber also says that these deep structures and corresponding states may develop in a developmental sequence, with common stages. Three transpersonal stages are subtle, causal, and non-dual. In meditation, first you learn how out of control the mind is, then gradually it quiets and you discover subtle experiences that you usually overlooked. Going further, all thoughts cease to arise, and there is only pure consciousness. Beyond that, images re-arise but are now recognized as projections of consciousness.

Subtle images may be formless (as in pure light, pure sound). The person may pay attention to more and more subtle sounds. Or the images may have form (as in shamanic power animals).

At the casual stage, the person may be aware of consciousness itself, only consciousness, with no objects: pure consciousness, void, the Atman of Vedanta, abyss of gnosticism.

At the non-dual stage, objects arise again: everything is recognized as expressions of consciousness--e.g., Zen's "one mind." Consciousness now has awoken and sees itself in all things, unbounded by space and time and limits because consciousness is what creates space, time, and limits. This is Moksha, Enlightenment, etc.

This is not the final task, because the final task is bringing the awakening to the world (Plato's re-entering the cave, to educate others; Zen oxherder entering the marketplace with help-bestowing hands; Christianity's "fruitfulness of the soul"). For Joseph Campbell, this was the hero's return. Toynbee observed that each great contributor had withdrawn and then returned to the world to offer what they had found.

[It is a process of] transforming a peak into plateau experience; an altered state into a trait; stabilized into enduring understanding, and then bringing it back into the world.

Is there evidence for enlightenment? There now is analogical and laboratory support for this. Analogical support is lucid dreaming. Until 20 years ago, Western psychology thought lucid dreaming was impossible, but now LaBerge at Stanford University has shown physiological evidence. We know from every night's experience that we can create worlds and bodies on which our lives seem to depend. The claim of spiritual traditions is that there is a state of consciousness that bears a relationship to the ordinary [waking] state as lucid dreaming has to nonlucid dreaming. The Dalai Lama said they train yogis to be aware during dreams, not to lose awareness 24 hours a day; then to be aware of dreaming while in a waking period. A Tibetan dream yoga aim is the "great realization," that everything in existence is like a dream.

Laboratory studies have been done on enlightened people. The EEG data obtained while they are sleeping is consistent with lucidity during their dreams and between dreams. Rorschach tests have been done on advanced Buddhist meditators; at the penultimate of enlightenment, they show no evidence of conflicts around sexuality and aggression. The 2000 year old Buddhist texts say that at this stage these issues are resolved.

The implications for our usual state are that normality is not the peak of human development; normality is arrested development. The link between apes and civilization is us! We experience a consensus trance, a collective psychosis, society's hypnosis. We live in the biggest cult of all: CULTURE. The answer is, "Wake up."

A most important question is, if it is true that our conventional state of development is suboptimal, how do we develop other states? The classic answer is: take up a discipline, a practice (e.g., meditation, service, being in nature). One problem is that spiritual traditions are usually couched in archaic language, and have accumulated nonsense around them over the years. It is desirable to abstract out the essential elements. That is a recent thrust of transpersonal research.

There are six common elements: 1. Ethics: the moment you sit down to meditate, what emerges is all the unethical stuff you've done and what was done to you. Ethical behavior (not conventional morality) is a tool for mind training. 2. Attentional training: ordinarily we cannot sustain attention. (William James said the maximum is 3 seconds.) The aim is to be able to maintain attention on what one wants. It leads to the stabilization of mind, calming. 3. Emotional training:

destroying negative emotions (well developed in Western psychology, maybe better than in the Eastern traditions, because we recognize the problem with repression); cultivating positive emotions (where contemplative practices do well, because they offer tools for unwavering, unconditional, and all-encompassing [positive regard]; what is known as agape in Christianity). 4. Redirection of motivation: changing what you want, etc. 5. Perceptual refinement: we mistake shadows for realities; according to St. Paul we "see through a glass darkly." This enhances sensitivity, accuracy, and subtlety of perception. 6. Wisdom: actually the first element, playing a role all through the path. Initial motivation sees suffering of the world; provides motivation for realizing that there must be another way of living, culminates with deep insight into nature of the world, mind, consciousness, reality (prajna; Christian's gnosis). When the mind is trained, stabilized, and clarified, the mind has a heightened capacity for understanding.

So for the first time we can recognize the common elements in religions; we can see that the contemplative core contain practices and road maps. This approach recognizes multi-state psychologies and philosophies.

**APPLICATION.** Many areas of research are developing in transpersonal psychology. These studies have implications for the state of the world. It is only 25 years since the founding of transpersonal psychology. The world's population has developed to the extent that every four months we are losing as many people from malnutrition as from a Holocaust. Our problems are still solvable. The best population explosion control is to make education available to women in the Third World. The transpersonal vision gives a frame to recognize that we are all connected.

For a fuller account of transpersonal psychology, see R. Walsh & F. Vaughan (Eds). (1993) *\_Paths Beyond Ego: The Transpersonal Vision.\_* New York: Tarcher/Putnam.

**1992**

Pekala, R. J.; Kumar, V. K.; Cummings, J. (1992). Types of high hypnotically susceptible individuals and reported attitudes and experiences of the paranormal and the anomalous. Journal of the American Society for Psychical Research, 86, 135-150.

A total of 575 subjects were given the Harvard Group Scale of Hypnotic Susceptibility and completed two self-report questionnaires that assessed the frequency of paranormal and unusual experiences and attitudes and beliefs towards such experiences. Subjects highly susceptible to hypnosis endorsed a significantly greater number of the psi-related items and anomalous and unusual beliefs and experiences than did subjects who were not highly susceptible to hypnosis. Subsequent cluster analyses of the responses of the highly-susceptible subjects suggested that about 10% of the high susceptibles (about 1% of the total subject population) were especially likely to report psi-related and unusual experiences. The implications of using such individuals in parapsychological research to increase the effect size associated with paranormal events are discussed.

Richeport, Madeleine M. (1992). The interface between multiple personality, spirit mediumship, and hypnosis. American Journal of Clinical Hypnosis, 34, 168-177.

The author draws parallels between multiple personality disorder (dissociative identity disorder), spirit mediumship, and hypnosis. She uses historical, anthropological, and clinical perspectives. According to the author, Milton Erickson's view of multiple personality disorder was that it was not necessarily pathological, and he employed hypnosis to gain access to personalities and to transform their behavior from involuntary to voluntary actions. "Natural trance therapies in other cultures offer a new perspective for viewing the normalcy or pathology of "other selves"" (p. 168).

**1991**

Nelson, Peter L. (1991-92). Personality attributes as discriminating factors in distinguishing religio-mystical from paranormal experients. Imagination, Cognition and Personality, 11, 389-406.

In the first section of this article, an operationalized notion of preternatural experience is described which includes two general classes of experience: religio-mystical (Ontic) and paranormal (Perceptual). The exploratory study which follows uses the personality measures of the complete Tellegen Differential Personality Questionnaire taken from 120 subjects who reported having had spontaneous religio-mystical and/or paranormal experiences at some time in the past. The scores on all eleven primary dimensions, three higher order affect factors, and two validity scales were used individually, in univariate ANOVAs, and together, in a Direct Discriminant Function Analysis, to successfully separate two classes of preternatural experiencers from non-experiencers and from each other.

in the past. The scores on all eleven primary dimensions, three higher order affect factors, and two validity scales were used individually, in univariate ANOVAs, and together, in a Direct Discriminant Function Analysis, to successfully separate two classes of preternatural experiencers from non-experiencers and from each other.

Persinger, M. A.; Makarec, Katherine (1991-92). Interactions between temporal lobe signs, imaginings, beliefs and gender: Their effect upon logical inference. Imagination, Cognition and Personality, 11, 149-166

Rotton's Paralogic Test, Wilson-Barber's Inventory of Childhood memories and Imaginings (ICMI) and the PPI (Personal Philosophy Inventory) were administered to 100 male and 100 female university students. Both sexes displayed moderately strong (0.50) correlations between content-selected and factor analyzed clusters of possible temporal lobe signs, exotic beliefs and the numbers of childhood imaginings. Although there were no sex differences between the accuracy of logical statements that contained paranormal or neutral content, males who displayed more temporal lobe signs were more accurate for logical items that contained paranormal content. Females who displayed more imaginings were more accurate for valid than for invalid items. Accuracy for items with paranormal content increased with exotic beliefs but not with conservative religious beliefs for both sexes. The relationship between exotic beliefs and accuracy for items with paranormal content was especially strong for females. These results suggest: 1) gender differences in the neurocognitive processes that contribute to logical problem solving and 2) accuracy may depend upon the degree to which the subject matter is commensurate with the person's history of enhanced temporal lobe signs, capacity for fantasy and imaginings and beliefs in exotic concepts.

Review of related literature indicates that Personal Philosophy Inventory (PPI) temporal lobe signs are correlated with temporal lobe EEG alpha but not occipital lobe alpha (Makarec & Persinger, 1990), with increased suggestibility (Persinger & DeSano, 1986; Ross & Persinger, 1987), with creativity and proneness towards fantasy (Persinger & DeSano, 1986; Ross & Persinger, 1987; Makarec & Persinger, 1987), and with reports of psi experiences and beliefs in such things as reincarnation and aliens in UFOs ('exotic themes') (Persinger & Makarec, 1987; Persinger & Makarec, 1990).

This experiment was designed to answer four questions: " 1) Do imagery and temporal lobe signs emerge from the same source of variance?; 2) Do males and females differ significantly in their incidence of imaginings and temporal lobe signs?; 3) Do males and females differ in their ability to solve logical problems?; and 4) Is the accuracy of problem solving affected by the subject matter of the problem and the problem solver's temporal lobe signs and capacity for imagery?" (p. 151).

The PPI consists of 140 true-false items that were selected with a goal of discerning temporal lobe signs within a normal population. One 30-item subscale has items that are similar to experiences reported by patients with verified electrical foci in the temporal lobes, albeit milder (the TLS or temporal lobe sign scale). Of these 30 items, 16 refer to ictal-like experiences (the CPES, or complex partial epileptic signs), and 14 refer to interictal-like behaviors (ILB). CPES items are items like "Sometimes an event will occur that has special significance for me only," and "While sitting quietly, I have had uplifting sensations as if I were driving over a rolling road." ILB items are items like "People tell me I blank out sometimes when people are talking," and "When I lose an argument I spend a lot of time thinking about what I should have said."

ILB items are items like "People tell me I blank out sometimes when people are talking," and "When I lose an argument I spend a lot of time thinking about what I should have said."

Wilson and Barber's Inventory of Childhood Memories and Imaginings (ICMI) has 52 true-false items that include reports of paranormal experiences (5 items), moderate imaginings (18 items) such as 'When I was a child I enjoyed fairytales,' and extreme imaginings (15 items) such as 'When I was a child or teenager, at times I was afraid my imagining would become so real to me that I would be unable to stop it.'

Rotton's Paralogic Test [unpublished, at Florida International University, Miami] has 16 syllogisms, each with major premise, minor premise, and conclusion. "The person must decide if the argument is valid (n = 8) or invalid (n = 8). Half of each of the valid and invalid arguments refer to mundane material while the other half of the arguments refer to paranormal-related material. An example of the former is 'If a president is a crook, he would be impeached; Congress did not impeach Nixon. Therefore Nixon is not a crook' and 'If flying saucers really existed, somebody would have photographed one. Nobody has ever photographed a flying saucer. Therefore, flying saucers do not exist'" (p. 153).

Correlations were computed separately for males and females. Both groups increased in accuracy for paranormal items as their belief in things like reincarnation and UFOs ('exotic concepts') increased. Males with a higher number of temporal lobe signs demonstrated more accuracy for logic test items with paranormal (psi) content than logic test items with mundane content.

"The single most important correlation was between exotic beliefs and the interaction term for the Rotton scale; the coefficient was unusually strong (0.54) and highly statistically significant ( $p < 0.001$ ) for females only. Because of the manner in which the interaction term was calculated, this correlation meant that females who

reported more exotic beliefs were also more accurate for valid items that contained paranormal content only" (p. 159).

In their Discussion, the authors write, "The significant positive correlations between exotic beliefs and the clusters of CPES items and extreme Wilson-Barber imagining items are expected associations according to Bear's concept of sensory-limbic hyperconnectionism [Temporal Lobe Epilepsy: A Syndrome of Sensory-Limbic Hyperconnectionism, *Cortex*, 15, pp. 357-384. It would predict that concepts (or word trains) that are unusual, strange or infrequent would be charged with emotional significance and personal value. Ideas that generate substantial imagery, such as time- travel, reincarnation and alien intelligence, would be particularly prone to this affective infusion from limbic sources.

Induction of such unique or intensified affective states, especially during childhood, would facilitate the development of more frequent or more extreme periods of dissociation in the adult. We have collected (unpublished) clinical evidence to suggest that the emergence of this pattern is found in the propensity for creative thinkers, including writers, poets, musicians, artists and scientists, to have had developmental histories that could have promoted temporal lobe lability without overt seizure activity; clusters of such "promoters" include mild physical abuse, febrile episodes, minor head injuries and likely hypoxic periods during extreme physical exertion (competitive athletics)" (pp. 161-162).

Another conclusion of the study is that males and females do not differ in their accuracy in solving syllogisms, but "the neurocognitive processes, as inferred from inventories of temporal lobe signs or childhood imaginings, by which the two sexes arrive at solutions may be quite different" (p. 162).

Richards, D. G. (1991). A study of the correlations between subjective psychic experiences and dissociative experiences. *Dissociation*, 19, 83-91.

Subjective psychic experiences, such as telepathy, clairvoyance, and out-of- body experiences, are often reported in conjunction with dissociative experiences. This study examined the relationship between the Dissociative Experiences Scale and a variety of psychic experiences in a nonclinical population with a high level of psychic experiences. The DES correlated moderately (.3 to .4) with most but not all of the experiences. The mean DES score was 17.2 (SD = 12.5), substantially above adult norms. Although psychic experiences are correlated with dissociation, they are not necessarily associated with pathology.

Adityanjee (1990). 'Multiple personality disorder in India': Reply. *American Journal of Psychiatry*, 147 (9), 1260-1261.

Replies to comments by J. Downs et al (see PA, Vol 78:4589) concerning the article on multiple personality and possession syndrome in India by Adityanjee et al (see PA, Vol 77:12344). Both syndromes reflect parallel dissociative disorder with similar etiologies. The present diagnostic classification for multiple identity phenomena is in need of revision.

Council, James R.; Huff, Kenneth D. (1990). Hypnosis, fantasy activity, and reports of paranormal experiences in high, medium and low fantasizers. British Journal of Experimental and Clinical Hypnosis, 7 (3), 9-15.

The personality construct "fantasy-proneness" (Wilson and Barber, 1983a) has important implications for theories of hypnosis, imagination, and paranormal phenomena. The present study compared characteristics of persons who received high, medium or low scores on a self-report measure of fantasy-proneness. Results revealed that the three groups differed significantly on measures of absorption, daydreaming styles, and reports of paranormal experiences. However, although high fantasizers were significantly more hypnotizable than low fantasizers, they did not differ from the middle group. These results are used to further characterize fantasy-prone persons, and implications of extremely low fantasy-proneness are discussed.

Hughes, Dureen J.; Melville, Norbert T. (1990). Changes in brainwave activity during trance channeling: A pilot study. Journal of Transpersonal Psychology, 22, 175-189.

Authors studied 10 people known trance channels--all had been channeling for more than one year. Used an anthropological field method. Electrode was placed only on left occipital (O1) area, referenced to left ear. Calculated difference between each S's pre- trance and trance EEG beta percentages, for alpha and theta percentages also.

Basically, the pre-trance versus trance sums of differences scores were greater than the post-trance versus trance sums of different scores for each of the three frequency bands--indicating a residual of the trance state. There were large, statistically significant increases in amount and percentage of beta, alpha and theta brainwave activity, and some suggestion of a pattern. The large amount of beta differentiates these Ss from what has been observed with meditators (increases in alpha and theta). Among the Subjects, large amounts of beta activity were recorded continuously throughout the trance period and were coupled with large amounts of high amplitude alpha and theta (relative to the pre- and post-trance states).

The authors compare these results to older hypnosis literature. They conclude that the trance channeling state may be a distinctive state characterized by a particular EEG profile that differs from that found in certain meditative states, hypnotic states, various pathological states, or the waking states of the trance channel Subjects who participated in the study. Authors also liken the differences seen between trance and non-trance states of these Subjects to the differences seen for different alter personalities among people diagnosed with Multiple Personality Disorder.

**DISCUSSION.** The foregoing research suggests that the trance channeling state, as measured in the current study, is characterized by large, statistically significant increases in amount and percentage of beta, alpha and theta brainwave activity. There appear to be definite neurophysiological correlates to the trance channeling state, and furthermore there is some evidence that these correlates may be

patterned. This pattern might be provisionally compared to those associated with other altered states of consciousness.

**Richards, D. G. (1990).** Hypnotic susceptibility and subjective psychic experiences. Journal of Parapsychology, 54, 35-51. (Abstracted in American Journal of Clinical Hypnosis, 34, 145-146)

Some studies have shown a correlation between hypnotic susceptibility and self-reports of psychic experiences. This study used a population reporting a very high level of psychic experiences and correlated the Harvard Group Scale of Hypnotic Susceptibility with psychic experiences as measured by two scales. The mean Harvard score (6.31) was approximately the same as published norms, suggesting that the population was not unusual in terms of hypnotic susceptibility. Studies of people with large numbers of psychic experiences who have low hypnotic susceptibility may aid in understanding other factors that are involved.

**1989**

**Zamore, Neal; Barrett, Deirdre (1989).** Hypnotic susceptibility and dream characteristics. Psychiatry Journal of the University of Ottawa, 14 (4).

This study examined the relationship of hypnotic susceptibility to a variety of dream characteristics and types of dream content. A Dream Questionnaire was constructed synthesizing Gibson's dream inventory and Hilgard's theoretical conceptions of hypnosis. Several dream dimensions correlated significantly with hypnotizability as measured by the Harvard Group Scale of Hypnotic Susceptibility and the Field Inventory. For Ss as a whole, the strongest correlates were the frequency of dreams which they believed to be precognitive and out-of-body dreams. Ability to dream on a chosen topic also correlated significantly with hypnotic susceptibility for both

genders. For females only, there was a negative correlation of hypnotizability to flying dreams. Absorption correlated positively with dream recall, ability to dream on a chosen topic, reports of conflict resolution in dreams, creative ideas occurring in dreams, amount of color in dreams, pleasantness of dreams, bizarreness of dreams, flying dreams, and precognitive dreams.

Azuma, Nagato; Stevenson, Ian (1988). 'Psychic surgery' in the Philippines as a form of group hypnosis. American Journal of Clinical Hypnosis, 31, 61-67.

Psychic surgeons and their patients were observed in the Philippines during a variety of procedures of 'minor surgery.' In six cases, subcutaneous tissues (cysts and benign tumors) were removed. Histological examination confirmed the gross diagnoses and left no doubt that the skin had been penetrated. Although the psychic surgeons used no analgesics or anesthetics, the patients appeared to experience little or no pain and only slight bleeding. The authors believe that a supportive group 'atmosphere' enables the patients to enter a quasi-hypnotic state that reduces pain and facilitates healing

Council, James R.; Greyson, Bruce; Huff, Kenneth D. (1988, November). Reports of paranormal experiences as a function of imaginative and hypnotic ability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

Wilson and Barber (1983) have suggested that some excellent hypnotic subjects ("fantasy prone" persons) may be more likely to report paranormal experiences than the rest of the population. Council and Greyson (1985), studying a sample of subjects who had reported near-death experiences (NDEs), found a significant relationship between fantasy-proneness and NDEs, and a much stronger relationship between fantasy-proneness and reports of paranormal experiences in general. This paper presents new data from the study of NDE reporters and a replication and extension of those findings with a sample not selected for NDEs. These data indicate a strong association between fantasy-proneness and reports of paranormal experiences. Hypnotic susceptibility bears a weaker relationship with such reports that appears dependent upon variance shared with measures of fantasy-proneness. Other data from these studies suggests that both imaginative ability and reports of paranormal experiences may be related to a history of stressful or traumatic childhood experiences.

Tobacyk, Jerome; Milford, Gary; Springer, Thomas; Tobacyk, Zofia (1988). Paranormal beliefs and the Barnum effect. Journal of Personality Assessment, 52 (4), 737-739.

Examined in 128 college students the hypothesis that paranormal beliefs emphasizing divinatory procedures that produce personalized feedback are associated with greater susceptibility to the Barnum effect, which is acceptance of bogus personality feedback consisting of relatively trivial statements with a high

base rate. 76% of the Ss rated the accuracy of their personality descriptions favorably, showing a robust Barnum effect.

Flatt, Jennifer R. (1983). What makes therapy work? Thoughts provoked by a case study. Australian Journal of Clinical and Experimental Hypnosis, 11 (2), 63-72.

The case described is offered as illustrating the doubt common to introspective therapists: what did cure the patient? "Francesca's" presenting problem and the object of the short-term psychological intervention described here, was a fairly circumscribed set of fears related to enclosed spaces. The therapeutic approach adopted was primarily hypnobeavioural, with hypnotically-assisted systematic desensitization and "in vivo" exposure being the main components of the planned programme. However, at the client's suggestion, one hypnotic session with content planned by the therapist as age regression produced rather dramatic and unexpected results claimed by the patient to effect complete cure.

The therapist suggested that "her mind would take her back to a time that was important in understanding her fears and that she would be able to stay calm and

relaxed while this past event was revealed to her" (p. 69). She subsequently imagined being in a cave, peaceful and calm. "On being roused from hypnosis, Francesca eagerly described her cave image. She was enthusiastic about the significance of this experience, claiming that it was evidence that in a previous life she had died from being locked into a cave as some sort of punishment and that this experience made her fear of enclosed places rational and comprehensible to her" (p. 69).

Vasilev, L. (1965). Mysterious phenomena of the human psyche. New York: University Books. (Abstracted in American Journal of Clinical Hypnosis, 1965, 8:2, 146-147)

The review of this book by Leo Wollman (American Journal of Clinical Hypnosis, 1965, vol. 8, pp. 146-147) states, "Many interesting theories about hypnosis are aired in this book. The opinions Pavlov propounded many years ago, about cortical inhibition are assiduously asserted, yet some statements made bear investigation. The mere sight of the experimenter in B. N. Birman's experiments with dogs put the dog into a hypnotic state. The appearance in the room of other people, who had not participated in the experiments, had no sleep inducing effect. For the experimental animal, therefore, the experimenter himself had been transformed into a conditioned hypnogenous stimulus. Similarly, in group hypnotherapy, the entrance of the physician-hypnotist into the room often effects a hypnotic state in some of the subjects. The doctor has become the stimulus for the conditioned response, that of hypnotic trance state induction.

" An interesting and perhaps little known fact elicited from Chapter III (Hypnotism and Suggestion) is the high percentage (12%) of those replies to questionnaires during the First International Congress on Experimental Psychology held in Paris in 1899, which indicated that 3,000 respondents had hallucinations while in a normal state of health. The majority were visual; auditory and tactile hallucinations were less frequent" (pp. 146-147).

Vasilev, L. (1965). Mysterious phenomena of the human psyche. New York NY: University Books. (Reviewed by Leo Wollman in American Journal of Clinical Hypnosis, 1965, 8 (2), 146-147)

AJCH Abstract by Leo Wollman: Many interesting theories about hypnosis are aired in this book. The opinions Pavlov propounded many years ago, about cortical

inhibition are assiduously asserted, yet some statements made bear investigation. The mere sight of the experimenter in B.N. Birman's experiments with dogs put the dog into a hypnotic state. The appearance in the room of other people, who had not participated in the experiments, had no sleep-inducing effect. For the experimental animal, therefore, the experimenter himself had been transformed into a conditioned hypnogenous stimulus. Similarly, in group hypnotherapy, the entrance of the physician-hypnotist into the room often effects a hypnotic state in some of the subjects. The doctor has become the stimulus for the conditioned response, that of hypnotic trance state induction.

An interesting and perhaps little known fact elicited from Chapter III (Hypnotism and Suggestion) is the high percentage (12%) of those replies to questionnaires during the First International Congress on Experimental Psychology held in Paris in 1899, which indicated that 3,000 respondents had hallucinations while in a normal state of health. The majority were visual; auditory and tactile hallucinations were less frequent.

Dr. P. P. Podyapolsky, in 1905, wrote 'I tried unsuccessfully to induce in a peasant a reddening of the skin from a mock mustard plaster not only was there no reddening, there wasn't even any appropriate sensation of burning or smarting. I surmised that this simple man had probably never experienced a mustard plaster; therefore, his mind lacked the corresponding images and the ability to reproduce them with all their consequences... And so it turned out--he had never experienced a mustard plaster. It happened that he later had occasion to put a mustard plaster on his chest, and when I hypnotized him thereafter, suggestion quickly created not only the appropriate burning sensation but also reddening of the skin where the mock mustard plaster was applied.' This phenomenon is explained by the fact that the connection between the skin and cerebral cortex by means of neural conductors may, under certain circumstances, alter the activity of different organs. The alteration operates, apparently, in the category of conditioned-reflex formation.

This book is interesting reading and from a historic point of view is worth having in one's library

**1990**

McNally, Richard J. (1990). Psychological approaches to panic disorder: A review. Psychological Bulletin, 108 (3), 403-419.

Panic disorder has been the subject of considerable research and controversy. Though biological conceptualizations have been predominant, psychological theorists have recently advanced conditioning, personality, and cognitive hypotheses to explain the etiology of panic disorder. The purpose of this article is to provide an empirical and conceptual analysis of these psychological hypotheses. This review covers variants of the "fear-of-fear" construal of panic disorder (i.e., Pavlovian interoceptive conditioning, catastrophic misinterpretation of bodily sensations, anxiety sensitivity), research on predictability (i.e., expectancies) and controllability, and research on information-processing biases believed to underlie the phenomenology of panic. Suggestions for future research are made.

**1989**

Gardner, Beatrix T.; Gardner, Allen R. (1989). Beyond Pavlovian classical conditioning. Behavioral and Brain Sciences, 12, 143-144.

This is a commentary on the article by Turkkan (1989) entitled "Classical conditioning: The new hegemony" in Behavioral and Brain Sciences, 12, 121-179. (Pavlov's theory of hypnosis was based on a conditioning model, which is why this material may be relevant.)

"Traditionally, the mechanism of stimulus association proposed by Pavlov early in this century is invoked to account for conditioning that is independent of the positive and negative consequences of responding. ... Pavlov attributed this result to stimulus substitution (i.e., the subject responds to the Sa as if it were the S\*) and this has been the dominant view throughout this century" (p. 143).

'In Pavlov's classical procedure, only increases and decreases in the original consummatory or defensive response are counted as conditioned responses. ... Pavlov's classical procedure is only a special case of a much broader case of a phenomena" (p. 143).

"Key-pecking by pigeons and lever-pressing by rats are responses that were long held up as prototypes of arbitrary behaviors that could only be shaped by response-

contingent reinforcement. In the autoshaping procedure, however, these same responses have been easily conditioned to an arbitrarily selected stimulus (Sa) when the delivery of food was entirely independent of the response of the subjects. Not only that, but robust rates of responding have been maintained when food was withheld if the pigeons pecked the key or the rats pressed the lever, that is, when the contingency was negative (Williams & Williams 1969)" (p. 143).

"Turkkan follows a grand tradition when she discusses the similarities between associative conditioning and fundamental aspects of human verbal behavior. Yet an essential characteristic of verbal behavior is the difference between the response to an object and the response to a word for the object. The response to the spoken or written word 'apple' must be distinctly different from the response to an actual apple. Whatever we learn when we acquire vocabulary, it cannot be the simple stimulus-stimulus connection advocated in Pavlov's classical theory.

Even the popular Rescorla (1967) design for separating stimulus-stimulus contiguity from stimulus-stimulus contingency only succeeds in comparing two sources of stimulus-stimulus association. Meanwhile, the recently discovered autoshaping experiment does offer us a laboratory model in which associative conditioning can result in a response to the Sa that is different from the consummatory response to the S\*" (p. 144).

"The theory of stimulus-stimulus association that Pavlov built upon the results of his special procedure is inadequate to deal with the wide range of phenomena of associative conditioning that have been discovered since his time.

"We wholeheartedly agree with Turkkan regarding the enormous theoretical and practical significance of the new discoveries but we are convinced that the terms 'Pavlovian conditioning' and 'classical conditioning' serve us best in their historical usage. ... The new discoveries seem to us to show that a wide range of significant phenomena fall outside the boundary conditions of traditional Pavlovian and Skinnerian theories" (p. 144).

Griffiths, M. D.; Gillett, C. A.; Davies, P. (1989). Hypnotic suppression of conditioned electrodermal responses. Perceptual and Motor Skills, 69, 186.

With 5 subjects who had previously been aversively conditioned to a stimulus, during hypnosis previously acquired electrodermal responses were found to be significantly lower than in 12 control Ss. Thus previously conditioned electrodermal responses were suppressed. This contradicts findings of Edmonston (1968) who found that neutral hypnosis does not influence conditioned electrodermal responses and the validity of Pavlov's (1927) conditioning (inhibition) theory of hypnosis.

1982

Chertok, Leon (1982). The unconscious and hypnosis. International Journal of Clinical and Experimental Hypnosis, 30 (2), 95-107.

This paper reviews Soviet approaches to the unconscious and to hypnotic phenomena, before examining psychoanalytic theories of hypnosis which are

generally based on transference. The author believes the existing theories are inadequate, arguing that there is a psychophysiological dimension to hypnosis; but what unconscious processes does this conceal? Psychoanalysis opened one road to the unconscious, but affect, nonverbal communication, and psychophysiological process are still uncharted territories towards which hypnosis may yet prove to be another royal road.

The author concludes, "hypnosis and the unconscious ... are closely linked. Historically, experiments on posthypnotic suggestion were in fact the starting point for the discovery of the unconscious. Posthypnotic suggestion is in effect one of the most irrefutable proofs that psychical contents can influence behavior, albeit eluding the subject's consciousness.

"In this paper, the present author provides a description of Soviet researchers' conceptions of the unconscious, and of the point of view from which they approach hypnotic phenomena. Psychoanalytic theories of hypnosis are then presented, which are essentially based on transference. It is shown why this notion seems to the present author powerless to account for the specific nature of the hypnotic relationship. There is, in effect, a psychophysiological dimension to hypnosis. It lies at the crossroads between the instrumental and the relational dimension. But nothing is known about what unconscious processes hide at the psychophysiological level. Psychoanalysis has brought to light the laws governing the functioning of unconscious representations. But the realm of the affect, the nonverbal communication, and bodily processes still remain beyond our knowledge. This is a hidden side of the unconscious, in relation to which hypnosis may serve as another 'royal road'" (pp. 104-105).

1970

Kratochvil, Stanislav (1970). Sleep hypnosis and waking hypnosis. International Journal of Clinical and Experimental Hypnosis, 18, 25-40.

Subjected 6 highly susceptible female students to a short-term training procedure to induce 2 different types of hypnosis: (a) a sleep hypnosis, and (b) an active waking hypnosis. Ss behavior in both types, during the carrying out of 11 standard suggestions, was rated by 2 independent Os. The behavior in both artificially induced types of hypnosis differed significantly at the 1% level in the expected direction. The failure to obtain more dramatic results is attributed to the shortness of training, to the implicit demands concerning activity, or to Ss' personality traits, which may lower the intrapersonal variability. The relevance of the results for the Pavlovian theory of hypnosis is discussed: They do not support the hypothesis that behavioral characteristics which resemble sleep are intrinsic phenomena of the

hypnotic state. (Spanish & German summaries) (34 ref.) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

1968

Sternbach, Richard A. (1968). Pain: A psychophysiological analysis. New York: Academic Press

Anxiety potentiates pain, no matter what the source of the anxiety ("meaning of the wound, intensity of the stimulus, a personality characteristic or introduced into the situation" (p. 25). "Local muscles show a marked increase in their electrical potentials following localized pain produced by pressure (Simons, Day, Goodell, and Wolff, 1943), and this striated muscle can potentiate and prolong the responses to the original stimulus (Hardy, Wolff, and Goodell, 1952)" (p. 51). Shor (1962) investigated the physiological response to pain during hypnotic analgesia and used procedures to minimize anxiety in both waking and hypnotized conditions. The 'pure pain' physiological response involved a slight increase in heart rate, depth of respiration, and palmar sweating, "little more than an orienting reflex" (p. 54).

Because people vary in the degree to which their pattern of response to pain is stereotyped, it is difficult to detect a pattern specific to pain. However, frequently there is inhibition of motility of the gastrointestinal tract and blocking of or more rapid contractions; increased oxygen consumption with hyperventilation; increase in muscle tension and hypermotility; and variable cardiovascular responses--sometimes elevated blood pressure, sometimes increased pulse, stroke volume, or peripheral vasoconstriction. The physiological changes appear to be preparing the person to take action.

Personality characteristics have been investigated with respect to pain reactivity and tolerance. Mueller (1962) predicted response to spinothalamic tractectomy for 14 patients with intractable pain due to spinal cord injuries with 85% accuracy using the Rorschach. Field dependence on the rod and frame test is associated with parasympathetic reactivity to pain, and less reaction to pain. "Those who can tolerate pain (intense stimulation) best can tolerate sensory deprivation (minimal stimulation) least, and vice versa" (p. 62). Also, the nondominant hand is more sensitive than the dominant hand.

Sternbach distinguishes pain tolerance from willingness to complain about pain. For example, cultural factors (ethnicity) affect not only pain toleration but also physiological response. Voluntary participation in a pain experience can in fact reduce the discomfort of the pain stimulus. "Pain tolerance may be in part a function of their ability to reduce anxiety concerned with the duration of time (a) a noxious stimulus will last, or (b) before a noxious stimulus will be experienced" (p. 67).

(minimal stimulation) least, and vice versa" (p. 62). Also, the nondominant hand is more sensitive than the dominant hand.

Sternbach distinguishes pain tolerance from willingness to complain about pain. For example, cultural factors (ethnicity) affect not only pain toleration but also physiological response. Voluntary participation in a pain experience can in fact reduce the discomfort of the pain stimulus. "Pain tolerance may be in part a

function of their ability to reduce anxiety concerned with the duration of time (a) a noxious stimulus will last, or (b) before a noxious stimulus will be experienced" (p. 67).

Phantom pain is an example of centrally occurring pain. It occurs in only a few patients who have a phantom limb, from 2-10% depending on how they are assessed. Scars and neuromas at the stump may reduce thresholds to peripheral stimulation or may themselves act as pain stimuli. Surgery on the neuromas and scar tissues seldom reduces the phantom limb pain. Most investigators assume it is a 'central' phenomenon of some sort, 'superadded sensations' which may be of psychogenic origin (Henderson & Smyth, 1948) or a 'central state of hyperexcitability' (Cronholm, 1951). Affect seems to be involved. The affects, and the individual's style of coping with them, seem to be the equivalents of the 'central' phenomena which result in pain. Two affects in particular seem to be associated with pain: anger, intropunitively expressed; and grief, the phantom pain representing both the loss and the wish to deny it. Both of these are likely to be associated with depression.

A psychological (rather than neurological) explanation for phantom limb pain is supported by the success demonstrated by three interventions: psychotherapy, electroshock therapy, and sensorimotor task concentration. The latter approach, reported by Morganstern (1984) requires patients to concentrate on sensorimotor tasks while ignoring distracting stimuli, for 2 hours/day. Morganstern attributed their improvement to a combination of concentration and distraction so that central sensory processes gradually are reorganized and the patients become habituated to stimulation of the stump. Sternbach notes that these factors also characterize hypnosis and hypnotic analgesia. He proposes that the Morganstern results should inform our neurological explanation of phantom pain.

Sternbach goes on to discuss hypnosis, particularly as it offers information that could inform us about pain. He notes that hypnotic inductions and the hypnotic state are characterized by "immobility and sensory canalization, a reliance on the hypnotist for information and direction, and an altered state of awareness in which the environs are perceived as suggested by the hypnotist" (pp. 136-137). The Kubie and Margolin (1944) description of a concentrated focus of excitation in the brain with surrounding areas of inhibition is like the description of hypnosis presented by Ivan Pavlov. During this process, the hypnotized subject becomes dependent on the hypnotist for contact with the outside world, but this emotional/motivational response is not central to the induction. "What is essential is the restriction of sensory and motor activity which, in a variety of natural or experimental settings, with or without another person present, will invariably produce hypnoidal states and hypnagogic reverie" (p. 134).

The profound alterations in perception that are observed in hypnosis are relevant to the understanding of pain because pain "involves perception of certain tissue changes." Sternbach notes that the experimental problem of ascertaining whether a subject is faking hypnotic phenomena is similar to the experimental difficulties inherent in evaluating the (internal) experiencing of pain. He suggests that the Orne (1959) test for toleration of logical inconsistencies is an independent means of evaluating for genuine hypnotic response. Other possible indices are less

spontaneous behavior (Gill & Brenman, 1959) or alterations in subjective awareness (Ludwig & Levine, 1965). On the Ludwig & Levine questionnaire, subjects reported changes in thinking, time sense, feelings of loss of control, body image changes, changes in sensations, etc.

It has been observed that physiological response depends on presence or absence of a shock, but behavioral and verbal response depends on suggested or not suggested analgesia (Sutcliffe, 1961).

Levine, 1965). On the Ludwig & Levine questionnaire, subjects reported changes in thinking, time sense, feelings of loss of control, body image changes, changes in sensations, etc.

It has been observed that physiological response depends on presence or absence of a shock, but behavioral and verbal response depends on suggested or not suggested analgesia (Sutcliffe, 1961).

In Sternbach's summary of the section on hypnosis in this book, he states, "Hypnotic analgesia adds to the above [hypnotic induction] the hypnotist's suggestion of pain relief, or the inability to perceive pain. Experimental and clinical data suggest that in most but not all instances, pain responses are then greatly attenuated. The data further suggest the reasonable inference that such hypnotic analgesia is effective either because attention is focused elsewhere, or because anxiety (concern about the stimulus effects) is very low. ...

"It seems to us reasonable to make a further inference from these data, concerning the relative roles of attention focusing and anxiety-reduction. It is our impression, from the studies cited above, that the focusing of attention is not in itself essential to the elimination of pain. It is necessary for the induction of hypnosis, and it is a useful (but not the only) means for a subject or patient to gain control over anxiety concerning pain stimuli. But the data strongly suggest that in hypnotic analgesia, as well as in other conditions, it is the absence of anxiety about the stimulation which is the single necessary and sufficient condition for perceiving the stimulus as a nonpainful sensation. This is suggested by the fact that subjects with hypnotic analgesia are able to attend to (focus attention on) the stimulus, and even describe it accurately as a sensation, and yet not produce pain responses. This is true also of subjects in control conditions without hypnosis. On the other hand, anxious subjects ( or patients), as we have seen elsewhere (Chapter V), typically produce marked pain responses to appropriate stimulation. Thus it seems reasonable to hypothesize that 'focusing attention' serves primarily to reduce a person's anxiety about his current situation, thus making possible either (1) the regression and altered state of consciousness of a hypnotic trance, or (2) the perception of a noxious stimulus as a nonpainful sensation" (pp. 140-141).

1959

Platonov, K. I. (1959). The word as a physiological and therapeutic factor: The theory and practice of psychotherapy according to I. P. Pavlov. ( 2nd). Moscow: Foreign Languages Publishing House.

On pp. 75-76 the author discusses conditioning in hypnosis. Most of the theoretical material is in the first part of the book; the rest consists of case studies. He presents

the position that the activity of the cortex and subcortex are different during states of waking and suggested sleep.

**Note:** Much of the Russian research done during "suggested sleep" involves subjects who are hypnotized for a long period of time--sometimes hours. Routinely, in treatment, they would give corrective suggestions and then tell the person to "sleep" and would leave them in the "sleep" for an hour or longer.

"Thus, it appears from the foregoing that the basic peculiarities of the activity of the cerebral cortex manifesting themselves in the state of suggested sleep are as follows: 1. In addition to the division of the cerebral hemispheres into sections of sleep and wakefulness typical of the hypnotic sleep of an animal, there is also a functional dissociation of the two signal systems and within the second signal system. 2

The activity of the second signal system under these conditions is not only confined to the narrow framework of the rapport zone, but is also frequently of a passive nature being directly dependent on the verbal influences of the hypnotist. Outside these influences there is no (or hardly any) activity. 3. A considerable increase in the coupling function with respect to the stimuli of the second signal system is noted at the same time in the rapport zone. This especially favours the formation of new cortical dynamic structures under the verbal influences of the hypnotist, these structures representing the physiological basis for effectuating the suggested actions and states.

"The foregoing peculiarities manifest themselves in the fact that the entire external second signal activity of the subject is reduced only to direct answers to the questions of the hypnotist with no independent reactions to any influences, including verbal, coming from other people (so-called isolated rapport). This is understandable, since the activity of the second signal system lying outside the rapport zone is inhibited" (pp. 73-74).

"As to the problem of the peculiarities of the conditioned reflex activity during suggested sleep, it will be noted that this problem has not been very extensively studied as yet. Nevertheless, the data of various authors are of indubitable interest, since they have revealed a number of specific peculiarities in the state of the higher nervous activity under these conditions.

"According to these data the conditioned reflex activity in suggested sleep undergoes certain changes. Thus, S. Levin observed in his early studies (1931) that in children under conditions of suggested sleep the motor and secretory conditioned reflexes elaborated earlier in the waking state grew very much weaker and that there was a dissociation both between the motor and secretory conditioned reflexes and between the unconditioned reflexes of salivation and mastication; he also observed the transitional (phasic) states--paradoxical, ultraparadoxical and inhibitory phases, all the way to the onset of complete sleep" (pp. 74-75).

Platonov indicates that conditioned reflexes may disappear during suggested sleep (Povorinsky & Traugott, 1936). Arousal from suggested sleep results in gradual restoration of the reflexes, with speech reactions inhibited first and restored last. Pen & Jigarov (1936) also showed that there is a weakening of conditioned reflexes, with increased latency, in suggested sleep. These authors showed that it is

**impossible to form new conditioned reflexes in deep states of suggested sleep, and the conditioning is difficult in lighter states.**

**"Y. Povorinsky's data (1937) indicate that the conditioned reflexes elaborated in the waking state have a longer latent period during suggested sleep and in some subjects they are completely absent. Under these circumstances, the reactions to the verbal influences of the hypnotist are retained even during the deepest suggested sleep. The more complex and ontogenetically later conditioned bonds of the speech-motor analyzer are inhibited first as the subject lapses into a state of suggested sleep and are disinhibited the last as the subject awakens from this state" (p. 75).**

**"B. Pavlov and Y. Povorinsky observe (1953) that the conditioned bonds reinforced by the words of the hypnotist are formed during suggested sleep faster than in the waking state. In this case, during the somnambulistic phase of suggested sleep verbal reinforcements, as a rule, provoke a stronger and longer reaction with a shorter latent period than a direct first signal stimulus" (p. 76). The conditioning that occurs during suggested sleep does not manifest during waking periods unless suggestions are given during the sleep to react after wakening. The author takes this to be evidence that conditioned reflex activity can be modified by verbal suggestions.**

During the somnambulistic stage of suggested sleep, subjects are less adept at performing addition. This indicates that inhibition has spread to the second signal system. However, inhibition of different sensory systems seems to vary from person to person. Krasnogorsky (1951) reported one subject did not react to light, but hearing seemed to be more sensitive than in the waking state.

"All of the above testifies to the considerable changes in the character of cortical activity regularly occurring during suggested sleep and determining, on the whole, the specific nature of higher nervous activity, the systematic study of which should be the object of further research" (p. 77).

## **Pediatrics**

### **2002**

Anbar, Ron (2002, Dec 3). Hypnosis in pediatrics: applications at a pediatric pulmonary center.. BMC Pediatrics, 2 (1), 11-18.

This report describes the utility of hypnosis for patients who presented to a Pediatric Pulmonary Center over a 30 month period.

**METHODS:** Hypnotherapy was offered to 303 patients from May 1, 1998 - October 31, 2000. Patients offered hypnotherapy included those thought to have pulmonary symptoms due to psychological issues, discomfort due to medications, or fear of procedures. Improvement in symptoms following hypnosis was observed by the pulmonologist for most patients with habit cough and conversion reaction. Improvement of other conditions for which hypnosis was used was gauged based on patients'" subjective evaluations.

**RESULTS:** Hypnotherapy was associated with improvement in 80% of patients with persistent asthma, chest pain/pressure, habit cough, hyperventilation, shortness of breath, sighing, and vocal cord dysfunction. When improvement was reported, in some cases symptoms resolved immediately after hypnotherapy was first employed. For the others improvement was achieved after hypnosis was used for a few weeks. No patients'" symptoms worsened and no new symptoms emerged following hypnotherapy.

**CONCLUSIONS:** Patients described in this report were unlikely to have achieved rapid improvement in their symptoms without the use of hypnotherapy. Therefore, hypnotherapy can be an important complementary therapy for patients in a pediatric practice.

Anbar, R. D. (2001). Self-hypnosis for management of chronic dyspnea in pediatric patients. Pediatrics, 107 (2), E21.

Instruction in self-hypnosis was offered to 17 children and adolescents with chronic dyspnea, which had not resolved despite medical therapy, and who were documented to have normal lung function at rest. ... Chronic dyspnea was defined as recurrent difficulty breathing or shortness of breath at rest or with exertion, which

had existed for at least 1 month in patients who had not suffered within a month from an acute pulmonary illness. ... Additionally, imagery relating to dyspnea was developed by coaching patients to change their imagined lung appearance from a dyspneic to a healthy state. ... The mean duration of their dyspnea before learning self-hypnosis was 2 years (range: 1 month to 5 years). ... A patient with a history of psychogenic cough declined to learn self-hypnosis. ... Thirteen of the 16 patients reported their dyspnea and any associated symptoms had resolved within 1 month of their final hypnosis instruction session. ... There was no recurrence of dyspnea, associated symptoms, or onset of new symptoms in patients in whom the dyspnea resolved."

**Liossi, Christina; Hatira, Popi (1999). Clinical hypnosis versus cognitive behavioural training for pain management with pediatric patients undergoing bone marrow aspirations. International Journal of Clinical and Experimental Hypnosis, 47 (2), 104-116.**

**Journal of Clinical and Experimental Hypnosis, 47 (2), 104-116.**

A randomized controlled trial was conducted to compare the efficacy of clinical hypnosis versus cognitive behavioral (CB) coping skills training in alleviating the pain and distress of 30 pediatric cancer patients (age 5 to 15 years) undergoing bone marrow aspirations. Patients were randomized to one of three groups: hypnosis, a package of CB coping skills, and no intervention. Patients who received either hypnosis or CB reported less pain and pain-related anxiety than did control patients and less pain and anxiety than at their own baseline. Hypnosis and CB were similarly effective in the relief of pain. Results also indicated that children reported more anxiety and exhibited more behavioral distress in the CB group than in the hypnosis group. It is concluded that hypnosis and CB coping skills are effective in preparing pediatric oncology patients for bone marrow aspiration.

**Felt, Barbara T.; Hall, Howard; Olness, Karen; Schmidt, Wendy; Kohen, Daniel; Berman, Brad D.; Broffman, Gregg; Coury, Daniel; French, Gina; Dattner, Alan; Young, Martin H. (1998). Wart regression in children: Comparison of relaxation-imagery to topical treatment and equal time interventions. American Journal of Clinical Hypnosis, 41 (2), 130-137**

Relaxation mental imagery (RMI), standard topical treatment (Top Tx), and equal time-control interventions were compared on measures of wart regression in sixty one, 6-12-year-old children. Subjects chose one common ("index") wart and attended 4 visits over 8 weeks. At each visit, total and "index" extremity wart number were counted and a photo was taken of the "index wart" for later measurement. On average, total wart number decreased by 10% and "index wart" area decreased by 20% with no significant group differences during the first eight weeks. Phone follow [sic] was conducted 6 to 18 months from study entry. At phone follow up, there was a trend for more RMI and Top Tx subjects to report complete

wart resolution ( $p = 0.07$ ) with a majority of RMI children reporting use of RMI or no specific treatment pursuit. We conclude there was no significant short-term benefit for RMI in this randomized controlled trial of wart regression in children. However, longer term benefits for RMI and Top Tx groups are suggested.

Hall, Howard; Papas, Angela; Tosi, Michael; Olness, Karen N. (1996). Directional changes in neutrophil adherence following passive resting versus active imagery. International Journal of Neuroscience, 85, 185-194.

This study was designed to determine whether increases or decreases in neutrophil adherence could be achieved following a self-regulation (relaxation/imagery) intervention. Fifteen subjects were randomly assigned to one of three conditions. Two experimental groups employed imagery focused on either increasing or decreasing neutrophil adherence. Subjects had two weeks of self-regulation practice (4 total training sessions) prior to blood drawings. A third group of control subjects had the same number of resting sessions without imagery training. All subjects had blood samples collected before and after either 30 minutes of self-regulation or resting practice for two sessions. Pulse and peripheral finger temperature measures were taken before and after the blood samples. Both experimental groups demonstrated decreases in neutrophil adherence, and the control group showed a tendency toward increases in this measure. The psychophysiologic data for the control group was suggestive of a relaxation response. The experimental group that attempted to increase neutrophil adherence demonstrated psychophysiologic responses that were contrary to relaxation. We concluded that an active cognitive exercise or process is associated with decreases in neutrophil adherence irrespective of the intent of the exercise. In contrast, relaxation without an active imagery exercise was associated with increases in neutrophil adherence. The results of this study are discussed in terms of behavioral engineering of directional immune changes.

-herence irrespective of the intent of the exercise. In contrast, relaxation without an active imagery exercise was associated with increases in neutrophil adherence. The results of this study are discussed in terms of behavioral engineering of directional immune changes

Sugarman, L. I. (1996). Hypnosis in a primary care practice: Developing skills for the 'new morbidities'.

Training in hypnotherapy provides the primary care practitioner with skills needed to address increasingly common, significant sources of childhood morbidity: stressful life events, psychophysiological symptoms, chronic disease, and behavioral problems. Although there are many reports on the utility of hypnosis in these areas, there are few on its use within primary care. This paper describes the integration of hypnotherapeutic methods into the continuum of pediatric encounters in a solo general pediatric practice. Specific techniques for approaching and examining young patients and their problems are illustrated. Preliminary data are presented

from a prospective chart review of those children and adolescents within the practice who use hypnosis. Guidelines for the application of hypnosis in pediatric primary care are summarized. Emphasis is placed on the necessity and opportunity for research on the efficacy of these methods in the primary care setting.

Culbert, Timothy P.; Reany, Judson B.; Kohen, Daniel P. (1994). Cyberphysiologic strategies for children: The clinical hypnosis/biofeedback interface. International Journal of Clinical and Experimental Hypnosis, 42 (2), 97-117.

This article presents an in-depth discussion of the integrated use of self-hypnosis and biofeedback in the treatment of pediatric biobehavioral disorders. The rationale for integrating these techniques and their similarities and differences are discussed. The concepts of children's imaginative abilities, mastery, and self-regulation are examined as they pertain to these therapeutic strategies. Three case studies are presented that illustrate the integrated use of self-hypnosis and biofeedback in the treatment of children with psychophysiological disorders. The authors speculate on the specific aspects of these self-regulation or "cyberphysiologic" techniques that appear particularly relevant to positive therapeutic outcomes.

1992

Zeltzer, Lonnie K. (1992). Hypnosis with children in pain. [Paper] Clinical Hypnosis Seminar, UCLA Department of Psychiatry & Biobehavioral Sciences (J. Holroyd, Instructor).

We use an active approach with children, e.g. "Wouldn't it be fun to ...? Do you have a bike? What's it like? What do the handlebars feel like?" We use lots of sensory images, and go back and forth between fantasy and the environment. Children often keep their eyes open because they have to check out the strange environment of the hospital.

Preparation for the medical or surgical procedure: 1. Cognitive (a rehearsal of what will happen, what to expect). 2. Sensory (rehearsing what it will feel like).

For someone who has had bad experiences one might say something like, "Wouldn't it be interesting if it could be different this time? I wonder how it might be different?"

If the child is anxious, the less controls they have, so we do things to help them reorganize. The one thing they can do is breathe. We might whisper something like, "It would be nice to take a nice deep breath" The child may continue screaming, but has to take a breath sooner or later, to which you might say, "Oh, that felt so good." And it continues along that line. So now the child has some control.

**PAIN**

Hypnoanalgesia in anesthesia. In hypnosis, child has readiness to call upon past anesthetic experiences. (We had one boy who was a skier and could anesthetize his hand by imagining that he put it into snow, but snow may produce vasoconstriction, so a thick warm leather glove was used with that child so the veins didn't close down

and prevent needle insertion.) We may use imagery of Disneyland here in Southern California, to get attention off the noxious stimulus.

How many sessions are needed? It depends on whether they have become frightened and phobic due to bad experiences; then they need desensitization. Otherwise, if they had no previous bad experience, 1/2 hour is sufficient. For children with chronic pain, the work takes longer. For younger children, you help the parents and child to be a team.

Screaming does not necessarily mean the child is in severe pain, because a child may scream to focus attention.

The goal is to assist the patient to cope with anxiety and pain, not to make it go away completely.

How young can a child be, to use hypnosis? Josie Hilgard dates fantasy to 3-4 years. Younger children, you may use props (e.g. a red block becomes a fire engine, even with their eyes open). Lee Orick Cutner uses stories for 2-5 year olds (with the parent telling the story), like a transitional object. Capturing the child's curiosity is critical, as a competing stimulus for the needle which is a potent stimulus.

"Wouldn't it be fun to take a hose and fill this room and make it into a swimming pool? Capture something dramatic in fantasy at the moment of greatest pain (e.g. "and here comes the big whale!"

Hilgard's dissociation theory is relevant: part of the patient is in Disneyland. There are 3 components of pain: 1. sensory 2. emotional (suffering) 3. motivational (drive to get rid of it)

With children, they don't need to relax, e.g. active imagery is useful.

For dying children who are withdrawn and have chronic pain, story telling is used to work through their worries, and fears that child might not have vocabulary for. As an example, one can use fantasy about taking a trip, whales (fear of being alone), or building a house (sense of accomplishment).

Elliott Blass found that stroking rats decreased their pain (and this was not mediated by opioid pathways); sucrose on tongue is mediated by opioid pathways (Naloxone) and also diminishes pain. (Cocaine babies settle down when you stroke them.) In the animal research if you use both together, the stroking wipes out the effect of sucrose.

Susan Jay in research on children published in the Journal of Consulting and Clinical Psychology article, presented a cafeteria of self-control techniques to the children. When there was pre-treatment with Valium, the patients did worse during the procedure, vs no pre-treatment with Valium. It may be because the Valium medicated patients didn't have clarity of attention during learning. Therefore, short-term gain may lead to long-term losses.

Can increase lockout period of patient- controlled analgesia (PCA). PCA can be used with patients as young as 4-5. You can make an agreement with the patient not to use PCA for a certain period, during which you teach the psychological control technique such as hypnosis.

There is no reason to use intramuscular injections with children; no need to cause pain to decrease pain.

There is no reason to use intramuscular injections with children; no need to cause pain to decrease pain.

**1991**

**Zeltzer, Lonnie K.; Dolgin, M. J.; LeBaron, Samuel; LeBaron, C. (1991). A randomized, controlled study of behavioral intervention for chemotherapy distress in children with cancer. Pediatrics, 88, 34-42.**

**Subjects were randomly assigned to hypnosis, nonhypnotic distraction/relaxation, or attention placebo control. children in the hypnosis group reported the greatest reduction in both anticipatory and postchemotherapy symptoms. Distraction/relaxation kept symptoms from getting worse, but they did not get better, and the control children's symptoms became much worse.**

**1988**

**Kuttner, Leora (1988). Favorite stories: A hypnotic pain-reduction technique for children in acute pain. American Journal of Clinical Hypnosis, 30, 289-295.**

**For young children (aged 3 to 6-11) with leukemia, a hypnotic trance consisting of a child's favorite story was found to be statistically more effective than behavioral distraction and standard medical practice in alleviating distress, pain, and anxiety during painful bone marrow aspirations. Measured by a behavioral checklist and judgment ratings by physician, parent, nurse, and observers, the favorite-story hypnotic technique had immediate therapeutic impact on these young patients, and the reduction in distress, pain, and anxiety was sustained on subsequent medical procedures. Self-report measures, however, were nonsignificant.**

**1987**

**Jay, Susan M.; Elliott, Charles H.; Katz, Ernest; Siegel, Stuart E. (1987). Cognitive-behavioral and pharmacologic interventions for children's' distress during painful medical procedures. Journal of Consulting and Clinical Psychology, 55, 860-865.**

**This study evaluated the efficacy of a cognitive-behavioral intervention package and a low-risk pharmacologic intervention (oral Valium), as compared with a minimal treatment-attention control condition, in reducing children's distress during bone marrow aspirations. The subjects were 56 leukemia patients who ranged in age from 3 years to 13 years. The three intervention conditions were delivered in a randomized sequence within a repeated-measures counterbalanced design. Dependent outcome measures included observed behavioral distress scores, self-reported pain scores, pulse rate, and blood pressure scores. Repeated-measures analyses of variance indicated that children in the cognitive-behavior therapy condition had significantly lower behavioral distress, lower pain ratings, and lower pulse rates than when they were in the attention- control condition. When children were in the Valium condition, they exhibited no significant differences from the attention control condition except that they had lower diastolic blood pressure scores.**

Lonnie Zelzer, M.D., in a UCLA Hypnosis Seminar lecture in 1992, stated that in pre-treatment with Valium the patients did worse during the procedure, vs no pretreatment with Valium, because the medicated patients didn't have clarity of attention during the cognitive behavioral learning

1986

Kohen, D. P. (1986). Applications of relaxation/mental imagery (self-hypnosis) in pediatric emergencies. International Journal of Clinical and Experimental Hypnosis, 34 (4), 283-294.

Problems for which children come to Emergency Rooms are anxiety-producing for children and parents, whether or not these problems are perceived as "true" emergencies by health care professionals. Fear and pain are important factors in the response to such situations. Self-hypnosis (relaxation/mental imagery) is a useful adjunct for rapid reduction of anxiety and discomfort in pediatric emergency situations; it can serve to diminish fear, improve self-control, and alter the perception of discomfort. Hypnosis can also enhance development of a sense of mastery in the injured or ill child. 6 case examples are described which illustrate the variety of specific clinical applications and hypnotherapeutic approaches.

1984

Kohen, D.; Olness, K.; Colwell, S.; Heimel, A. (1984). The use of relaxation-mental imagery (self-hypnosis) in the management of 505 pediatric behavioral encounters. Journal of Developmental and Behavioral Pediatrics, 5, 21-25.

This report assessed outcomes of hypnotherapeutic interventions for 505 children and adolescents seen by four pediatricians over a period of one year and followed from four months to two years. Presenting problems included enuresis, acute pain, chronic pain, asthma, habit disorders, obesity, encopresis, and anxiety. Using strict criteria for determination of problem resolution (e.g., all beds dry) and recognizing that some conditions were intrinsically chronic, the authors found that 51% of these children and adolescents achieved complete resolution of the presenting problem; an additional 32% achieved significant improvement, 9% showed initial or some improvement; and 7% demonstrated no apparent change or improvement. Children as young as three years of age effectively applied self-hypnosis techniques. In general, facility in self-hypnosis increased with age. There was an inverse correlation (p less than 0.001) between clinical success and number of visits, suggesting that prediction of responsivity is possible after four visits or less.

Discusses the treatment of 505 pediatric patients with a variety of problems(enuresis, pain, obesity, anxiety reactions, habit problems, encopresis, headache, fear of pelvic examinations).

Gardner, G. Gail; Lubner, Alison (1982-83). Hypnotherapy for children with cancer: Some current issues. American Journal of Clinical Hypnosis, 25 (2-3), 135-142

The authors review some of the problems that now face clinicians and researchers working in the field of hypnotherapy for pediatric cancer patients. These include (1) understanding and dealing with resistance and refusal, (2) developing preventive hypnotherapeutic strategies for children who will survive cancer, and (3) carrying out research that

children who will survive cancer, and (3) carrying out research that clarifies the value of hypnotherapy with childhood cancer patients and elucidates when and how specific approaches can best be utilized.

1982

Hall, Marian D. (1982-83). Using relaxation imagery with children with malignancies: A developmental perspective. American Journal of Clinical Hypnosis, 25 (2-3), 143-149.

Developmental theory has been the foundation for this program of relaxation-imagery therapy with its goal of increasing the efficacy of immune mechanisms, thus increasing the survival rate of children with malignancies and/or improving the comfort and quality of their lives. Three basic constructs--the impact of social stress, the positive development of attachment and the negative effects of separation and loss, and the stages of concept formation relating to the functioning of the human body, the processes of disease and death--are basic approaches to the use of imagery-relaxation as an integral part of a comprehensive care plan.

LeBaron, Samuel; Zeltzer, Lonnie (1982, October). The effectiveness of behavioral intervention for reducing chemotherapy related nausea and vomiting in children with cancer. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Indianapolis, IN.

Eight children (nine to seventeen years, Mean age 12.1) with cancer received behavioral intervention for chemotherapy related nausea and vomiting. Within three to five days after the administration of each course of chemotherapy, patients rated (1-10 scale; 1 = none, 10 = all the time or maximal amount) their nausea and vomiting and the extent to which chemotherapy bothered them and disrupted their daily routine. After a pre-intervention assessment of 2.5 courses of chemotherapy, patients received intervention (Mean = 2.6 courses). Significant reductions following intervention (Wilcoxon matched-pairs signed ranks test) were found in nausea ( $Z = 2.37, p < .02$ ), vomiting ( $Z = 2.52, p < .01$ ), bother ( $Z = 2.24, p < .02$ ), and disruption of activities ( $Z = 2.38, p < .02$ ). This preliminary study indicates that chemotherapy side effects can be reduced through behavioral intervention.

1976

**Gardner, G. Gail (1976). Attitudes of child health professionals toward hypnosis: Implications for training. International Journal of Clinical and Experimental Hypnosis, 24, 63-73.**

A survey of child health professionals -- pediatricians, pediatric nurses, child psychologists, and child psychiatrists -- revealed that they have generally positive attitudes toward hypnosis but little knowledge of its specific advantages or applications. Recommendations are made for designing training opportunities in hypnosis which might enhance the probability that the professional will actually use hypnosis or refer a child elsewhere for hypnotherapy.

**Gardner, Gail G. (1976). Hypnosis and mastery: Clinical contributions and directions for research. International Journal of Clinical and Experimental Hypnosis, 24 (3), 202-214.**

This paper explores the concept of mastery in relation to hypnotherapy by pulling together clinical observations and suggesting directions for research. It is suggested that a sense of mastery may enhance the effectiveness of hypnosis, either by facilitating induction, or by strengthening hypnotherapeutic suggestions, or by maintaining hypnotherapeutic gains. Moreover, the question is raised as to whether hypnotherapy, as compared with other psychotherapeutic approaches, better facilitates the development of a sense of mastery.

1965

Bernstein, Norman R. (1965). Observations on the use of hypnosis with burned children on a pediatric ward. International Journal of Clinical and Experimental Hypnosis, 13 (1), 1-10.

Several cases are described and observations made about the interplay of forces between staff, patient, and therapist, as well as the expectations of the patients to assess how these factors influenced the use of hypnosis. Hypnosis appears to be a particularly useful means for reaching isolated and depressed children with burns and for improving the morale of the staff team working with these children. The results may be along specific lines in terms of pain tolerance and improved eating, or in general improvement of cooperativeness and mood on the part of the child. Perception

1995

Crawford, Helen J.; Kapelis, Lia; Harrison, David W. (1995). Visual field asymmetry in facial affect perception: Moderating effects of hypnosis, hypnotic susceptibility level, absorption, and sustained attentional abilities. International Journal of Neuroscience, 82 (n1-2), 11-23.

Effects of hypnotic level, affect valence and cerebral asymmetry on reaction time (RT) in the discrimination of Ekman and Friesen (1978) stimuli of angry and happy faces were studied in counterbalanced conditions of waking and hypnosis. Assessed previously on two hypnotic susceptibility scales (Harvard Group Scale of Hypnotic Susceptibility; Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C)], non-depressed subjects were 16 low (0-4 SHSS:C) and 17 highly (10-12 SHSS:C) hypnotizable, right-handed college students. Subjects were required to identify affect of faces, presented tachistoscopically to left (LVF) or right (RVF) visual fields, by using a forced-choice RT paradigm. Highs were significantly faster than lows in angry and happy affect recognition. Hypnosis had no significant effects. For highs only, angry emotional valence was identified faster when presented to the right hemisphere (RVF), but there were no significant hemispheric effects for happy emotional valence. For lows there were no hemispheric differences. Gender was a nonsignificant factor. Significant correlations showed that faster reaction times to angry and happy stimuli, in both LVF and RVF in waking and hypnosis, were obtained by subjects who reported more deeply absorbed and extremely focused

and sustained attention on the Tellegen (1982) Absorption Scale and a subscale of the Differential Attentional Processes Inventory (Grumbles & Crawford, 1981). Vividness of Visual Imagery Questionnaire (Marks, 1973) and Affect Intensity Measure (Larsen, 1985), in general, did not correlate with RTs. The potential role of the fronto-limbic attentional system in the recognition of external visual sensory affect is discussed.

**Spiegel, David (1995, November). Neurophysiological effects of hypnotic perceptual alteration. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.**

We studied the relationship between selective attention and hypnotic processes. Michael Posner's theory has different centers for different kinds of attentional processes. Posterior (anterior to the occipital) cortex seems related to arousal. Anterior system has 2 loci: anterior cingulate and [missed words] pole, which relates to the narrowing of attention in hypnosis. We used cued target detection tasks, with MRI measures.

We think hypnotic attention is related to the anterior system.

In an earlier study we used 10 Highs, measured their visual ERPs, with both hypnotic obstructive hallucination and normal attention conditions. We found early and late evoked potential wave component differences: P100, P200, and P300. We were surprised by the P100 or attentional component.

Steven Hilliard's work used an ERP model, and an attentional paradigm with only 1/2 visual field involved. Usually N1 and P1 loci of EEG are the most affected in attentional studies using the evoked response potential measure.

He compared hypnotic attention with hypnotic obstruction (which was a suggestion that a brick wall was "covering" the L or R visual field). They found a difference between attended and ignored stimuli in the Frontal area ERP!

In an earlier study we used 10 Highs, measured their visual ERPs, with both hypnotic obstructive hallucination and normal attention conditions. We found early and late evoked potential wave component differences: P100, P200, and P300. We were surprised by the P100 or attentional component.

Steven Hilliard's work used an ERP model, and an attentional paradigm with only 1/2 visual field involved. Usually N1 and P1 loci of EEG are the most affected in attentional studies using the evoked response potential measure.

He compared hypnotic attention with hypnotic obstruction (which was a suggestion that a brick wall was "covering" the L or R visual field). They found a difference between attended and ignored stimuli in the Frontal area ERP!

However, there are problems with ERPs and localization due to diffusion of signal throughout the scalp.

In a hypnotic obstruction condition the effect is a bit later than in selective inattention; and it is more posterior than in selective inattention. Thus, if we find a difference due to hypnotic obstruction at P100, it may be due to selective inattention. The difference we can produce with hypnotic obstruction comes at P200 and posterior in the occipital cortex, where a visual stimulus is processed. Generation of internal images may contribute. Are there differences if you tell yourself not to see vs to see something obstructing the image?

Ability to do the hypnotic obstruction is related to the eyeroll item on the Hypnotic Induction Profile (HIP). (High eyeroll score makes it easier to reduce P200 amplitude in response to the obstruction suggestion.) So eyeroll score on the HIP has some validation as a biological marker.

Effects of supportive group therapy for cancer patients study: anxiety and depression modulate the pain more than the location of the cancer. Melzack's theory indicates input from cortex can modulate pain. We taught Self Hypnosis for pain control: used metaphors that induce relaxation, suggestions to filter hurt out of the pain, not fight the pain, focus on a competing sensation. By end of year the intervention group had half the pain that the non-intervention group had. The frequency and duration of pain attacks were not different.

We are now in year 5 of a 10 year replication study.

ignored stimuli in the Frontal area ERP!

However, there are problems with ERPs and localization due to diffusion of signal throughout the scalp.

In a hypnotic obstruction condition the effect is a bit later than in selective inattention; and it is more posterior than in selective inattention. Thus, if we find a difference due to hypnotic obstruction at P100, it may be due to selective inattention. The difference we can produce with hypnotic obstruction comes at P200 and posterior in the occipital cortex, where a visual stimulus is processed. Generation of internal images may contribute. Atkinson, Richard P. (1993, October). Shifts in Muller-Lyer Illusion difference thresholds: Are high hypnotizables more sensitive than lows in hypnosis?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Refers to Wallace (1979) finding that hypnotizability correlates with afterimage persistence. Atkinson showed highs perform better than lows in perceptual tasks in hypnosis only. Also studies indicate highs are more susceptible to illusions. Our study showed difference in threshold and point of subjective equality for highs and lows.

32 undergraduates had Harvard and Group Stanford Form C, were 9-12 or 0-3 on both scales. Counterbalanced conditions of waking and hypnosis. Used computer monitor to compare length of lines. Waking condition Ss had to close eyes for 15 minutes before the trials, same length of time as for hypnosis condition.

Significant interaction between hypnotizability and sessions was observed: highs had significantly decreased difference thresholds in hypnosis compared to waking, and significantly decreased difference thresholds compared to lows in hypnosis. Thus they had greater sensitivity than lows.

The point of subjective equality ANOVA did not yield significant effects.

Highs show higher sensitivity to illusion in hypnosis than in waking, and more than the lows.

McCormack, K.; Gruzelier, J. (1993). Cerebral asymmetry and hypnosis: A signal-detection analysis of divided visual field stimulation. Journal of Abnormal Psychology, 102 (3), 352-357.

These authors studied the effect of hypnosis on brightness discrimination with the aid of a signal-detection procedure in three sessions, the second with hypnosis. After two or three training sessions with hypnosis, which involved listening to a taped hypnotic relaxation induction, subjects were subdivided into high- and medium-susceptible groups on the

subjects were subdivided into high- and medium-susceptible groups on the basis of a 'scale inspired by the Stanford Scales.' High-susceptible subjects were found to show increases in perceptual sensitivity in the left visual field (right hemisphere) with hypnosis, whereas medium-susceptible subjects showed bilateral enhancements. The attitudes, or criterion set by the subjects remained invariant in both groups across the three sessions. It was concluded that the results provided evidence of altered brain function with hypnosis and an association of focal right hemispheric changes with high susceptibility, and through the invariance of motivational factors, failed to support the attribution of perceptual changes to attitudinal, non-state factors

Wallace, Benjamin (1993, October). The importance of considering imagery in hypnosis research. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

We looked at both hypnotizability (Harvard Scale) and imagery (Vividness of Imagery - Marks) ability in an embedded words task (like the letter matrices in newspapers). Ss were grouped on both variables, forming four groups: high-high, high- low, low-high, and low-low.

Search time in the embedded figures task was greatest for low-lows and least for high-Highs, whether the words are easy, average, or difficult. A list of the possible words was also provided.

Strategies the subjects in different groups used are different. High-high's use holistic (Crawford) or efficient (Wallace) strategies--studying the list of possible solutions as if storing the words in long-term memory. Low-low's seem to use the list as a check-off list.

Embedded in the matrix were false alarm words, that weren't on the list. The low-lows were also prone to more of these errors. Getting rid of those false alarm trials, when presented with matrices with no false alarms, we still get a differences in search time with the same relationship as before.

CONCLUSION. It's insufficient to simply look at hypnotic susceptibility as there's an imaging component, a memory or a storage component that we should examine. The percent of variance associated with the embedded figures task success was the same-- 20%--for each ability. The correlation between the two (imaging ability and hypnotizability) was significant at .26.

1992

Atkinson, Richard P.; Crawford, Helen J. (1992). Individual differences in afterimage persistence: Relationships to hypnotic susceptibility and visuospatial skills. American Journal of Psychology, 105 (4), 527-539.

To investigate the moderating role of individual differences in hypnotic susceptibility and visuospatial skills on afterimage persistence, we presented a codable (cross) flash of light to 40 men and 46 women who had been dark adapted for 20 minutes. In an unrelated classroom setting, subjects had previously been given two standardized scales of hypnotic susceptibility (Harvard Group Scale of Hypnotic Susceptibility, Shor & Orne, 1962; Group Stanford Hypnotic Susceptibility Scale, Form C, Crawford & Allen, 1982) and the Mental Rotations Test (Vandenberg & Kuse, 1978). The first afterimage interval and the afterimage duration correlated significantly with hypnotic responsiveness, supporting Wallace (1979), but did not show the anticipated relationships with mental rotation visuospatial skills. Individuals in the high hypnotizable group had (a) significantly longer afterimage intervals between its first appearance and first disappearance than did those in low groups, but those in medium groups did not differ significantly from the other groups. Discriminant analysis using the afterimage persistence measures classified correctly 65.2% of high hypnotizables, 37.5% of medium hypnotizables, and 54.8% of low hypnotizables. Hypothesized cognitive skills that assist in the maintenance of afterimages and underlie hypnotic susceptibility include abilities to maintain focused attention and resist distractions over time and to maintain vivid visual images.

"Because there is no apparent evidence for physiological differences of the visual system between low and high hypnotizables (e.g., Wallace, 1979), cognitive factors are suggested as possible moderators of afterimage persistence.

"Hypnotic susceptibility per se is not the moderator of afterimage duration. Rather, we argue that hypnotic susceptibility represents a constellation of underlying cognitive skills (e.g., for reviews, see Crawford, 1989; Kihlstrom, 1985) that assist an individual to respond to hypnotic suggestions as well as assist in the persistence of afterimages by interacting with more primary causal mechanisms that are physiological in origin. These cognitive skills are thought to include the abilities to focus attention selectively upon both external stimuli and internally generated images, to maintain vivid visual images, to sustain attention over time and remain absorbed in the experience at hand, and to resist distractions. The relationships between these cognitive skills and hypnotic susceptibility are reported in a large body of literature (e.g., Crawford, 1982, 1989; Crawford et al., 1991; Crawford & Grumbles, 1988; Finke & Macdonald, 1978; Grumbles & Crawford, 1981; Mitchell, 1970; Tellegen & Atkinson, 1974)....

"Sustained and selective attention without interference from extraneous stimuli plays an important role in hypnosis. Individuals who are responsive to hypnosis demonstrate greater skills in extremely focused and sustained attention (e.g., Crawford et al., 1991; Tellegen & Atkinson, 1974). Electrophysiological research had found that high hypnotizables often generate substantially more theta electroencephalogram (EEG) power than do low hypnotizables (e.g., Crawford 1990, 1991; Crawford & Gruzelier, 1992; Sabourin, Cutcomb, Crawford, & Pribam, 1990). Such a relationship may be interpreted as further evidence of greater attentional skills in highs, because certain theta waves have been correlated with

enhanced problem solving and attentional task performance (e.g., Crawford & Gruzelier, 1992; Schacter, 1977)....

"Hypnosis is seen often as a condition of amplified attention, where attention can be either more focused or diffuse dependent upon set (e.g., Krippner & Binder, 1974). Increases in vigilant performance during hypnosis have been reported, albeit inconsistently (e.g., Barabasz, 1980; Fehr & Stern, 1967; Kissen, Reifler, & Thaler, 1964; Smyth & Lowy, 1983). Fehr and Stern's results suggest that hypnotized subjects devote more attention to a primary task with less available attentional resources for a secondary task. Hypnosis has been found to have an enhancing effect on the imaginal processing of information-to-be-remembered that consists of literal or untransformed representations of pictorial or nonverbal information for high but not low hypnotizables (Crawford & Allen, 1983; Crawford, Nomura, & Slater, 1983; Crawford, Wallace, Nomura, & Slater, 1986). This may possibly be the result of increased attention and/or shifts in cognitive strategies. Supportive of the hypothesis that sustained attention can be enhanced during hypnosis, Atkinson (1991) recently found that high but not low hypnotizables report significantly more persistent afterimages in hypnosis than in waking.

"Although we have argued for a cognitive explanation for individual differences in afterimage persistence and their possible relationship to hypnotic susceptibility and sustained attentional abilities, as has Wallace (1979, 1990), we must point out the possibility that high hypnotizables may be more suggestible to imagery instructions or more willing to discuss or experience imagery than low hypnotizables, particularly in the context of hypnosis and hypnotic susceptibility testing (e.g., Zamansky, Scharf, & Brightbill, 1964). A contextual account of the longstanding relationship between hypnotic susceptibility and absorption was raised by Council, Kirsch, and Hafner (1986), but was not supported by two independent, and more methodologically sound, studies reported by Nadon, Hoyt, Register, and Kihlstrom (1991). The context of hypnosis was not an issue in the present study, because none of the subjects was aware of the investigated relationship between afterimage persistence and hypnotic susceptibility at the time of recruitment or participation" (pp. 533-535).

imagery than low hypnotizables, particularly in the context of hypnosis and hypnotic susceptibility testing (e.g., Zamansky, Scharf, & Brightbill, 1964). The context of hypnosis was not an issue in the present study, because none of the subjects was aware of the investigated relationship between afterimage persistence and hypnotic susceptibility at the time of recruitment or participation" (pp. 533-535).

Bruner, Jerome (1992). Another look at New Look 1. American Psychologist, 47, 780-783.

New Look 1 was not initially about the unconscious. It was the new mentalism on its way to becoming the Cognitive Revolution. Its subsequent concern with

"unconscious defense mechanisms," although useful, was not its main theoretical thrust. Its principal questions have always been how and where selective processes operate in perception. Obviously, many such processes are unconscious, for consciously guided attention and search become automatized easily in use. And they are fairly flexible as well. So how smart is "the unconscious"? Not very, but a big help anyway.

Greenwald, Anthony G. (1992). New Look 3: Unconscious cognition reclaimed. American Psychologist, 47, 766-779.

Recent research has established several empirical results that are widely agreed to merit description in terms of unconscious cognition. These findings come from experiments that use indirect tests for immediate or long-term residues of barely perceptible, perceptible-but-unattended, or attended-but-forgotten events. Importantly, these well-established phenomena--insofar as they occur without initially involving focal attention--are limited to relatively minor cognitive feats. Unconscious cognition is now solidly established in empirical research, but it appears to be intellectually much simpler than the sophisticated agency portrayed in psychoanalytic theory. The strengthened position of unconscious cognitive phenomena can be related to their fit with the developing neural network (connectionist) theoretical framework in psychology.

Jacoby, Larry L.; Lindsay, D. Stephen; Toth, Jeffrey P. (1992). Unconscious influences revealed: Attention, awareness, and control. American Psychologist, 47, 802-809.

Recent findings of dissociations between direct and indirect tests of memory and perception have renewed enthusiasm for the study of unconscious processing. The authors argue that such findings are heir to the same problems of interpretation as are earlier evidence of unconscious influences--namely, one cannot eliminate the possibility that conscious processes contaminated the measure of unconscious processes. To solve this problem, the authors define unconscious influences in terms of lack of conscious control and then describe a process dissociation procedure that yields separate quantitative estimates of the concurrent contributions of unconscious and consciously controlled processing to task performance. This technique allows one to go beyond demonstrating the existence of unconscious processes to examine factors that determine their magnitude.

In response to Greenwald's article on contemporary research on unconscious mental processes, the authors address three issues: (a) the independence of much recent research and theory from psychodynamic formulations; (b) the broad sweep of the psychological unconscious, including implicit perception, memory, thought, learning, and emotion; and (c) the possibility that the analytic power of unconscious processing may depend both on the manner in which mental contents are rendered unconscious and the manner in which they are to be processed.

Lewicki, Pawel; Hill, Thomas; Czyzewska, Maria (1992). Nonconscious acquisition of information. American Psychologist, 47, 796-801

The authors review and summarize evidence for the process of acquisition of information outside of conscious awareness (covariations, nonconscious indirect and interactive inferences, self-perpetuation of procedural knowledge). Data indicate that as compared with consciously controlled cognition, the nonconscious information - acquisition processes are not only much faster but are also structurally more sophisticated, in that they are capable of efficient processing of multidimensional and interactive relations between variables. Those mechanisms of non-conscious acquisition of information provide a major channel for the development of procedural knowledge that is indispensable for such important aspects of cognitive functioning as encoding and interpretation of stimuli and the triggering of emotional reactions.

Merikle, Philip M. (1992). Perception without awareness: Critical issues. American Psychologist, 47, 792-795.

This is the introduction to a group of articles. "To a large extent, this entire controversy over perception without awareness has centered on the issue, What constitutes an adequate behavioral measure of conscious perceptual experience? Depending upon one's answer to this question, the evidence for perception without awareness is either overwhelming or nonexistent.

The distinction is much more significant and interesting if conscious and unconscious processes lead to qualitatively different consequences than if unconscious processes are simply quantitatively weaker versions of unconscious processes. Three different qualitative differences have been established: 1. Groeger (1984, 1988) has demonstrated that words are coded differently depending on whether they are perceived with or without awareness. 2. Stroop effect research showed that prediction based on stimulus redundancy only occurs when subjects consciously perceive the predictive stimuli (Cheesman & Merikle, 1986). The fact that the color word predicted the name of the color patch on 75% of the trials was only used by the subjects to facilitate naming of the color patches when the words were clearly visible. 3. Marcel (1980) showed that conscious awareness is necessary for the selection of a context-relevant interpretation of a stimulus.

The important findings are that performance differs qualitatively across the aware and nonaware conditions

Rondi, Glenys (1992, October). Postoperative impact of information presented during general anesthesia. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

We tried to improve on the methodology in the literature. Thus we included a limited range of surgery procedures; standardized anesthesia; monitoring of anesthesia; suggestions that were only positive (the suggestions did not mention pain or nausea); patient-controlled analgesia in order to have a more accurate measure;

and hypnotizability was measured. They do not equate the hypnotic state with the anesthesia state, but there may be an overlap in the ability to perceive and respond to suggestions in these two states.

All hysterectomy and bilateral [missed word ...ectomy] patients were approached, excluding those without English language, etc.

Bowers and she phrased simple, positive suggestions to maximize benefits; Suggestions lasted 3 minutes, and were repeated 3 times on a 60 minute tape. Brief melodies alternated with suggestions or with silence. Conditions included: 1. Suggestions 2. Melody 3. Suggestions + melody 4. Blank tape

Half of the tapes contained suggestions; half not. It was a counterbalanced design. Double blind ratings were made by students.

State-trait Anxiety and Profile of Mood States were measured before surgery. Patients were reminded to listen to suggestions for recovery just before they fell asleep. MDs ordered premedication for the surgery "only if very necessary."

Patients rated their own recovery as -3 worse than expected to +3 better than expected; and completed a visual analogue scale. Then 24 hours later the researchers asked them if they remembered the tape, and if they had been given suggestions or not.

On Day 5 post operation they administered the Stanford C hypnotizability scale.

**RESULTS.** None of the patients recalled or dreamed anything that could be attributed to the period of anesthesia. There was a response bias to say "Yes" to "Did you have suggestions?" (34 of Suggestion patients and 28 of non-suggestion patients said "Yes" and there were 48 in each group. Taking response bias into consideration, patients with suggestions were above chance in saying "Yes" to "Did you have suggestions?"

Only 73 of the 96 completed the hypnotizability scale. Duration of the tape (therefore of surgery) was longer for the suggestion group (90 vs 72 minutes). So authors also did a univariate measure.

They divided morphine use by patient weight for each post operative day. The difference in dose for suggestion and no suggestion groups did not reach significance on Day 1 but on Day 2 patients who had suggestions used significantly less morphine.

The correlation matrix showed that patient age was negatively correlated with morphine use; subjected to 1-way ANOVA of covariance; the effect of suggestions remains significant.

Surgery time was covaried out, as it was associated with more negative post operative symptoms; patient age was a second covariate. None of the main effects or 2- way interactions were significant.

Hypnotizability, suggestion group, and their interaction were analyzed. Neither hypnotizability nor its interaction with suggestion contributed to any outcome variable.

Using only highs (13) and lows (12) for another analysis and 2x2 ANOVAS to examine suggestion by hypnotizability. Highs used significantly less morphine in the first hours, whether or not they received suggestions.

Even when weight is taken into account, hypnotizability accounted for significant amount of variance in first 24 hours. Highly hypnotizables' guesses about whether they were played a tape with suggestions was 100% accurate; guesses of lows were 42% accurate.

with suggestions was 100% accurate; guesses of lows were 42% accurate.

**CONCLUSIONS.** Some patients show evidence of hearing, and of responding to suggestions. Hypnotic ability did not mediate the response; but patients with high ability showed 100% accuracy in guessing whether they were played suggestions, in the absence of confidence in their response. They may be particularly sensitive to their environment during general anesthesia.

Schacter, Daniel L. (1992). Understanding implicit memory. *American Psychologist*, 47 (4), 559-569.

Dissociations between implicit and explicit memory have attracted considerable attention in recent memory research. A central issue concerns whether such dissociations require the postulation of separate memory systems or are best understood in terms of different processes operating within a single system. This article presents a cognitive neuroscience approach to implicit memory in general and the systems-processes debate in particular, which draws on evidence from research with brain-damaged patients, neuroimaging techniques, and nonhuman primates. The article illustrates how a cognitive neuroscience orientation can help to supply a basis for postulating memory systems, can provide useful constraints for processing views, and can encourage the use of research strategies that the author refers to as cross-domain hypothesis testing and cross-domain hypothesis generation, respectively. The cognitive neuroscience orientation suggests a complementary role for multiple systems and processing approaches.

"Implicit memory is an unintentional, nonconscious form of retention that can be contrasted with explicit memory, which involves conscious recollection of previous experiences" (p. 559). The author provides examples of memory dissociations, some of them from neuropathology and some from experimental psychology.

Different brain systems may account for some of the dissociations. For example, there are "studies of patients who show relatively intact access to perceptual-structural knowledge of words or objects, despite severely impaired access to semantic knowledge of the same items. ... Similarly, studies of lexical processing using positron emission tomography (PET) indicate that visual word form information and semantic information are handled by separate brain regions. ... These kinds of observations suggest the existence of a perceptual representation system (PRS)" (p. 561).

"Marsolek et al. (1992) drew on independent evidence from cognitive neuroscience concerning the characteristics of the hemispheres to argue that a left hemisphere subsystem computes abstract word form representations that do not preserve specific features of particular inputs, whereas a right-hemisphere subsystem computes perceptually specific word form representations (in the present terminology, both could be viewed as PRS subsystems)" (p. 562)..

"Our approach to auditory implicit memory was guided by neuropsychological studies of patients who exhibit dissociations between access to form and semantic information in the auditory domain that are similar to those discussed earlier in the visual domain. ... More specifically, patients with so-called word meaning deafness are unable to understand spoken words (e.g. Ellis & Young, 1988). However, they can repeat spoken words quite well and show some ability to write words to dictation, thus suggesting that they can gain access to stored auditory word form representations. ... Rather more frequently encountered are patients with transcortical sensory aphasia (e.g. Kertesz, Sheppard, & MacKenzie, 1982), who exhibit spared abilities to repeat spoken words and write them to dictation, together with impaired comprehension. In these patients, however, the comprehension deficit is also observed in other modalities, thus indicating damage to the semantic system itself.

"These dissociations point toward the existence of a PRS subsystem that handles information about auditory word forms separately from semantic information (cf. Ellis & Young, 1988)" (p. 565)..

"Various investigators have argued that auditory processing differs in the two hemispheres: The left hemisphere relies on categorical or abstract auditory information and operates primarily on phonemes, whereas the right hemisphere relies more on 'acoustic gestalts' and operates primarily on prosodic features of speech, including voice information... In addition, studies of normal subjects using dichotic listening techniques have shown a left-ear (i.e., right-hemisphere) advantage for certain types of voice information, in contrast to the usual right-ear advantage for speech" (p. 566).

Wallace, Benjamin; Kokoszka, Andrzej (1992). Experience of peripheral temperature change during hypnotic analgesia. International Journal of Clinical and Experimental Hypnosis, 40, 180-193.

Many Subjects who experience hypnotic analgesia in a portion of their body often report that it is accompanied by sensations of coldness in the affected area. Experiments were conducted to determine if such reports are the result of a physical change in peripheral temperature or are due to psychological factors. When analgesia was induced in a limb or in the back of the neck, a concomitant physical change in temperature was not observed. Subjects did report experiencing coldness, however, in the affected body part. Such experiences were attributed to associations that Subjects developed between numbness or analgesia and a drop in peripheral temperature. As a result, coldness as an associate of hypnotic analgesia is suggested as a manipulation check for the presence of such sensation reduction.

When a limb feels numb, there also appears to be degradation of proprioceptive abilities (Wallace & Garrett, 1973, 1975; Wallace & Hoyenga, 1980). When Ss are asked to touch their nose with finger, either subjects miss the nose or they take longer to do the task. This kind of proprioceptive decrement has also been reported by Spanos, Gorassini, and Petrusic (1981) and Welch (1978, p. 27).

This study used highly hypnotizable Ss (10-12 on Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) and low hypnotizables (0-2) in Experiment 1 which established temperature variability in an arm and sites for measuring temperature during hypnotic analgesia.

In Experiment 2, 40 subjects (20 highs and 20 lows by above standards, with group assignment confirmed by Stanford Hypnotic Susceptibility Scale, Form C, on which highs  $M = 10.4$ , lows  $M = 1.2$ ) were given relaxation imagery (e.g. to imagine a white, fluffy cloud gently moving across a deep, blue sky during a count of 20, while at the same time, listening only to the voice of E describing the scene to them.

The analgesia suggestion was that "their right arm had been injected with massive doses of Novocain, that Novocain had been injected in their shoulder, in their elbow, in their forearm, in their hand, and in their fingers ... their arm would become progressively more and more numb as E counted backward from 20 to 1" (p. 185; for more details see Wallace & Hoyenga, 1981). They were asked to perform the nose touch test as confirmation of the analgesia suggestion response

They were asked to perform the nose touch test as confirmation of the analgesia suggestion response.

Highs and lows who served as control subjects had the same treatment except instead of analgesia instructions they were told their arm would become progressively more and more relaxed as E counted backwards from 20 to 1.

The peripheral skin temperature was monitored during the procedures, and following the experimental manipulation Ss completed a questionnaire on their experience of numbness, heaviness, changes in limb temperature (very warm to very cold), and changes in mobility.

Analyses of variance were used to analyze the results. Although there were no objective skin temperature changes, there was a significant interaction effect for pointing error. Highs who received analgesia suggestions were off 4.35 cm; the other 3 groups had mean error of .45 cm or less. There was also an interaction effect for latency of response: highs with analgesia instructions took 3.05 seconds longer than in relaxation condition, while other three groups only took .27 sec longer, on average. Additionally, there was a correlation between receiving analgesia instructions and feeling limb heaviness for the high hypnotizables ( $r = .68$ ) but not for lows or for any Ss asked to relax their arm during the procedures.

The sensation of coldness was reported by the majority of highs receiving analgesia suggestions (7 of 10), but 2 Ss scoring 12 on the SHSS:C did not report coldness. Cold sensation was not reported by any S in any of the three other groups. The correlations between cold sensation and heaviness ( $r = .65$ ,  $p < .05$ ) and cold sensation and immobility ( $r = .79$ ,  $p < .05$ ) were found only in the High hypnotizable, analgesia suggestion group.

The authors performed a third experiment to determine whether temperature change could be used to confirm analgesia. This would be useful when one cannot confirm with inability to move the body part, e.g. when the analgesia is being developed in a part of the body that usually doesn't move. The design for Experiment 3 was the same as for Experiment 2.

Analgesia rated on a 7-point scale was reported as 6.1 by high hypnotizables and 1.2 by low hypnotizables. "Reports of a temperature change during the induction were

also related to hypnotic analgesia and being classified as high in hypnotizability. Such a relationship was only significant, however, for a feeling of coldness ( $r = .63$ ,  $p < .05$ ), and 7 of the 10 high hypnotizable Subjects assigned to the analgesia group reported the aforementioned sensation. A significant experiencing of a temperature change (cold or warm) was not reported by the other three groups of Subjects" (p. 189).

In their Discussion, the authors suggest that expectancy might account for the results, since during post-experiment interviews many Ss said that they expected their arm would become cold when it was numb. That was based on their previous experience, e.g. in placing ice on the skin. Notable, people did not exhibit this association if they were not able to develop the analgesia in response to suggestion. The authors also take note of the fact that none of the Subjects reported associating cold with pain, though cold and pain often are concurrently experienced. This might be because only extreme cold is painful, and coolness might actually be perceived as pleasant.

1991

Brown, Jason W. (1991). Self and process: Brain states and the conscious present. New York: Springer-Verlag.

Author, from the Department of Neurology at New York University Medical School, presents a theory about the genetic unfolding of mental content (mind) through stages, from mental state into consciousness or into behavior. He relates the genesis of mind to brain development but avoids assuming that there is a straightforward correlation between brain development (e.g. myelination) and cognitive development or perception. To some degree, the theory is based on subjective report data and psychological symptoms. The author discusses issues that bear on the phenomena of nonvoluntary responding and dissociation that are reported or described by hypnotized persons.

"The nature of the mental state will determine the relation between self and world, and thus the interpretation given to agency and choice. ... The crossing of the boundary from self to world is a shift from one level in mind to another" (pp. 10-11).

"... if we begin with mind as primary and seek to explain objects from inner states and private experience, the discontinuity between inner and outer evaporates: mind is everywhere, a universe. ... Whereas before we thought to perceive objects, now we understand that we think them" (p. 19).

"The concept of a stratified cognition is central to the notion of a mental state .... This entails an unfolding from depth to surface, not from one surface to the next, a direction crucial to agency and the causal or decisional properties of consciousness" (p. 52). By unfolding from depth to surface, he means from Core, through Subconscious, then Conscious Private Events, and finally Extra-Personal Space.

He goes on to provide a definition of mental states. "A mental state is the minimal state of a mind, an absolute unit from the standpoint of its spatial and temporal structure. ... The state also has to include the prehistory of the organism. ... The concept of a mental state implies a fundamental unit that has gestalt-like properties,

in that specific contents-- words, thoughts, percepts--appear in the context of mind as a whole (p. 53).

"The entire multitiered system arborizes like a tree, with levels in each component linked to corresponding levels in other components. For example, an early (e.g., limbic) state in language (e.g., word meaning) is linked to an early stage in action (e.g., drive, proximal motility) and perception (e.g., hallucination, personal memory) ... In sum, a description of the spatial and temporal features of a single unfolding series amounts to a description of the minimal unit of mind, the absolute mental state" (p. 54).

The author's discussion of an individual's physical movement relates to the concept of nonvoluntary movement (or movement without awareness of volition) in hypnosis. "More precisely, levels in the brain state constitute the action structure. As it unfolds, this structure generates the conviction that a self-initiated act has occurred. This structure--the action representation--does not elaborate content in consciousness. ... As with the sensory-perceptual interface, the transition to movement occurs across an abrupt boundary. In some manner, perhaps through a translation of cognitive rhythms in the action to kinetic patterns in the movement, levels in the emerging act discharge into motor (physical) events" (p. 57).

"The self has the nature of a global image or early representation within which objects-to-be are embedded. ... The self is the accumulation of all the momentary cognitions developing in a brain configured by heredity and experience in a particular way (p. 70).

"The deposition of a holistic representation ... creates the deception of a self that stands behind and propagates events. The feeling of the self as an agent is reinforced by the forward thrust of the process and the deeper locus of the self in relation to surface objects. The self appears to be an instigator of acts and images when in fact it is given up in their formation. The self does not cause or initiate, it only anticipates (p. 70).

The foregoing notes cover only the first five chapters, less than half the book. Other chapters relevant to hypnosis would be those titled 'The Nature of Voluntary Action,' 'Psychology of Time Awareness,' 'From Will to Compassion,' and 'Mind and Brain.'

cause or initiate, it only anticipates (p. 70).

Dixon, Norman F.; Henley, Susan H. (1991). Unconscious perception: Possible implications of data from academic research for clinical practice. Journal of Nervous and Mental Disease, 179 (5), 243-252.

Evidence for the reality of unconscious perception and perceptual defense suggests that the experimental paradigms used to investigate these phenomena might play a role in the understanding and treatment of mental disorders. The literature on applying subliminal stimulation to problems of diagnosis and therapy indicates that

data support the view that the meaning of external stimuli of which the recipient is unaware may be responded to and determine emotional responses, lexical decisions, overt behavior, and subjective experience. Data confirm the reality of psychopathology as a substrate of emotionally colored, stored information with a potential for producing somatic symptoms and disorders of thinking, affect, and behavior. To the extent that psychopathology is screened from conscious scrutiny and thus impervious to supraliminal information, it may be accessed and ameliorated by drive-related stimuli of which the S is not aware.

Kunzendorf, Robert G.; Beltz, Susan McLaughlin; Tymowicz, Gina (1991-92). Self-awareness in autistic subjects and deeply hypnotized subjects: Dissociation of self-concept versus self-consciousness. Imagination, Cognition and Personality, 11, 129-141.

By refining past tests of self-awareness in mirrors, current testing demonstrates that autistic subjects' percepts are dissociated from self-concept, whereas hypnotized subjects' sensations are dissociated from self-consciousness. In the current test of self-concept, subjects could not directly see a line inside the box on their lap, but subjects could see the line indirectly in a televised mirror image. When instructed to touch the line, autistic subjects reached towards the televised line, whereas nonautistic subjects reached towards the actual line occluded inside the box. This first result suggests that the autistic subject's visual percept of the televised line is dissociated from its spatial relationship to the subject's self-concept. In the current test of self-consciousness, subjects were told to use a televised mirror-image to move their hands together until touching, but were not told that they were actually seeing a pre-recorded tape of their hands struggling unsuccessfully to touch. When queried, hypnotized subjects denied that their tactually joined hands were touching, whereas nonhypnotized subjects confirmed that their hands were touching. This latter result suggests that the hypnotized subject's hand-touching sensations are dissociated from the immediate and incontrovertible self-consciousness that one is perceiving the hands touching (not imaging them touching).

Nelson, Peter L. (1991-92). Personality attributes as discriminating factors in distinguishing religio-mystical from paranormal experients. Imagination, Cognition and Personality, 11, 389-406.

In the first section of this article, an operationalized notion of preternatural experience is described which includes two general classes of experience: religio-mystical (Ontic) and paranormal (Perceptual). The exploratory study which follows uses the personality measures of the complete Tellegen Differential Personality Questionnaire taken from 120 subjects who reported having had spontaneous religio- mystical and/or paranormal experiences at some time in the past. The scores on all eleven primary dimensions, three higher order affect factors, and two validity scales were used individually, in univariate ANOVAs, and together, in a Direct Discriminant Function Analysis, to successfully separate two classes of preternatural experients from non- experients and from each other.

**Bornstein, Robert F. (1990). Critical importance of stimulus unawareness for the production of subliminal psychodynamic activation effects: A meta-analytic review. Journal of Clinical Psychology, 46, 201-210.**

Performed meta-analysis that assessed the magnitude of behavior change produced by subliminal vs supraliminal drive-related stimuli (DRS) on 11 subliminal psychodynamic activation (SPA) studies (published 1966-1989) that employed both types of stimuli. The analysis revealed that subliminal presentation of DRS produced significantly stronger effects on behavior than supraliminal presentation of the same stimuli. Stimulus content, type of outcome measure, and S characteristics influenced the magnitude of subliminal/supraliminal response differences. Results support L. H. Silverman's (1983) hypothesis that DRS must be presented subliminally to produce SPA effects.

**Cikurel, Katia; Gruzelier, John (1990). The effect of an active-alert hypnotic induction on lateral asymmetry in haptic processing. British Journal of Experimental and Clinical Hypnosis, 7, 17-25.**

In order to elucidate further left hemispherical inhibitory dynamics in response to instructions of hypnosis, bilateral haptic processing times were compared before and during a traditional hypnotic relaxation procedure and an active-alert procedure in which subjects pedaled a bicycle ergometer and instructions on mental alertness were incorporated with hypnosis. Previous evidence suggesting a slowing of left hemispherical processing and a facilitation of right hemispherical processing in susceptible subjects was replicated, and was shown to characterize high rather than medium susceptibles, the latter showing a bilateral slowing of processing. These effects occurred with both induction procedures whose influence on susceptibility was highly correlated. In fact the lateral shift in processing in the direction of left hemispherical inhibition and right hemispherical facilitation was favoured by the active-alert procedure, indicating that neuropsychological changes which occur with hypnosis cannot be discounted as a by-product of relaxation.

**McLintock, T. T.; Aitken, H.; Downie, C. F.; Kenny, G. N. (1990). Postoperative analgesic requirements in patients exposed to positive intraoperative suggestions. British Medical Journal, 301 (6755), 788-790.**

Sixty-three women undergoing elective abdominal hysterectomy were randomly assigned to a tape of positive suggestions or a blank tape during the operation. Anesthesia was standardized for all of the women. Postoperative analgesia tape of positive suggestions or a blank tape during the operation. Anesthesia was standardized for all of the women. Postoperative analgesia was provided through a patient-controlled analgesia system for the first 24 hours. Pain scores were recorded every 6 hours. The outcome measures were morphine consumption in the first 24 hours and pain scores. Mean morphine requirements were 51.0 mg in women who

were played positive suggestions, and 65.7 mg in those played a blank tape ( $p = 0.028$ ). Pain scores were similar in the two groups. It was concluded that intraoperative suggestions seem to have a positive effect in reducing patients' morphine requirements in the early postoperative period.

Wallace, Benjamin (1990). Hypnotizability and the modification of cognitive search strategies. International Journal of Clinical and Experimental Hypnosis, 38, 60-69.

An experiment was conducted to determine if Ss judged to be low in hypnotizability could be taught the efficient search strategies used by high hypnotizable Ss in the performance of a cognitive search task. Ss were requested to find objects embedded within a variety of pictorial scenes. High hypnotizable Ss were found to be more adept than low hypnotizables at finding more objects correctly. When low hypnotizable Ss were taught the efficient search strategies used by the high hypnotizables, their performance improved and was not significantly different from that of the high hypnotizable Ss. Implications of these results for teaching search strategies are discussed.

Wallace, Benjamin (1990). Imagery vividness, hypnotic susceptibility, and the perception of fragmented stimuli. Journal of Personality and Social Psychology, 58, 354-359.

Two experiments were conducted to determine the role of hypnotic susceptibility level (high or low) and imaging ability (vivid or poor) in the performance of gestalt closure tasks. In Experiment 1, subjects were required to identify fragmented stimuli in the Closure Speed Test and in the Street Test. In Experiment 2, subjects reported on fragmented stimuli that were projected to the right eye and subsequently produced an afterimage. Individuals were asked to identify the composite if possible and to report on the duration of the afterimage. In both experiments, hypnotic susceptibility level and imaging ability affected reports of gestalt closure. The greatest number of correct closures was reported by those who were both high in hypnotic susceptibility and vivid in imaging ability. In addition, in the second experiment, this group also reported the longest enduring afterimage. These results are discussed in terms of the processes required to perform in a gestalt closure task.

Weinberger, Joel; Hardaway, Richard (1990). Separating science from myth in subliminal psychodynamic activation. Clinical Psychology Review, 10, 727-756.

This paper reviews subliminal psychodynamic activation (SPA). Eight common criticisms are described and evaluated: (a) SPA data analysis is too liberal; (b) there are enough nonsignificant unpublished SPA studies to offset those showing effects; (c) SPA studies are difficult to replicate; (d) the claims of SPA proponents rely on unpublished studies; (e) SPA stimuli are not really subliminal; (f) experimenter expectancy effects and/or demand characteristics can account for SPA effects; (g) the mediating events said to underlay SPA effects have never been evinced; and (h)

alternative explanations for SPA effects are superior to the psychoanalytic ones typically offered. Theoretical and statistical analyses revealed that only the argument concerning mediating events has serious merit. The SPA stimulus for which the most support was found was Mommy and I Are One. Oedipal sanction stimuli were also found to yield reliable effects whereas Oedipal prohibition stimuli did not. Suggestions for future research are offered. Resistance to SPA findings are considered in Kuhnian terms.

Friswell, Rena; McConkey, Kevin M. (1989). Hypnotically induced mood. Cognition and Emotion, 3 (1), 1-26.

This article addresses theoretical and methodological issues that are central to an understanding of hypnotically induced mood. Initially, the hypnotic procedures that are typically used to induce moods are examined. Then the empirical research that has employed hypnotic moods is reviewed; specifically, the impact of hypnotic moods on physiological responses, behavioural performance, perceptual and cognitive responses, and personality, and clinical processes is examined. Finally, major theoretical and methodological issues are highlighted, and the research directions that will lead to a greater understanding of hypnotic mood are specified.

Hall, H.; Minnes, L. (1989). Psychological modulation of auditory responses. International Journal of Psychosomatics, 36 (1-4), 59-63.

Psychological modulation of auditory response, the effects of imagery and suggestion on auditory thresholds were examined in naive subjects. After a hypnosis-like induction, the subjects, who were not aware of the purpose of the study, were asked to generate and maintain a specific set of images before, during, and after which their auditory thresholds were tested. Following the imagery, which represented cooling and vasoconstriction in the cochlea, audiograms revealed a temporary auditory threshold shift (TTS) in the experimental group only. This TTS pattern was similar to that produced by exposure to loud noise. Information carried in the image is suggested as the basis for the observed auditory changes. Although a hypnosis-like induction was employed, the subjects' level of hypnotizability did not appear to be related to the findings.

Kunzendorf, Robert G. (1989-90). Posthypnotic amnesia: Dissociation of self-concept or self-consciousness?. Imagination, Cognition and Personality, 9, 321-334.

Two studies of posthypnotic amnesia tested predictions derived from the 'source' monitoring theory of self-consciousness. Experiment 1 tested the prediction that posthypnotic source amnesia is irreversible, because hypnosis attenuates self-consciousness of whether one's sensations have an imaginal source or a perceptual source. In this initial study, recall amnesia was reversed by posthypnotic cueing with a prearranged signal, but source amnesia was not reversed by such cueing. Experiment 2 examined whether the cued reversal of recall amnesia is attributable, in part, to the hypnotic attenuation of self-conscious 'source monitoring' and, in part, to the reversal of recall criteria: from a criterion rejecting 'seemingly imaginary' or 'sourceless' memories, to a criterion accepting 'sourceless but familiar' memories. In this latter study, posthypnotic recall amnesia was breached when subjects were instructed to trust their seemingly imaginary memories, but not when they were instructed to try harder to remember [emphasis removed from quoted text].

Litz, Brett T.; Keane, Terence M. (1989). Information processing in anxiety disorders: Application to the understanding of post-traumatic stress disorder. Clinical Psychology Review, 9, 243-257.

Several of the key defining features of PTSD are symptoms that reflect problems related to perception, attention, and memory processes (hypervigilance, flashbacks, nightmares, psychogenic amnesia, and concentration difficulties). Although there have been several recent attempts to explain such phenomena through facets of cognitive psychology, little empirical work has been completed to confirm or explicate such processes in PTSD. This paper critically reviews the theoretical and empirical work done to date in the area of information processing in anxiety disorders, so as to provide a context for future empirical work to identify the specific psychological mechanisms and controlling variables responsible for symptoms of PTSD. A working theoretical model of information processing variables in PTSD is also proposed to stimulate future research in this area.

Borgeat, Francois; Rezanowicz, Thaddeus; Chaloult, Louis (1988). La stimulation preconsciente et consciente de l'imaginaire erotique. Revue Canadienne de Psychiatrie, 33, 394-398.

The stimulation of erotic fantasies through the association of relaxation and erotic conscious or preconscious suggestions has been evaluated. This study was attempted following positive results in the stimulation of fantasmatic activity in alexithymic subjects with a similar procedure. Thirty female subjects, allocated into three groups practiced relaxation daily for two weeks including three sessions with psychological measures. During the second week, erotic suggestions, preconscious for one group and conscious for another one were added. The third group (control) received only relaxation throughout. Results have shown an increase of sexual arousal and erotic imagery during the sessions with erotic suggestions. Sexual activities and desire increased in the two experimental groups. There was no

difference between the effects of the preconscious and conscious suggestions. Possible clinical applications of such a procedure are discussed.

Council, James R.; Loge, D. (1988). Suggestibility and confidence in false perceptions: A pilot study. British Journal of Experimental and Clinical Hypnosis, 5, 95-98.

Subjects received audiotaped instructions implying that they would perceive increases in odor or heaviness while comparing stimuli in a sensory-judgment task. Stimuli were actually indiscriminable. Subjects pretested as higher or lower in hypnotizability performed the task in either hypnotic or non-hypnotic conditions. In both treatments, greater hypnotizability was associated with more perceived changes in the stimuli and greater confidence in the reality of those perceptions. Results support a general factor underlying suggestibility in hypnotic and nonhypnotic situations. The findings are discussed in relationship to false confidence effects reported in hypermnesia research.

Fine, C. G. (1988). Thoughts on the cognitive perceptual substrates of multiple personality disorder. Dissociation, 1, 5-10.

Although MPD [multiple personality disorder] patients typically present to treatment with affective symptoms, trauma-related information is originally encoded in the patients' perceptions and mediated by their cognitions. This paper describes the dysfunctional assumptive and perceptual categories that form the building blocks of MPD patients' distorted experiences. Perceptual shifting techniques and cognitive reframing will consequently be the recommended interventions prior to therapeutic abreactive work

Jones, Lynette A. (1988). Motor illusions: What do they reveal about proprioception. Psychological Bulletin, 103 (1), 72-86.

Five illusions involving distortions in the perception of limb position, movement, and weight are described in the context of their contribution to understanding the sensory processes involved in proprioception. In particular, these illusions demonstrate that the position sense representation of the body and the awareness of limb movement results from the cross-calibration of visual and proprioceptive signals. Studies of the vibration illusion and phantom-limb phenomenon indicate that the perception of limb movement and position are encoded independently and can be dissociated. Postural aftereffects and the illusions of movement induced by vibration highlight the remarkable lability of this sense of limb position, which is a necessary feature for congruence between the spatial senses. Finally, I discuss the role of corollary discharges in the central processing of afferent information with respect to the size-weight and vibration illusions.

Sheehan, Peter W.; Donovan, Paul; MacLeod, Colin M. (1988). Strategy manipulation and the Stroop effect in hypnosis. Journal of Abnormal Psychology, 97, 455-460.

When asked to name the ink color of an incompatible color word (e.g., the word red printed in green ink), people show strong interference from the word. This study examined Stroop interference in subjects who were either high or low in susceptibility to hypnosis. Compared with performance in the waking state, the Stroop effect actually increased under hypnosis, a result particularly evident in the high- susceptible subjects. This contradicts the notion that high susceptibility subjects freely select appropriate strategies when hypnotized, a conclusion strengthened by an analysis of reported strategies in the two states. However, when provided with an attentional focusing instruction under hypnosis, high susceptibility subjects sharply reduced the Stroop effect, whereas low-susceptible subjects decreased it only slightly. One role of hypnosis may be to assist the subject in tuning attention, but only when an appropriate strategy is provided.

Wallace, Benjamin (1988). Hypnotic susceptibility, visual distraction, and reports of Necker cube apparent reversals. Journal of General Psychology, 115, 389-396.

Subjects, either susceptible (n = 50) or resistant (n = 50) to hypnotic suggestion, were asked to report on frequency of apparent reversals (ARs) to the Necker cube illusion. Such reports were made in the presence or absence of various types of visual, geometric surrounds (squares, triangles, crosses, or parallelograms). In agreement with a number of previous experiments, susceptible subjects reported perceiving more ARs than did resistant subjects. This difference held whether visual surrounds were present or absent. The presence of surrounds did serve to reduce AR reports regardless of hypnotic susceptibility level. The results are examined in terms of the ability of subjects to selectively attend when confronted with potential visual distractors.

AR reports regardless of hypnotic susceptibility level. The results are examined in terms of the ability of subjects to selectively attend when confronted with potential visual distractors.

1987

Friedman, Howard; Taub, Harvey A.; Sturr, Joseph F.; Monty, Richard A. (1987). Visual information processing speed in hypnotized and nonhypnotized subjects. Journal of General Psychology, 114 (4), 363-372.

Using a backward-masking paradigm with a bias-free and ceiling-free psychophysical task, we tested hypnotized and control subjects for speed of visual information processing. Approximately half of each group received visual imagery suggestions in an attempt to influence attention. Imagery produced no significant differential effect. Although an absence of a hypnotizability-performance relationship was in keeping with findings of a previous study, those subjects in the present study who performed under hypnosis were, as a group, significantly superior to the other subjects in speed of information processing

Kihlstrom, John F. (1987). The cognitive unconscious. Science, 237, 1445-1452.

Contemporary research in cognitive psychology reveals the impact of nonconscious mental structures and processes on the individual's conscious experience, thought, and action. Research on perceptual-cognitive and motoric skills indicates that they are automatized through experience, and thus rendered unconscious. In addition, research on subliminal perception, implicit memory, and hypnosis indicates that events can affect mental functions even though they cannot be consciously perceived or remembered. These findings suggest a tripartite division of the cognitive unconscious into truly unconscious mental processes operating on knowledge structures that may themselves be preconscious or subconscious.

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott; Carlson, Victor (1987). Subjectively complete hypnotic deafness and auditory priming. International Journal of Clinical and Experimental Hypnosis, 35 (1), 32-40.

The present study examined the cognitive and attentional mechanisms by which auditory information is maintained out of awareness during complete hypnotic deafness. Adopting a methodology from recent work on subliminally presented pattern-masked words and dichotic listening, the study tested whether spoken words presented during complete hypnotic deafness affect lexical decisions concerning subsequently presented word choices. The response of 9 hypnotized and 15 simulating Ss to spoken stimulus words presented following hypnotic deafness instructions was compared to the response of 20 baseline control Ss who never were exposed to the stimulus words. While the response pattern of hypnosis Ss appeared different from that of baseline control Ss, hypnotic Ss showed no evidence of the priming effect found in subliminal perception and dichotic listening studies. Simulator response deviated significantly from hypnotized and baseline control responses.

10 highs capable of hypnotic deafness, screened by Harvard Group and Stanford Profile Scales (Means 11.0 and 24.7, respectively) and 15 lows (means 1.7 and 1.7, respectively) participated in the study; the low hypnotizables being in the simulation group. For the experimental session, a different E administered a standard hypnotic induction and the deafness suggestion, testing for deafness by snapping fingers near S's ear and making loud requests for motor responses.

a different E administered a standard hypnotic induction and the deafness suggestion, testing for deafness by snapping fingers near S's ear and making loud requests for motor responses.

An experimental trial consisted of tapping an S on the hand, saying the stimulus word out loud, and visually presenting four words for the S to read out loud and circle one. "Of the 18 main experimental trials, the four-word array consisted of two words which were related to the stimulus (one word which was semantically related to the spoken stimulus word and one word which was phonetically related), and two neutral unrelated words" (p. 34). For example, if the spoken word were 'dream,' the word array might include 'cream, tennis, sell, sleep.' There also were "3 phonetically unrelated trials (whose arrays consisted of one phonetically related

choice and 3 unrelated choices) and 2 stimulus word-unrelated trials (whose arrays consisted of the stimulus word and 3 unrelated choices) ... [and] 7 dummy trials with 4 unrelated choices only" (p. 34). Ss rated their degree of deafness on a 10-point scale after hypnosis was terminated.

Possible sources of bias were examined by having 20 control Ss respond to blank tachistoscopic slides with the instructions that they were participating in a study of 'subliminal perception.' Another 22 Ss were asked to identify the semantically and phonetically related words from the word array, which for the most part they did successfully.

All Ss rated themselves as '10' on the deafness scale, indicating total deafness. The principal results are seen in Tables 1 and 2.

**Table 1 Mean Number of Related and Unrelated Responses (Percentage of Responses) for all S Groups on the 18 Mean Experimental Trials**

**Response Category S Group N Related Unrelated Total**

**Hypnotized 9 7.22 10.78 18**

**(40.13%) (59.88%) (100%)**

**Simulating 15 12.13 5.87 18**

**(67.43%) (32.61%) (100%)**

**Baseline 19 8.79 9.21 18 Controls (48.82%) (51.17%) (100%)**

**Table 2 Mean Number of Phonetic and Semantic Responses within the Related Response Category on the 18 Main Experimental Trials**

**Related Responses S Group Phonetic Semantic Hypnotized 1.78 5.44**

**(9.89%) (30.24%) Simulating 7.07 5.07**

**(39.27%) (28.16%) Baseline 4.21 4.58 Controls (23.38%) (25.44%)**

Hypnotized Ss were significantly different from simulators (Table 1) in number of related responses. Simulators gave significantly more related responses than baseline controls. Simulators also gave more phonetically related words than either the hypnotized or baseline Ss (Table 2); there was no difference between groups on semantically related words. (Authors performed other useful and detailed analyses.)

In their Discussion section, the authors note that they did not obtain the expected results of hypnotized Ss producing more related responses than baseline Ss. "In fact, internal analyses of hypnotized and baseline responses revealed that the pattern of choices for hypnotic deaf Ss was opposite to the direction predicted by subception. Hypnotic Ss appeared to avoid phonetically related word choices, even for items on which baseline control Ss scored above chance. ...

"This kind of non-baseline performance by hypnotic Ss can be accounted for by either a strategic enactment conceptualization of hypnosis (Spanos, 1982; Wagstaff, 1981) or Hilgard's (1979) neo-dissociation theory. Spanos might emphasize the hypnotic S's active strivings to meet the hypnotist's perceived expectations. ... Neo-dissociation theory might stress the mechanisms by which processing of auditory inputs are maintained outside of awareness via a dissociative barrier.

" ... Given the tendency for simulating Ss to 'overplay' hypnotic phenomena (Levitt & Chapman, 1979), one might have expected simulators to pointedly avoid related

responses, thus producing a lower frequency of related words than either the hypnotic Ss or the baseline controls (in effect being more deaf than the deaf). Just the opposite occurred. One possible explanation for this behavior presents itself: In their work with posthypnotic suggestion and the 'disappearing hypnotist' ... M. T. Orne and others found that simulating Ss may be more alert and responsive to demand cues than are hypnotic Ss. In the present study, the authors' original hypothesis was that hypnotic Ss might reveal a subception effect by above-chance responding on related word choices. If we assume that this expectation was somehow communicated to Ss by some subtle aspect of the experimental procedure, then it is conceivable that simulating Ss were able to detect and act upon these cues, while hypnotized Ss remained relatively unattuned to such subtleties.

"In sum, the priming effect noted in the subliminal perception research does not appear to be a feature of complete hypnotic deafness, at least as measured in this study. The behavior of simulating Ss in the present study should be another caution to researchers that differences between hypnotized and simulating Ss may reflect simulation effects in addition to, or instead of, hypnotic effects" (pp. 37-38).

**Popham, Coralee; Bowers, Kenneth (1987, October). A non-replication of the effects of hypnotizability and hypnosis on holistic processing. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Los Angeles**

This reports a non-replication of findings of Crawford & Allen's work with Meir Memory for Pictures art task (retaining a picture in memory while comparing it to a second picture). Only highs got an increase in picture memory while hypnotized. Crawford attributed improvement during hypnosis to holistic processing. This study replicates and extends Crawford, using her task and a second task to assess whether the underlying process is holistic processing (using a Gestalt test they developed). The test involved an incoherent Gestalt produced by rotating parts of a coherent Gestalt. (Ss were required to select the coherent one, and to make a forced choice if they couldn't identify which was correct).

Research Design 1. measured the number correct and percent of unsolved Gestalts correctly selected (Guiding Index) 2. Items were in 2 subsets (40 and 35 items) so Ss could be used as their own controls 3. 48 Ss were screened with the Harvard and then the Waterloo Group Scale form C

Order

Pretest: 1. Waterloo - no effect of hypnosis ability on solving Gestalts 2. Waking condition - when Ss don't know hypnosis is relevant, highs don't do better 3. Lows in Waking condition do better

Posttest: 1. The second subset of 35 pictures was more reliable than the first used above in the pretest. 2. There was no increase from baseline to posttest on Memory for Pictures. 3. There was a significant 3-way interaction: lows' performance was worse hypnotized than during baseline; highs performance was about the same. 4. The Waterloo had a 6% increase but no group interaction. 5. Hypnosis ability didn't lead to the effect. 6. The same goes for the Guiding Index - just practice effects were

found. 7. There was an absence of the 3-way interaction found by Crawford. But the Gestalt task used by Crawford also was different. The shift may be due to primary process thinking (the stimulus is a jumping off point for decreased memory and organization) as opposed to holistic perception (in which there is increased synthesis while remaining responsive to stimulus). This may account for changes observed in highs. That is, highs may be responsible to rather than responsive to the stimulus.

1986

Friedman, Howard; Taub, Harvey A.; Sturr, Joseph F.; Church, Katherine L.; Monty, Richard A. (1986). Hypnotizability and speed of visual information processing. International Journal of Clinical and Experimental Hypnosis, 34, 234-241

Following the determination of the luminance threshold of each S, high and low hypnotizable Ss were tested for speed of information processing using a backward masking paradigm with a bias-free and ceiling-free psychophysical task. No significant relationship between hypnotizability as measured by the Stanford Hypnotic Susceptibility Scale, Form A (SHSS:A) of Weitzenhoffer and Hilgard (1959) and speed of information processing was observed. The order of administering SHSS:A, pre- or postthreshold task, was significantly related to luminance threshold. Results were compared to other studies wherein some evidence for a relationship between hypnotizability and speed of visual information processing had been offered.

106 college students were tested using tachistoscopic presentation of stimuli. 52 Ss received the SHSS:A immediately prior to the experimental tasks, 54 immediately after, and testing was terminated for each Subject after they failed 3 successive items. The test flash was set at 0.3 log units above threshold, i.e. double the threshold intensity. A trial consisted of 2 observation intervals, separated by warning tones. The test flash occurred randomly in one of the two intervals. The S indicated which observation interval contained the test flash by pressing a button. Feedback tones gave S information about the correct response.

"The masking experiment was begun with the suprathreshold test flash occurring 250 milliseconds prior to the onset of the larger bright masking stimulus. As before, a two-interval forced -choice staircase procedure was used, but this time the test intensity was constant, and ISI was changed. If S 'hit' three trials in a row, ISI was decreased by 10 milliseconds. The ISIs continued to decrease in 10-millisecond steps, until S "missed," causing an increase in ISI" (p. 348).

RESULTS were analyzed by 2 x 2 x 2 ANOVA (Hypnotizability, sex, and order of hypnotizability measurement). High hypnotizables = 7-12 on the SHSS:A, and low hypnotizables = 0-6. Ss receiving SHSS:A prior to the tasks had a significantly lower luminance threshold (-1.99 log mL) than did those having it after tasks (-1.93 log mL),  $p < .05$ . None of the other analyses were significant. No significant relationships were observed vis a vis the masking task, and the mean masking thresholds were almost identical for the lows and highs.

**DISCUSSION.** "Spanos (1982), in studying the effects of hypnotizability and suggestions in altering auditory sensitivity, reviewed the difficulties inherent in the measurement of perceptual accuracy and emphasized the role of response bias in the confounding of results" (p. 239). Secondly, these tasks reflect more fundamental, central processes and use more neutral stimuli than letter recognition used earlier. "Thus, while the masking effects of both the previous recognition tasks (masking by pattern) and the current detection tasks (masking by nearby contours) are presumably mediated through similar high level central processes, the differences in findings could possibly have been related to additional processing cues required in letter recognition" (p. 239). A footnote mentions, "Other studies have shown that with stimulus configurations similar to that used in the present study, there are significant central masking effects (Battersby & Wagman, 1962; Markoff & Sturr, 1971; Turvey, 1973)" (p. 239).

"Quite intriguing is the luminance threshold finding which, although not as robust as one would desire, suggests that a hypnotic induction procedure given prior to a task may significantly affect sensitivity on that task. Speculatively, the relaxation suggestions inherent in SHSS:A may account for the changes in luminance threshold" (p. 239).

Priebe, Frances A.; Wallace, Benjamin (1986). Hypnotizability, imaging ability, and the detection of embedded objects. International Journal of Clinical and Experimental Hypnosis, 34, 320-329.

40 Ss participated in an experiment designed to determine the influence of hypnotizability and imaging ability on cognitive performance. Individuals were asked to locate objects embedded within a series of pictorial scenes. For each scene, Ss were allocated a total of 6 minutes to find as many objects as possible. The objects were described to Ss prior to their search for them. Although there were no significant differences in total number of objects found as a function of hypnotizability, high hypnotizable Ss made significantly fewer errors in locating and identifying objects. This difference was attributed to the superior ability of the high hypnotizability Ss in visualizing the hidden objects and in using produced images as a means for correctly identifying them. This did not appear to be the case for the low hypnotizability Ss. It was this difference in search strategy that may ultimately have led to the error difference between high and low hypnotizable Ss.

High hypnotizables "have been shown to be better able to resist distractions in a tracking task (Mitchell, 1970); to concentrate on their own breathing or on a candle flame (Van Nuys, 1973); to listen to a target story along with a nontarget story and to report what they could remember about the target story (Karlin, 1979); and to perceive Necker cube and Schroeder staircase illusory reversals (Wallace, Knight, & Garrett, 1976).

"Cognitive performance also has been shown to be influenced by imaging ability. For example, Paivio & Ernst (1971) found that when Ss were asked to identify letters, pictures, and geometric forms flashed to either the left or right visual field, those judged to be high imagers on a self-report test demonstrated better visual

recognition. Similar findings were reported by Gur and Hilgard (1975) and Paivio (1978a, b).

"In addition to reports that imaging ability and hypnotizability affect performance on a variety of cognitive tasks, there have also been reports that these two variables are related, at least to some degree (Diamond & Taft, 1975; Palmer & Field, 1968; Sutcliffe, Perry, & Sheehan, 1970). Some, however, have found that ... low imagers tend to be low in hypnotizability but high imagers may not necessarily be high in hypnotizability (Perry, 1973)" (pp. 320-321). A correlation between hypnotizability and imaging ability also was found by T'Hoen (1978) in a paired associates learning task in which imagery and concreteness of the word pairs was varied; and by other investigators using other research designs (Gur & Hilgard, 1975; Paivio, 1978a, b; Paivio & Ernst, 1971).

Cognitive performance of high hypnotizable people was superior to low hypnotizables when the task was locating an imbedded letter ('Z') or completing double-digit arithmetic problems (Wallace and Patterson, 1984), possibly because highs may be using imagery to facilitate their performance. Highs performed better in detecting small differences in picture pairs when hypnotized but not when awake (Crawford and Allen, 1983). It appears that both highs and lows may use memorization of details for task performance, but only highs switch to a 'holistic' cognitive processing style, and mostly during hypnosis. Actually, Wallace and Patterson (1984) found that highs also used a holistic strategy in the waking state, not just in the hypnotized condition.

In the present study, subjects were 40 volunteers (20 highly hypnotizable subjects with scores of 9-12 on the Harvard Group Scale of Hypnotic Susceptibility, and 20 lows with scores of 0-3). The task was to locate hidden objects in pictures, with level of difficulty rated as hard, medium, or easy. The outcome data were analyzed by analysis of variance for hypnotizability, picture difficulty, and time (six successive 1-min periods).

In Session 1 subjects were administered the Harvard Scale and the Marks Vividness of Visual Imagery Questionnaire; in Session 2 the group Stanford Hypnotic Susceptibility Scale: C was administered.

Before the actual experimental task of circling hidden pictures within larger pictorial scenes, each subject was given a list of words representing things that were embedded in the scenes, and asked to visualize each item. Then they were given six minutes to complete the item-finding task. They received three scores: the total number of objects located in six minutes, the number of objects correctly found, and number of errors. The 2x3x6 ANOVA was performed for each of these three dependent variables.

high imagers may not necessarily be high in hypnotizability (Perry, 1973)" (pp. 320-321). A correlation between hypnotizability and imaging ability also was found by T'Hoen (1978) in a paired associates learning task in which imagery and concreteness of the word pairs was varied; and by other investigators using other research designs (Gur & Hilgard, 1975; Paivio, 1978a, b; Paivio & Ernst, 1971).

Cognitive performance of high hypnotizable people was superior to low hypnotizables when the task was locating an imbedded letter ('Z') or completing double-digit arithmetic problems (Wallace and Patterson, 1984), possibly because

highs may be using imagery to facilitate their performance. Highs performed better in detecting small differences in picture pairs when hypnotized but not when awake (Crawford and Allen, 1983). It appears that both highs and lows may use memorization of details for task performance, but only highs switch to a 'holistic' cognitive processing style, and mostly during hypnosis. Actually, Wallace and Patterson (1984) found that highs also used a holistic strategy in the waking state, not just in the hypnotized condition.

In the present study, subjects were 40 volunteers (20 highly hypnotizable subjects with scores of 9-12 on the Harvard Group Scale of Hypnotic Susceptibility, and 20 lows with scores of 0-3). The task was to locate hidden objects in pictures, with level of difficulty rated as hard, medium, or easy. The outcome data were analyzed by analysis of variance for hypnotizability, picture difficulty, and time (six successive 1-min periods).

In Session 1 subjects were administered the Harvard Scale and the Marks Vividness of Visual Imagery Questionnaire; in Session 2 the group Stanford Hypnotic Susceptibility Scale: C was administered.

Before the actual experimental task of circling hidden pictures within larger pictorial scenes, each subject was given a list of words representing things that were embedded in the scenes, and asked to visualize each item. Then they were given six minutes to complete the item-finding task. They received three scores: the total number of objects located in six minutes, the number of objects correctly found, and number of errors. The 2x3x6 ANOVA was performed for each of these three dependent variables.

Hypnotizability was not an important variable determining the number of correct objects located, but was significantly associated with the occurrence of fewer errors. Mean errors were 4.5 for Lows and 2.7 for Highs. Furthermore, hypnotizability was associated with using a 'holistic strategy' rather than a 'detail strategy' for finding items (self report on storing a memory of the list of objects-to-be found, preparatory to making the search, rather than checking back with the list during the search). Hypnotizability correlated with imaging ability  $r = .34, p < .05$ .

In their Discussion, the authors noted that low hypnotizable people did not tend to use imagery for locating hidden objects, but would glance back and forth between the list and the picture--sometimes using a check-off mark next to items. High hypnotizables spent an average of 20 seconds looking at the list and becoming more familiar with it before starting to try to find the hidden objects. "One can assume this was a preparatory step in the formation of images for a subsequent visual search and the deployment of a holistic strategy during the search.

"When asked why they engaged in their respective behaviors, low hypnotizables generally said that they were not too concerned with the list initially because they searched for hidden items by constructing objects out of discrepancies in the picture. Only when they found what they thought had the properties of an embedded object did the list become important. At that point they would refer back to the list to determine if the object was among those to be located. The list thus served as a tool for confirming the existence of an object they had found as well as a means for enabling them to double check which items they still had to find. High hypnotizable Ss generally claimed that they formed mental images in their heads for

each item on the list. Once they found an object in the picture, they compared that object to the formed, mental image rather than referring back to the actual list.

"As was previously mentioned, Crawford and Allen (1983) only found a difference in cognitive strategy between high and low hypnotizable Ss in the hypnotic state. In the present study, however, a strategy difference between these groups was noted in the waking state but only in terms of number of errors produced. A significant difference between high and low hypnotizables was not found in terms of the number of objects correctly found in a pictorial scene within a set period of time. It is possible that had cognitive strategies used in the hypnotic state been compared to those used in the waking state, our results might have been different. It is equally plausible, however, that hypnosis is not the critical factor in producing the difference between the results of the present study and those of Crawford and Allen (1983). It is possible that high hypnotizable Ss may show a holistic strategy when they are encouraged to involve themselves imaginatively and this encouragement is naturally provided in hypnosis, but it could also be present in the waking state if the task being used is appropriately structured. The task used in the present study is one that could be said to especially encourage the use of imagery, and in this sense, it may be relatively distinct from that used by Crawford and Allen. The fact that Ss practiced imagery on the element list beforehand simply reinforces the difference. Thus, the nature of the cognitive task may be what is at issue and not the presence or absence of

as a means for enabling them to double check which items they still had to find. High hypnotizable Ss generally claimed that they formed mental images in their heads for each item on the list. Once they found an object in the picture, they compared that object to the formed, mental image rather than referring back to the actual list.

The fact that Ss practiced imagery on the element list beforehand simply reinforces the difference. Thus, the nature of the cognitive task may be what is at issue and not the presence or absence of hypnosis" (p. 327).

Wallace, Benjamin (1986). Latency and frequency reports to the Necker cube illusion: Effects of hypnotic susceptibility and mental arithmetic. Journal of General Psychology, 113 (2), 187-194.

An experiment (N = 32) was conducted to assess latency of first apparent reversal (AR) and AR frequency while observing the Necker cube illusion. Subjects who were either high in hypnotic susceptibility (susceptibles) or low in hypnotic susceptibility (resistant subjects) observed the cube either while performing or not performing mental addition problems. Susceptibles reported perceiving the first AR more quickly and a greater frequency of ARs than did resistant subjects. Also, latency of the first AR was negatively correlated with AR frequency. These results were interpreted in terms of the ability of susceptibles to allocate concentrative or selective attention in a manner that was conducive to faster performance when faced with competing tasks.

1985

Acosta, Enrique; Crawford, Helen J. (1985). Iconic memory and hypnotizability: Processing speed, skill or strategy differences?. International Journal of Clinical and Experimental Hypnosis, 33, 236-245.

The purported relationship between hypnotizability and speed of information transfer from iconic to short-term memory was studied in a comparison of 12 low and 12 high hypnotizable Ss. As in Ingram, Saccuzzo, McNeill, and McDonald (1979), high hypnotizable Ss showed less interference from a visual mask in the report of a briefly presented item than did low hypnotizable Ss when the mask delays were predictable. When the delay of the mask could not be anticipated, however, differences between high and low hypnotizable Ss disappeared. It is suggested that differences in information processing related to hypnotizability may be due to differences in strategy, skills, or other factors, rather than underlying information processing speed.

that differences in information processing related to hypnotizability may be due to differences in strategy, skills, or other factors, rather than underlying information processing speed.

Hypnosis may require concentrative or selective attention, which usually is measured by self-report (e.g. Absorption) or by experimental measures. Several investigations indicate that high hypnotizable people are better than low hypnotizables at focusing on a task and ignoring extraneous information (Brown, Crawford, Smith, Leu, & Brock, 1983; Graham & Evans, 1977; Karlin, 1979; Miller, 1975; Wallace, 1979; Wallace, Garrett, & Anstadt, 1974; Wallace, Knight, & Garrett, 1976). One way to study attentional processes is through the effect of presenting a mask (e.g. \$\$\$\$) shortly after presenting a stimulus (e.g. ABCDE). Ingram (1979) found that highs had faster information processing, but that might be due to anticipation bias associated with the method of limits employed. This study uses both an ascending method of limits, like Ingram, and a condition in which the mask delays were presented randomly within another block of trials.

## RESULTS

"While the present study replicated Ingram et al.'s (1979) findings when an ascending method of limits was used (the same used by Ingram et al.) differences were not found in processing when ISIs were presented randomly. Thus, these results suggest that high and low hypnotizable Ss do not differ in their information transmission rates, but rather they may differ in other aspects which mediate performance in this task" (pp. 241- 242).

"Several lines of evidence point towards strategy or skill differences between high and low hypnotizable Ss as a possible explanation for the present findings. First, it was found that when Ss could anticipate the mask delay (the ascending condition), high hypnotizable Ss outperformed the low hypnotizables. When this anticipation was controlled, as in the random condition, the two groups did not differ when the data were scored by serial position. When the data were scored by a free recall scheme, there was a nonsignificant trend for high hypnotizable Ss to score higher than did the low hypnotizables. This trend suggests that high hypnotizable Ss may be more willing to guess, and to guess more accurately than low hypnotizables, when they have partial information about a letter, and/or they may have greater skill in perceiving incomplete information. The latter suggestion finds indirect support from Crawford (1981) who reported that high hypnotizable Ss can process fragmented stimuli (Gestalt Closure tests, see Thurstone & Jeffrey, 1966), significantly better than can low hypnotizables. High imagers have been shown also to perform significantly better than low imagers in Gestalt Closure tasks (Ernest, 1980). At a speculative level, given that recent research has suggested that iconic memory may be a right hemisphere phenomenon (e.g. Cohen, 1976, but also see DiLollo, 1981), and high hypnotizable Ss outperform low hypnotizables on certain right hemisphere tasks (e.g. Crawford, 1981), it may be asked if the trends found with the free recall scoring scheme in the present study might be a reflection of differential right hemisphere processing. Such a hypothesis could be investigated in future research by comparing the performance of high and low hypnotizable Ss, as possibly moderated by visuo-spatial ability, for stimuli presented to the left versus the right visual hemifield (Ernest, 1983).

"A second set of evidence in favor of strategy differences was found in Saccuzzo et al. (1982) which was published after the data for the present experiment were collected. In the Saccuzzo et al. (1982) paper, which was an extension and replication of Ingram et al. (1979), the same mask delay was used throughout a 10-trial block. The order of the blocks (i.e., the mask delays) was random. Thus, while S did not know which mask delay was used in the first trial of a block, the remaining 9 trials were the same and could be anticipated. During the first session, high hypnotizable Ss outperformed the low hypnotizables, but these differences disappeared on the second testing session. These results suggest that practice may have affected performance, rather than any underlying information processing speed differences" (pp. 242-243).

Oliver, J. M.; Burkham, Robert (1985). 'Comments on three recent subliminal psychodynamic activation investigations': Reply to Silverman. Journal of Abnormal Psychology, 94 (4), 644.

Contends that the present authors' (see PA, vol 69:1571) failure to replicate L. H. Silverman's (1976) description of subliminal psychodynamic activation, which was disputed by Silverman (see PA, vol 73:12007), can be traced in part to Silverman's (1978) description of the "symbiotic" stimulus (MOMMY AND I ARE ONE"), 1 of the 2 experimental stimuli used, as a "ubiquitous therapeutic agent". It is suggested that, although Silverman's willingness to modify his theory in light of empirical findings is commendable, modifications that are too frequent and numerous will pose problems for both theory and research. (5 ref)

Porterfield, Albert L.; Golding, Stephen L. (1985). Failure to find an effect of subliminal psychodynamic activation upon cognitive measures of pathology in schizophrenia. Journal of Abnormal Psychology, 94 (4), 630-639.

Replicated the work of L. H. Silverman and colleagues (see PA, vols. 43:14557 and 46:1566) using 30 21-59 year old schizophrenics. Ss were exposed to an aggressive, a merging, and a meaningless lexical stimulus in a within-S design. Dependent variables were inkblot through pathology and form quality, as measured on Rorschach and Holtzman Inkblot Techniques, and performance on the interference task of the Stroop Color-Word Test. Analyses of variance conducted on simple poststimulation scores, rather than on unreliable change scores, revealed no effect of stimulus content. Predicted interactions between stimulus content, Ss self-object differentiation, and temporal position of the assessment tasks did not emerge. Findings do not support Silverman's hypothesis that subliminal tachistoscopic presentations of stimuli with aggressive content temporarily increase thinking disorder in schizophrenics. (44 ref.)

Porterfield, Albert L. (1985). 'Comments on three recent subliminal psychodynamic activation investigations': Reply to Silverman. Journal of Abnormal Psychology, 94 (4), 645-646.

Contends that in defending his nonverbal pathology measure against the claim that it lacks demonstrated validity, L. H. Silverman (see PA, vol 73:12007) painted a misleading picture of its face validity. A correction to that picture is presented, and the impact of the present author and S. L. Golding's (see PA, vol 73:11992) findings on subliminal psychodynamic activation explanations of schizophrenic thought disorder is defended, despite the absence of a nonverbal pathology measure. (5 ref)

Silverman, Lloyd H. (1985). 'Comments on three recent subliminal psychodynamic activation investigations': Rejoinder to Oliver and Burkham and to Porterfield. Journal of Abnormal Psychology, 94 (4), 647-8.

Considers the replies of A. L. Porterfield (see PA, vol 73:11991) and J. M. Oliver and R. Burkham (see PA, vol 73:11985) to the critique of the present author (see PA,

vol 73:12007). The original criticisms are seen as valid. A critical deficiency in the design of Porterfield and S. L. Golding's (see PA, vol 73:11992) study is viewed as disqualifying it as a fair attempt at replication. It is suggested that although Oliver and Burkham's (see PA, vol 69:1571) study was well-designed, statements made in their write-up are unwarranted. (12 ref)

Silverman, Lloyd H. (1985). Comments on three recent subliminal psychodynamic activation investigations. Journal of Abnormal Psychology, 94 (4), 640-643.

Contends that unwarranted statements about subliminal psychodynamic activation research by the present author (1976, 1983, 1984) were made in the work of J. M. Oliver and R. Burkham (see PA, vol. 69:1571); K. C. Haspel and R. S. Harris (see PA, vol 69:4952) and A. L. Porterfield and S. L. Golding (see PA, vol 73:11992). Issues considered include the choice of subliminal stimuli, the present author's statistical analyses, and the necessity of a nonverbal measure of psychopathology in this research (17 ref).

Silverman, Lloyd H. (1985). Research on psychoanalytic psychodynamic propositions. Clinical Psychology Review, 5 (3), 247-257

Discusses a research program in which the present author has been involved that deals with the subliminal psychodynamic activation method. In this method, verbal and/or pictorial stimuli, some of which contain content related to unconscious wishes, fears, and fantasies and other of which are (relatively) neutral, are presented to Ss at 4-msec exposures. A variety of psychoanalytically based hypotheses have been tested on various clinical and nonclinical populations. Two major findings have emerged: (a) a number of clinical groups (e.g., schizophrenics, depressives, stutterers) have shown intensifications of their symptoms after the subliminal exposure of stimuli designed to stir up particular unconscious conflicts; and (b) various clinical and nonclinical groups have manifested enhanced adaptive behavior after the subliminal exposure of the message "Mommy and I are one," conceived as activating unconscious symbiotic fantasies.

1984

Bryant-Tuckett, Rose; Silverman, Lloyd H. (1984). Effects of the subliminal stimulation of symbiotic fantasies on the academic performance of emotionally handicapped students. Journal of Counseling Psychology, 31 (3), 295-305.

Divided 64 10.8 - 19.3 yr old emotionally disturbed residents of a treatment school into an experimental and control group matched for age, IQ, and reading ability. Both groups were seen 5 times/week for 6 weeks for tachistoscopic exposures of a subliminal stimulus. The stimulus for the experimental group was the phrase, "Mommy and I are one," conceived of as activating symbiotic fantasies that in a number of previous studies with varying groups of Ss had led to greater adaptive behavior. The control group was exposed to the phrase, "People are walking." Results show that experimental Ss

manifested significantly greater improvement on the California Achievement Tests--Reading than did the controls. On 5 of 6 secondary variables--arithmetic achievement, self-concept, the handing in of homework assignments, independent classroom functioning, and self-imposed limits on TV viewing--the experimental Ss showed better adaptive functioning. It is suggested that activation of unconscious symbiotic fantasies can increase the effectiveness of counseling and teaching. (42 ref)

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott (1984). The direct hypnotic suggestion of altered mind/body perception. American Journal of Clinical Hypnosis, 27, 95-102.

Attentional and emotional shifts are examined following a hypnotically suggested out-of-body experience (OBE). Two hypotheses were tested: 1) that the OBE is maintained by blocking the perception of body-relevant stimulation at a sensory level; 2) that a hypnotically produced OBE is an emotionally neutral or even pleasant experience. Fourteen hypnotic subjects and 15 simulating Ss were administered a standardized induction followed by suggestions for an OBE. Geometric figures were then presented to the body but not to the "awareness." Although hypnotic Ss reported that they could not see the information, they still correctly "guess" the identity of the figures beyond chance levels. Thus, body-relevant information was obviously not blocked at a sensory level, but was kept out of awareness by some other mechanism. In addition, a significantly greater number of hypnotized than simulating Ss reported the OBE to be troubling and unpleasant, despite explicit suggestions for a positive experience. The potentially disturbing nature of OBEs and ways to minimize risk of negative affect are discussed.

Palumbo, Robert; Gillman, Irene (1984). Effects of subliminal activation of oedipal fantasies on competitive performance: A replication and extension. Journal of Nervous and Mental Disease, 172 (12), 737-741.

Conducted a subliminal psychodynamic activation experiment in which the effects of 5 subliminal stimuli were sought on the dart-throwing performance of 40 male Ss (aged 22-46 years). The stimuli consisted of the following messages, each accompanied by a congruent picture: "beating dad is ok," "beating dad is wrong," "beating him is ok," "beating him is wrong," and "people are walking." The 1st 2 stimuli were intended to activate competitive motives within the context of the Oedipus complex; the next 2, competitive motives outside that context; and the last message was intended as a control stimulus. Findings show that "beating dad is ok" led to greater dart-throwing accuracy than each of the other 4 conditions, which, in turn, did not differ from each other. This finding replicates a result reported by L. H. Silverman et al (1978) and is in keeping with the formulation that the activation of oedipal motives can affect competitive performance (7 ref)

Venturino, Michael (1984, August). Perceptual monitoring and allocation of attention (Dissertation, University of Maine). Dissertation Abstracts International, 45 (2), 707-B.

"The processing ability of perceptual monitoring was investigated using a dichotic listening and shadowing task. Individual differences in the effectiveness of perceptual monitoring were also investigated by using susceptibility to hypnosis as a grouping factor. Subjects' skin conductance response (SCR) was conditioned to specific words by an electric shock. These conditioned words, and words semantically and acoustically related to them were presented in the relevant and irrelevant messages of the dichotic listening and shadowing task. Probability and magnitude measures of SCRs and subjects' verbal shadowing accuracy were used to assess performance. SCRs to critical words were significantly greater than to control words in both the relevant and irrelevant messages. However, the SCRs to words in the irrelevant messages were not as great as those responses elicited to words in the relevant message. The pattern of responding to the semantically and acoustically related words was similar for both the relevant and irrelevant messages. Subjects low in hypnotic susceptibility responded to critical words with significantly greater probability and magnitude of response than did subjects high in hypnotic susceptibility. Analysis of the shadowing performance data showed that the perceptual monitoring process was quite effective. The occurrence of the conditioned word in the irrelevant message caused a shift in attention to the irrelevant message, manifested by a shadowing error. Subjects shadowing the message in their left ear committed significantly more shadowing errors than subjects shadowing the message in their right ear. No differences in shadowing performance were obtained for the hypnosis factor. The results were interpreted in terms of the deployment of attention to the environment, and the relationship of this deployment to the perceptual monitoring process" (p. 707).

Wallace, Benjamin; Patterson, Sondra Lou (1984). Hypnotic susceptibility and performance on various attention-specific cognitive tasks. Journal of Personality and Social Psychology, 47, 175-181.

Conducted two experiments to investigate cognitive performance as related to level of hypnotic susceptibility. In Experiment 1 time-to-location of a target in a visual search task was assessed. For this task the letter Z was embedded either within straight- form or round-form letters. Results indicated that high hypnotizable Subjects were significantly faster than low-hypnotizability Subjects in locating the embedded letter. Experiment 2 investigated performance on single- and double-digit arithmetic (addition) problems as a function of hypnosis susceptibility level. Subjects were presented with arithmetic problems and were asked to complete them within a 60-s time period. Highs completed a significantly greater number of double-digit problems but not single-digit problems within this time frame than did lows. The results of the two experiments are explained in terms of the application of differing strategies or operations by highs and lows in the performance of cognitive tasks.

1983

**Borgeat, Francois; Goulet, Jean (1983). Psychophysiological changes following auditory subliminal suggestions for activation and deactivation. Perceptual and Motor Skills, 56, 759-766.**

**This study was to measure eventual psychophysiological changes resulting from auditory subliminal activation or deactivation suggestions. 18 subjects were alternately exposed to a control situation and to 25-dB activating and deactivating suggestions masked by a 40-dB white noise. Physiological measures (EMG, heart rate, skin-conductance levels and responses, and skin temperature) were recorded while subjects listened passively to the suggestions, during a stressing task that followed and after that task. Multi-variate analysis of variance showed a significant effect of the activation subliminal suggestions during and following the stressing task. This result is discussed as indicating effects of consciously unrecognized perceptions on psycho- physiological responses.**

**Crawford, Helen J.; Allen, Steven N. (1983). Enhanced visual memory during hypnosis as mediated by hypnotic responsiveness and cognitive strategies. Journal of Experimental Psychology: General, 112 (4), 662-685.**

**To investigate the hypothesis that hypnosis has an enhancing effect on imagery processing, as mediated by hypnotic responsiveness and cognitive strategies, four experiments compared performance of low and high, or low, medium, and high hypnotically responsive subjects in waking and hypnosis conditions on a successive visual memory discrimination task that required detecting differences between successively presented picture pairs in which one member of the pair was slightly altered. Consistently, hypnotically responsive individuals showed enhanced mean number of correct performance during hypnosis, whereas nonresponsive ones did not. Hypnotic responsiveness correlated .52 ( $p < .001$ ) with enhanced performance during hypnosis, but it was uncorrelated with waking performance (Experiment 3). Reaction time was not affected by hypnosis, although high hypnotizables were faster than lows in their responses (Experiments 1 and 2).**

**Subjects reported enhanced imagery vividness on the self-report Vividness of Visual Imagery Questionnaire during hypnosis. The differential effect between lows and highs was in the anticipated direction but not significant (Experiments 1 and 2).**

**Two cognitive strategies appeared to mediate visual memory performance: (a) detail strategy (memorization and rehearsal of individual details) and (b) holistic strategy (looking at and remembering the whole picture with accompanying imagery). Both lows and highs reported predominantly detail-oriented strategies during waking; however the highs shifted to a more holistic strategy during hypnosis. It appears that high hypnotizables have a greater capacity than lows for cognitive flexibility (Battig, 1979).**

**Results are discussed in terms of Paivio's (1971) dual coding theory and Craik and Tulving's (1975) depth of processing theory. The authors also discuss whether**

hypnosis involves a shift in cerebral dominance, as reflected by the cognitive strategy changes and enhanced imagery processing.

Spanos, Nicholas P.; Dubreuil, Debora L., Saad, Carol L., Gorassini, Donald (1983). Hypnotic elimination of prism-induced aftereffects: Perceptual effect or responses to experimental demands?. Journal of Abnormal Psychology, 92 (2), 216-222.

Two experiments assessed adaptation to displacing prisms in hypnotically limb-anesthetized Ss. Experiment I with 18 college students disconfirmed the hypothesis that the displacement aftereffect is eliminated in limb-anesthetized hypnotic Ss who adapt to prisms in the absence of a visual target. Such Ss showed as large a displacement aftereffect as control Ss who received neither a hypnotic induction procedure nor an anesthesia suggestion. Experiment II with 30 undergraduates demonstrated that under some testing conditions hypnotic Ss complied with experimental demands and eliminated the behavioral but not the perceptual component of the aftereffect.

Undergraduates demonstrated that under some testing conditions hypnotic Ss complied with experimental demands and eliminated the behavioral but not the perceptual component of the aftereffect.

1982

Farthing, G. William; Brown, Scott W.; Venturino, Michael (1982). Effects of hypnotizability and mental imagery on signal detection sensitivity and response bias. International Journal of Clinical and Experimental Hypnosis, 30, 289-305.

It was hypothesized that the ability to selectively concentrate attention on mental images would be greater among high hypnotizable Ss than among low hypnotizable Ss, as indicated by a greater interference with visual signal detection by concurrent visual mental imagery in response to specified nouns. This hypothesis was not supported in the overall results, though the finding of a significant interference effect among the high hypnotizable female Ss, but not among other subgroups, indicates that further research with a more refined procedure might be worthwhile. On the control trials without images, the high hypnotizable Ss made more false alarms than lows, and had a significantly different bias index indicating that high hypnotizable Ss were more likely than lows to respond "yes" when uncertain about whether the signal was present; false alarms can be interpreted as a nonhypnotic measure of suggestibility. The high and low hypnotizable Ss did not differ in their times to generate images in response to the specified nouns.

Saccuzzo, Dennis P.; Safran, Deborah; Anderson, Virginia; McNeill, Brian (1982). Visual information processing in high and low susceptible subjects. International Journal of Clinical and Experimental Hypnosis, 30, 32-44.

High and low hypnotically susceptible Ss were compared in their ability to identify a briefly exposed informational target stimulus consisting of a letter when it was preceded (forward masking) or followed by (backward masking) a

noninformational mask stimulus. There were 4 intervals between the target and mask and a no mask control for both forward and backward masking. The experiment was replicated in 2 independent sessions. In Session 1 high susceptible Ss were superior to lows in identifying the target stimulus. The superiority was not maintained in Session 2. Implications of the findings and directions for future research are discussed.

Silverman, Lloyd H.; Lachmann, Frank M.; Milich, Robert H. (1982). The search for oneness. New York: International Universities Press.

This book summarizes research on preconscious activation (subliminal psychodynamic activation) of fantasies of oneness, following tachistoscopic presentation of words like, "Mommy and I are one." It represents an attempt to test and validate, through experimental investigation, psychoanalytic concepts. The authors show how such fantasies can improve psychosocial adaptation for people with varying kinds of psychopathology.

Wallace, Benjamin; Fisher, Leslie E. (1982). Hypnotically induced limb anesthesia and adaptation to displacing prisms: Replication requires adherence to critical procedures. Journal of Abnormal Psychology, **91** (5), 390-391.

N. P. Spanos et al. (see PA, vol 66:7289) reported a failure to confirm the results of an experiment on prism adaptation reported by the present authors (see PA, vol 65:6956) that required Ss to adapt to a prismatically displaced environment when their adapting limb was hypnotically anesthetized. The present authors argue that the failure of Spanos et al to replicate their findings is due to their failure to duplicate the critical conditions of the experiment. (7 ref)

Bauer, Herbert; Berner, Peter; Steinringer, Hermann; Stacher, Georg (1980). Effects of hypnotic suggestions of sensory change on event-related cortical slow potential shifts. Archiv fur Psychologie, **133** (3), 161-169.

"The purpose of this study was to evaluate whether cortical slow potentials related to a S1-S2 paradigm are influenced by hypnotic suggestions of sensory change. Five healthy subjects susceptible to hypnosis participated each in two identical experiments with three conditions. In condition (1) and (2) each three intensities of 800 and 4000 Hz tones were presented. Preceding condition (2) hypnosis was induced and the subjects received the suggestion to hear the 800 but not the 4000 Hz tones. In condition (3), the tones were presented as S1 and a flash as S2. The subjects received the same suggestions as in (2) and a motor response to S2 was required. EEG was recorded from Cz. In (1) 800 and 4000 Hz tones caused negativities of equal amplitude, in (2) only minute negativities developed, possibly due to hypnosis induced deactivation. In (3) the S1-S2 related negativities were significantly smaller in amplitude during 4000 Hz tones than during 800 Hz tones, while the negativities preceding S2 differed only after the most intense S1. Hypnotic

suggestions attenuate S1-S2 related negative potentials, possibly by affecting cognitive functions.

Hilgard, Ernest R. (1980, October). Hypnotic modification of sensitivity and control. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Chicago.

The author presents a factor analysis of several scales in the hypnosis domain: HGSHS:A, Wilson-Barber CIS, Stanford Hypnotic Susceptibility Scale Form C, Questionnaire on Mental Imagery (Sheehan's modification of Betts) and the Tellegen- Atkinson Absorption Scale. Scales were broken down into components first. He didn't report all of the factors, but shows how these tests fall on a graph defined by Factor 1 (Amnesia/Cognitive) and Factor 4 (Absorption/Imagery). "Capacity for fantasy and amnesia are so different that hypnosis probably includes both."

Hilgard concludes that he doesn't like a state theory for hypnosis or the idea of "trance" because it is unidimensional. He prefers "dissociation" because we think of it as a continuum. Even Highs differ one from another in the nature of their responses. Altered- state-of-consciousness theories don't readily explain partial dissociation (e.g. persistence of a suggestion such as arm rigidity after hypnosis is terminated; or hysterical paralysis).

Shevrin, Howard; Dickman, Scott (1980). The psychological unconscious: A necessary assumption for all psychological theory?. American Psychologist, 35 (5), 421-434.

The notion of complex psychological processes operating outside of awareness has traditionally been associated with the concept of the unconscious used by psychodynamically oriented clinicians; it has never found an equivalent place in the mainstream of American experimental psychology. However, mounting evidence from several rather diverse fields of empirical research (e.g., selective attention, cortical evoked potentials, subliminal perception) provides support for such a concept, and, in fact, explanatory constructs of a similar nature have been embodied in several current models of perceptual processing. While there clearly remains an enormous gap between the clinically based conception and the experimentally based conception of the nature of these unconscious processes, they nevertheless seem to provide an interface between two seemingly disparate approaches to the understanding of personality.

1979

Ingram, Rick E.; Saccuzzo, Dennis P.; McNeill, Brian; McDonald, Roy (1979). Speed of information - processing in high and low susceptible subjects - preliminary study. International Journal of Clinical and Experimental Hypnosis, 27 (1), 42-47.

A backward masking paradigm was employed to test the hypothesis that high hypnotic susceptible Ss are able to process information at a faster rate than low

susceptible Ss. The critical interstimulus interval was determined for 8 high and 8 low susceptible Ss. A t-test analysis of the critical interstimulus intervals showed a significant difference between high and low susceptible Ss with the high susceptible Ss showing a lower critical interstimulus interval. Mean critical inter-stimulus intervals for the high (76 milliseconds) and low (98 milliseconds) susceptible groups suggested that the high susceptible Ss were an average of 22 milliseconds faster at processing information. Results were interpreted as being consistent with, and providing support for attentional theories of hypnosis.

Spanos, Nicholas P.; Ansari, Ferhana; Stam, Henderikus J. (1979). Hypnotic age regression and eidetic imagery: A failure to replicate. Journal of Abnormal Psychology, 88 (1), 88-91.

Walker, Garrett, & Wallace (1976) reported the restoration of eidetic imagery in hypnotically age-regressed subjects. In an attempted replication of that study, 60 subjects who previously scored high on hypnotic susceptibility were 'hypnotically regressed' to age 7. Before administration of the hypnotic procedures and again after age regression, subjects were tested for eidetic imagery using the random-dot stereograms employed by Walker et al. None of our subjects including those who were age regressed according to standard criteria and who reported having been eidetikers as children, were successful at the stereogram tasks. Although these results fail to replicate those of Walker et al., they are consistent with the available evidence concerning the performance of children on stereogram tasks. Contrary to the impression conveyed by Walker et al., children tested to date, including those classified as eidetikers by Haber and Haber's criteria, have been unsuccessful at stereogram tasks.

1978

Blum, Gerald S.; Porter, M. L.; Geiwitz, P. J. (1978). Temporal parameters of negative visual hallucination. International Journal of Clinical and Experimental Hypnosis, 26, 30-44.

Negative visual hallucination was investigated by hypnotically programming two highly trained undergraduates not to see the colored lines of consonants while perceiving clearly a set of dots superimposed on the lines in another color. Effects of three temporal parameters were noted in tachistoscopic presentations of the consonants: priming time, i.e., opportunity for the subject to prepare to execute the negative visual hallucination after the posthypnotic cue was flashed and before the consonant appeared; duration of consonant exposure; and intensive practice over protracted periods of time. Signal strength and inhibitory skill emerged as significant variables.

This paper reports 4 experiments with two highly trained subjects. The authors conclude, "From these observations, signal strength and inhibitory skill emerge as major determinants of the outcome in NVH. The stronger the input, the greater the likelihood of insufficient inhibitory action. Differences in skill show up at both the intra- and inter-individual levels of analysis. Even the initially skilled F1 improved

her NVH ability with practice, as inferred from the disappearance of undercalling. The lesser skill of F2 was evidenced in her longer required priming time, higher accuracy of color guesses, greater number of color breakthroughs, and reported feeling of mental strain" (p. 42).

1977

Fisher, R. (1977). On flashback and hypnotic recall. International Journal of Clinical and Experimental Hypnosis, 217-235.

This essay deals with both the intra-individual and inter-individual varieties of arousal state-bound experiences. The former are labelled as "flashbacks" while the latter embrace the great fantasies and repetitive schemes, the ever re-written plots and images of literature, art, and religion.

Flashbacks are both arousal-state and stage (i.e., set and setting) bound experiences. Flashback and hypnotic recall differ only in the ways by which they are induced. Induction methods should be distinguished from induced states on the hyperaroused perception-hallucination and hypoaroused perception-meditation continuum.

Flashbackers may be characterized by their (a) variability on perceptual-behavioral tasks; (b) tendency to minimize (or reduce) sensory input; (c) high resting heart rates; (d) hypnotizability; and, hence (e) preferential right-cerebral-hemispheric cognition; and (f) a display of EEG-alpha dominance in the resting, waking state.

1976

Slade, P. D. (1976). An investigation of psychological factors involved in the predisposition to auditory hallucinations. Psychological Medicine, 6 (1), 123-132.

Previous research by the author (Slade, 1972, 1973) and others has suggested that psychological stress plays an important role in triggering off the experience of auditory hallucinations. Clearly, however, predispositional factors are involved as well. The present study is an attempt to investigate some of the psychological factors which may predispose the individual to such experiences. A battery of tests involving cognitive, personality and mental imagery variables and the verbal transformation effect was administered to two small groups of psychotic patients differing only in respect of a history of auditory hallucinations and a normal control group. The main conclusion was that the results lend direct support to the proposition of Mintz & Alpert (1972) that a combination of vivid mental imagery and poor reality-testing in the auditory modality provides the basic predisposition for the experience of auditory hallucinations.

1972) that a combination of vivid mental imagery and poor reality-testing in the auditory modality provides the basic predisposition for the experience of auditory hallucinations.

1972

Graham, Charles; Leibowitz, Herschel W. (1972). The effect of suggestion on visual acuity. International Journal of Clinical and Experimental Hypnosis, 20, 3.

In experiment one, all subjects participating attained the maximum score on the BSS. The subjects were hypnotized and post-hypnotic suggestions were given to the effect that the subject really knew how well they could see, and this was contingent upon relaxation. The patient was now given an opportunity to re-read the eye charts. It was found that in this experiment, myopic visual acuity was significantly improved through the use of hypnosis and positive suggestion.

In experiment two, subjects who scored the maximum and the minimum on the BSS were used. The same procedure was used as in number one except that the highly susceptible subjects were told that "various studies had demonstrated that being hypnotized was not a pre-requisite for obtaining improvement." The insusceptibles were told that "acuity improved under hypnosis, but like many other phenomena associated with hypnosis, improvement in vision was also well within the reach of the non-hypnotizable subjects, if they simply learned to relax their eyes." It was found that myopic visual acuity was significantly improved in the absence of a formal hypnotic induction. This improvement was for the highly hypnotizable subjects only, and did not transfer to outside the experimental situation.

In experiment three, subjects were used who scored the maximum on the BSS and the Harvard Group Scale. Testing was done in both the hypnotized and waking state. It was found that the rank order correlation between initial and final acuity levels was .98 ( $p < .001$ ), indicating the effect of suggestion was selective.

**Sutcliffe, J. P. (1972). Afterimages of real and imaged stimuli. Australian Journal of Psychology, 24 (3), 275-289.**

Tested 45 university students and 15 7-10 yr. olds for after-images of images and of real stimuli. 8 different colored stimuli were used and observations made enabled a check on reliability. Real stimuli typically produced negative afterimages in most Ss. Only half the Ss could project images of the stimuli, only 1/3 reported afterimages of those images, and of those images only 7% were negative. Afterimages of images had a longer latency and a shorter duration than afterimages of real stimuli. Thus qualitatively and quantitatively afterimages of images differ from afterimages of real stimuli. Findings are related to individual differences in general vividness of imagery. (18 ref.) **Fromm, Erika; Oberlander, Mark I.; Gruenewald, Doris (1970). Perceptual and cognitive processes in different states of consciousness: The waking state and hypnosis. Journal of Projective Techniques and Personality Assessment, 34, 375-387.**

Hypnosis was assumed to influence perceptual and cognitive functioning in the direction of increased primary process ideation and adaptive regression. The Rorschach test was administered to 32 Ss in the waking state and under hypnosis in counterbalanced order. Hypnosis was induced by a standardized procedure. Ss received identical instructions for the Rorschach in both conditions. Protocols were scored according to Holt's system for manifestations and control of primary

-duced by a standardized procedure. Ss received identical instructions for the Rorschach in both conditions. Protocols were scored according to Holt's system for manifestations and control of primary process. Hypnotic Rorschachs showed an increase in primary process manifestations, but no changes in defensive and coping functioning, and no overall changes in the Adaptive Regression Score. However, the nature of the data was found to be influenced by Ss' sex and level of adjustment.

**Graham, Kenneth (1969). Brightness contrast by hypnotic hallucination. International Journal of Clinical and Experimental Hypnosis, 17, 62-73.**

Tested the veridicality of a hypnotic hallucination elicited by a buzzer through a conditioning procedure. The stimulus to be hallucinated consisted of 2 gray circles, 3 in. in diameter, mounted on a white card. 11 highly susceptible Ss were able to produce this hallucination upon hearing the buzzer during a series of test trials following the training. Following a 2nd training series, a black and white background was provided for the hallucination and Ss tended to report the hallucinated circles as a brightness contrast. A 2nd group of highly susceptible Ss was not hypnotized, but was asked to respond as if hypnotized. These Ss tended not to report the contrast. **1966**

**Andreasen, A. G.; Singer G. (1966). Hypnosis and hypnotizability: Delusion or simulation?. International Journal of Clinical and Experimental Hypnosis, 14 (3), 257-267.**

Because Sutcliffe (see 36:4) showed that hypnotic suggestions are not comparable in sensory content with real stimuli, the postulated difference between "pseudoperception" and "simulation" as indexed by reported subjective experiences of hypnotic Ss was tested. From 215 undergraduates, 30 high-susceptibility (HS) and 30 low-susceptibility (LS) Ss made kinesthetic and visual judgments of horizontality. A significant response, not attributable to simulation, was found only for the HS-hypnosis induction group; the effect was not attributable individually to susceptibility, hypnosis induction, or motivation. It is concluded that hypnosis, defined by this significant interaction effect between high susceptibility and hypnosis induction can be interpreted as a pseudoperceptual response to suggestion. **Brady, J. P.; Levitt, E. E. (1964). Hypnotically-induced 'anosmia' to ammonia. International Journal of Clinical and Experimental Hypnosis, 12, 18-20.**

The procedure to demonstrate anosmia by the inhalation of ammonia is discussed. Deeply hypnotized Ss who are not knowledgeable of the relevant facts of physiology may fail to respond to ammonia fumes when it is suggested that they have no sense of smell (anosmia). However, persons who, in fact, are anosmic do respond to ammonia fumes because they are a powerful stimulus to the pain fibers in the nasal mucosa. This procedure illustrates that the crucial factor in the response of the hypnotized S is not the actual facts of anatomy and physiology, but the S's concept of them. **1961**

**Pearson, R. E. (1961). Response to suggestion given under general anesthesia. American Journal of Clinical Hypnosis, 4, 106-114.**

Employed a double-blind design with placebo control. Audio tapes containing therapeutic suggestions were played to 43 experimental patients during anesthesia. The main theme of the suggestions was that the patient would cope better and recover faster if he could become relaxed. Placebo tapes (music or blank tapes) were played to the 38 control patients. Only E, who had no contact with the patients, knew which tape was played to a given patient. Three postoperative variables were studied: (a) number of doses of narcotics in the first 5 postoperative days; (b) a numerical rating by the surgeon of the postoperative course; and (c) number of postoperative days until release. Although no significant differences were found between the suggestion group and placebo group on need for narcotics or rated course of recovery, patients receiving suggestions were discharged an average of 2.42 days sooner ( $p < .05$ ).

Sukhakarn, Khun Vichit (1960/1962). Extra ocular vision [Letter]. British Journal of Medical Hypnotism, 14 (2), 41-47

The article is in the original form of a letter to Herbert Spiegel, M.D. The author describes experiences training subjects, both blind and with normal vision, to 'see' through the skin of their cheeks. Training involved concentrative meditation (Buddhist) and hypnosis. Simple tests were performed, apparently independently, by two other scientists.

"From information available from our subjects, the Extra Ocular Vision gained through the cheek-skin is different from those through the eyes as best explained here below:-- (1) The vision through the cheek-skin first takes a form of a series of spots somewhat like the image of coarse gain prints. Only after further training the spots are transformed into a clear object, so clear that needle threading is possible. (2) Objects seen through the cheek-skin are as clear as through the eyes. Distant objects can be magnified by the subject's wish, just like looking through an opera glass. (3) The vision gained through the cheek-skin is first 'seen' in black and white, and the 'colour picture' is achieved only after further training. But the colour 'seen' through the cheek is more intense than those through the eyes. (4) The field of vision 'seen' through each side of the cheek is more narrow than those seen through each eye. (5) There is a sign indicating that the vision through the cheek is only two-dimensional, the subjects find it difficult at first to stand the finger to another finger test" (p. 42).

1957

Barber, Theodore Xenophon (1957). Hypnosis as perceptual-cognitive restructuring: I. Analysis of concepts. Journal of Clinical and Experimental Hypnosis, 5 (4), 147-166.

"Summary

1. 'Trance' involves a selective and relative inattention to internal and external stimulation.

2. Hypnosis involves one type of 'trance' behavior but hypnosis differs from other types of 'trance' in that it is an interpersonal relationship in which one person, the operator, restructures the 'perceptions' and conceptions of the other person, the subject.

3. The operator can restructure the thoughts and 'perceptions' of the 'good' hypnotic subject because (a) the subject is relatively detached and inattentive to his self and his surroundings and (b) the subject is 'set' -- he is ready and willing -- to accept the operator's words as true statements and to 'literally think as the operator wants him to think.'

4. 'Perceptual-cognitive restructuring' and not 'suggestion' is the essential element in hypnosis.

5. We can begin to understand hypnosis and the phenomena of hypnosis by one general principle: the hypnotic subject behaves differently because he 'perceives' and conceives differently. The behavior of the hypnotic subject is in strict accordance with his altered conceptions of his self and his surroundings" (p. 162).

1955

Naruse, Gosaku; Obonai, Torao (1955). Decomposition and fusion of mental images in the post-hypnotic hallucinatory state. II: Mechanism of image composing activity. Journal of Clinical and Experimental Hypnosis, 3 (1), 2-23.

**Summary.** This is a report of the studies continued from the previous work, as regards the mode and law of modification of images, by experiments on the image-fusion which is observed in a post-hypnotic hallucinatory state. The writers investigated the configuration law of the Gestalt school, also whether there was nothing other than the overlapping of images. Various experiments were performed using accorded figures (Fig.1), discorded figures (Fig. 3), the composed image partly changed in size (Fig. 4), the incomplete figures with concrete meaning (Fig. 5,A) and the figures in which the perception and meaning were discorded with each other (Fig. 6). The results were as follows:

(1) There were some subjects whose images were clear, and others whose images were vague. In general, the images were clear in deep hypnotic trance, and vague in the medium trance.

(2) In the case of the clear images, they were prominently overlapping while in the case of the vague images, they overlapped one another and were disjointed or integrated.

(3) After conditioning two kinds of figures with two kinds of sounds, a composed image could be aroused by the two stimuli; in this case, by changing the tempo of one kind, a part of the composed image was changed. This fact would prove that the composed images were combinations of elements.

(4) In the case of the integrated images, the modification of both clear and vague images could be explained satisfactorily not by the Gestalt theory but by the intervention of the meaning. Moreover, the hypothesis of the integration or hierarchy of cerebral functions corresponding to these phenomena was possible.

(5) Modification through meaning was more frequent in the vague images than in the clear ones.

(6) The spontaneous effect of meaning of the image was dependent on the depth of trance. This effect was comparatively weak in deep trance and strong in medium trance. It was assumed that in medium trance which reproduced the integrated images, meaning activity still remained.

(7) Having presented incomplete figures with concrete meanings to examine the effect of meaning, it was clear that the modification of images by meaning took place distinctly under the influence of suggestion.

If perception and meaning of the figure were made to be in discord with each other, the meaning suggested at the time of conditioning produced more effect on the modification of the image than that at the time of recall" (p. 22).

**Kline, Milton V. (1953).** Hypnotic retrogression: A neuropsychological theory of age regression and progression. Journal of Clinical and Experimental Hypnosis, 1, 21-28.

**Author's Summary -** In a review of the salient aspects of research in hypnotic age regression an evaluation of the data tended to indicate that under certain conditions valid age regression is discussed in the light of a neuropsychological theory of age regression. This theory based upon a concept of hypnotic retrogression views regression and progression phenomena in hypnosis as a form of psychological

activity involving disorientation for the subject and a reorganization of his perceptual equilibrium and control mechanisms with particular reference to time-space perception. The term hypnotic retrogression is used to describe the centrally induced state which alters time-space perception and renders hypnotic regression and progression possible.

## **Performance**

**1997**

Schoenberger, Nancy E.; Kirsch, Irving; Gearan, Paul; Montgomery, Guy; Pastyrnak, Steven L. (1997). Hypnotic enhancement of a cognitive behavioral treatment for public speaking anxiety. Behavior Therapy, 28, 127-140.

The effectiveness of a multidimensional cognitive behavioral treatment for public speaking anxiety was compared with that of the same treatment supplemented by hypnosis. The hypnotic treatment included all components of the cognitive behavioral treatment. It differed from the nonhypnotic treatment only in that relaxation training was presented as a hypnotic induction, automatic thoughts were referred to as self-suggestions, and explicit hypnotic suggestions for improvement were added. Participants in both treatment conditions improved more than those in a wait-list control group. Moreover, labeling the treatment "hypnotic" appeared to enhance treatment effectiveness. The hypnotic treatment generated expectancies for greater change among participants than did the nonhypnotic treatment, and these expectancies were correlated with treatment outcome. Implications for the use of hypnosis in treatment are discussed.

**1994**

Wormnes, Bjorn (1994, October). Hypnosis in working with performance anxiety and peak performance. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Better training facilities and procedures combined with scientific methods and knowledge bring athletes' performance continuously to a higher standard. Being able to perform at their very best in important competitions depends on mental training and mental ability. Hypnosis is important to integrate in systematic training programs for peak performance. Important psychological factors influencing peak performance are discussed. Self-confidence, ability to concentrate, imagery training, goal-setting capacity, openness to communication and body signals, team building, delay capacity, and secure relations with coaches are shown to be significant. Integrating hypnosis into mental training is valuable both for working on temporary obstacles and in long-term programs.

**1991**

Cochrane, Gordon J. (1991). Client-therapist collaboration in the preparation of hypnosis interventions: Case illustrations. American Journal of Clinical Hypnosis, 33, 254-262.

Therapists can use hypnosis in a variety of situations to help clients utilize their own resources effectively. In both heterohypnosis and tape-assisted self-hypnosis, the respectful collaboration of therapist and client in the development of specific intervention strategies can be effective. I have described four cases to illustrate the collaborative aspect of heterohypnosis in a surgical setting and tape-assisted self-hypnosis for anxiety, tinnitus, and situational depression. In each case the clients were willing and able participants.

"Hypnotic interventions as adjunctive therapeutic modalities for a variety of surgical procedures have been well documented (Frankel, 1987; Gravitz, 1988; Nathan, Morris, Goebel, & Blass, 1987). The availability, relative safety, dependability, and ease of use have made chemical agents the anesthetic of choice in the majority of surgical situations, but hypnosis, either alone or in conjunction with chemical agents, can have a number of advantages for some patients (Udolf, 1987, p. 248). Some patients who have extreme preoperative pain and anxiety can learn to use self-hypnosis (Frankel, 1987); others may use hypnosis when experiencing postoperative nausea and other uncomfortable side effects of chemical anesthetics. Some may fear death under general anesthesia or react to a previous trauma arising from general anesthesia and the operating room procedures in general (Udolf, 1987, p. 250) and therefore choose hypnotic strategies. In the following case illustration the patient feared general anesthesia because of a previous negative postoperative experience" (p. 255).

While collaboratively planned hypnosis often empowers the patient, contributing to a sense of personal control and well being, some patients are not able to participate in that manner. Cochrane cites patients who are severely depressed or "who struggle with narcissism and other severe pathologies" (p. 260). He notes that audiotapes are useful for supplementing in-session therapy, contributing to skill development, attitude change, and a sense of self-worth. He cites Eisen and Fromm (1983) as indicating that self hypnosis is also useful for clients "who struggle with issues of control and intimacy" (p. 260).

Wagaman, Jeffrey D.; Barabasz, Arreed F.; Barabasz, Marianne (1991). Flotation rest and imagery in the improvement of collegiate basketball performance. Perceptual and Motor Skills, 72, 119-122.

22 expert collegiate basketball players were exposed to either imagery training only or restricted environmental stimulation (REST) with imagery training. The REST group showed significantly better performance on both objective game performance and coaches' blind ratings.

1990

Clark, Duncan B.; Agras, W. Stewart (1990). The assessment and treatment of performance anxiety in musicians. American Journal of Psychiatry, 148 (5), 598-605.

94 adults with a performance anxiety problem were recruited by mass media announcements and were seen in a university-based outpatient psychiatric clinic. Assessments were questionnaires for all 94 ss, diagnostic interview of 50 ss, and laboratory performance of 34 ss. Treatment conditions were 6 weeks of buspirone, 6 weeks of placebo, a five-session group cognitive-behavior therapy program (CBTP) with buspirone, or the CBTP with placebo. All Ss fulfilled criteria for Diagnostic and Statistical Manual of Mental Disorders-III-Revised (DSM-III-R) social phobia. Of the 15 full-time professional musicians, 10 had tried propranolol and 3 had stopped performing. Most Ss had substantial anxiety and heart rate increases during lab speech and musical performances. CBTP resulted in significant reductions in subjective anxiety, improved quality of musical performance, and improved performance confidence.

McAleney, Patrick J.; Barabasz, Arreed; Barabasz, Marianne (1990). Effects of flotation restricted environmental stimulation on intercollegiate tennis performance. Perceptual and Motor Skills, 72, 1023-1028.

The study investigated the effects of flotation Restricted Environmental Stimulation (REST) with an imagery message on the competitive performance of intercollegiate tennis players (10 men, 10 women). Pre- and posttreatment athletic performance was measured during intercollegiate competition. Posttreatment results indicated that subjects exposed to flotation REST with an imagery message performed significantly better than subjects exposed to imagery only on a measure of first service accuracy. Findings suggest that flotation REST can be used to enhance the performance of a well learned skill by athletes of high ability.

1989

Palan, B.M.; Chandwani, S. (1989). Coping with examination stress through hypnosis: An experimental study. American Journal of Clinical Hypnosis, 31, 173-180.

Fifty-six volunteer medical students participated in three groups balanced for number of subjects, performance at last examination, and hypnotizability. The hypnosis and waking groups attended eight group sessions once a week with general ego- strengthening and specific suggestions for study habits, with a ninth session of age progression and mental rehearsal. Subjects in these two groups practiced self-suggestions (in self-hypnosis or waking respectively) daily for the study period of 9 weeks. The control group experienced sessions of passive relaxation induced by light reading for the same period of time. The hypnosis group improved significantly in coping with examination stress, but there was no significant change in performance on examinations by any of the groups.

1988

Neiss, Rob (1988). Reconceptualizing arousal: Psychobiological states in motor performance. Psychological Bulletin, 103 (3), 345-366.

This review of research dealing with psychologically induced arousal and motor performance focuses on the hypothesized inverted-U function relating arousal to performance. The inverted-U hypothesis is supported only in a weak and psychologically trivial fashion. More useful research in human motor performance would investigate discrete psychobiological states, which include affect and cognition as well as physiology. Examination of profound individual differences in response to incentive and threat suggests that psychobiological states have their genesis in response expectancies and hypnotic-like self-inductions. The cognitive and affective components of these states are highly interactive and perhaps not profitably separated. Because performance anxiety is a central problem in the motor realm, it is carefully delineated and the test anxiety literature is scrutinized. Psychophysiological test batteries and other investigations in the area are described, and guidelines for future research are provided.

Neiss, Rob (1988). Reconceptualizing relaxation treatments: Psychobiological states in sports. Clinical Psychology Review, 8 (2), 139-159.

Reviews studies relating relaxation treatments to motor performance and attempts to explain these treatments from a psychological perspective. The inverted-U hypothesis is based on arousal, which has construct validation problems and is a physiological, rather than a psychological, construct. Arousal cannot distinguish among fear, anger, sexuality, and other psychobiological states; predictive validity is low in the area of motor performance. The inverted-U hypothesis is effectively refutable in current usage, and empirically weakly supported. Relaxation treatments are reconceptualized as relatively nonspecific psychological therapies, potentially useful in alleviating dysphoric, debilitating psychobiological states. These treatments are particularly apt for athletics, where performance anxiety is a pervasive problem.

1987

Jacobs, Sharon B.; Salzberg, Herman C. (1987). The effects of posthypnotic performance-enhancing instructions on cognitive-motor performance. International Journal of Clinical and Experimental Hypnosis, 35, 41-50.

The effects of performance-enhancing instructions on a cognitive-motor task (typing) was assessed using 3 groups: hypnosis and control groups with performance-enhancing instructions, and a control group without instructions. Unlike previous hypnosis research, the performance-enhancing instructions were given after substantial learning had occurred. Results indicated that posthypnotic performance-enhancing instructions, or performance-enhancing instructions alone, did not have a facilitative effect on performance. The results also suggested potential negative performance effects following hypnotic induction, depending on Ss' initial typing ability. The implications of these findings are discussed.

The research investigated whether hypnotic suggestions could influence various factors thought to inhibit peak performance by increasing confidence, increasing motivation, and decreasing performance anxiety. 84 undergraduates of varying

levels of typing ability were recruited, not mentioning in advance that the research involved hypnosis (in order to avoid selection bias). The experimental materials included a modified version of the Apple Typing Tutor program, which measures words per minute (WPM), key strokes missed (KM), and net words per minute (NWPM, which was obtained by subtracting 2 (KM) from WPM). These measures were obtained for the average of every 9 paragraphs.

Subjects received nine practice sessions and then were assigned to Experimental or Control group based on NWPM and sex. The hypnosis group received the Stanford Hypnotic Susceptibility Scale, Form C, minus suggestions for drowsiness, sleepiness, or posthypnotic amnesia. Additional suggestions for performance enhancement were introduced. The control group watched a film. The average of every nine paragraphs was used.

The analyses of variance for dependent measures revealed no significant effects except for one interaction effect that actually was in the unexpected or wrong direction. That effect appeared to be spurious as it was due to extreme errors produced by one subject.

"Only speed of typing (WPM) changed from pre to posttreatment, and this effect interacted with ability level. Post hoc analyses (Scheffe) indicated that beginner typists became less proficient, intermediate typists did not change, and advanced typists became more proficient" (p. 46).

Hypnotizability on SHSS:C did not correlate with change on NWPM.

A 3 x 3 x 2 ANOVA indicated a significant change over time on KM. "Although no change occurred from pretreatment to posttreatment, there was a decrease in errors at follow-up. There was also a significant Group x Level x Time interaction for KM ( $F = 2.57$ ,  $p < .05$ ). This was accounted for by post hoc analyses showing that hypnotized beginner Ss changed over time, while control beginner Ss did not. Hypnotized Ss made significantly more errors following hypnosis than at pretreatment or follow-up" (p. 46).

"There was a significant main effect for time on NWPM. ... The Ss' overall typing performance decreased from pretreatment to posttreatment, but increased at follow-up. Only the advanced Ss demonstrated significant improvement between pretreatment and follow-up.

"There was also a significant interaction between time and ability level on WPM. ... beginner Ss typed significantly slower at posttreatment than at pretreatment or follow-up" (p. 47).

In their Discussion, the authors note that the outcomes of their investigation are consonant with results obtained by other investigators studying hypnosis effects on skills (Arnold, 1971; Edmonston & Marks, 1967). In contrast, earlier studies on reaction time demonstrated that either motivational instructions and/or alert hypnotic inductions improved performance (e.g. Ham & Edmonston, 1971; Rader, 1972). They raise the question whether Ss' relaxation following hypnosis may have slowed response time and canceled the effects of motivating instructions.

"When looking at all groups combined, Ss did not improve between pretreatment and posttreatment. At follow-up, however, Ss showed significant improvement on two out of the three measures. This suggests that learning had occurred, but that

temporary inhibitory factors such as S restlessness and indifference observed by Es may have affected performance at posttreatment. The length of the task (90 minutes in one sitting) may have been responsible for the fatigue and boredom that seemed to set in. It is probable that the performance-enhancing instructions were not potent enough to counteract these effects. At follow-up (which took much less time) fatigue and boredom were apparently absent, hence typing improved. In addition, other factors may have affected performance (e.g., anxiety, lack of motivation). The data indicate that Ss of different ability levels responded differently over time.

"The results of the present study cast doubt on the utility of hypnosis in improving performance on a cognitive-motor task. Although there are many anecdotal reports of hypnosis improving performance, research studies indicate that hypnosis, with motivational instructions, is effective only in improving reaction time and not more complex measures of performance. This apparent inconsistency may be explained by considering the level of motivation of participants. It is likely that a person requesting hypnosis to help improve performance is more motivated than experimental Ss" (p. 48).

1981

Wallace, Benjamin; Hoyenga, Katharine Blick (1981). Performance of fine motor coordination activities with an hypnotically anesthetized limb. International Journal of Clinical and Experimental Hypnosis, 29, 54-65.

3 experiments were conducted to determine the effects of induced hypnotic anesthesia in S's dominant arm upon the performance of various motor coordination tasks. Experiment 1 assessed the ability of Ss to tap a pencil within a 20 mm diameter circle while the limb performing the task was or was not anesthetized. Experiment 2 determined the effect of hypnotic anesthesia upon the ability to perform a hand-turn task. Experience 3 considered the effects of hypnotic anesthesia on the ability to draw and duplicate a sine-wave pattern. IN all 3 experiments, hypnotic anesthesia adversely affected task performance. Their results were interpreted as indicating a possible relationship between induced hypnotic anesthesia and mimicked cerebellar dysfunction.

notic anesthesia on the ability to draw and duplicate a sine-wave pattern. IN all 3 experiments, hypnotic anesthesia adversely affected task performance. Their results were interpreted as indicating a possible relationship between induced hypnotic anesthesia and mimicked cerebellar dysfunction.

"Although the induction of hypnotic anesthesia in a limb appears to mimic cerebellar dysfunction or damage, the present authors are not implying that this is actually happening. In fact, there are few physiological correlates of hypnosis or hypnotic anesthesia (Evans, 1979; Sarbin & Slagle, 1979) and, to date at least, cerebellar involvement does not appear to be one of them. There appears to be a curious relationship, however, between performance on a motor task as a function of induced hypnotic anesthesia in a limb and as a function of cerebellar damage. This relationship may simply be coincidental at best but before it can be dismissed

as such, further experimentation should take place to study this interesting phenomenon" (p. 61).

1980

Russell, Robert J. (1980). The effects of hypnosis and mastery imagery on task performance (Dissertation, Western Michigan University). Dissertation Abstracts International, 41 (n6-B), 2368. (Order No. DA 8027229)

"The purpose of this study was to determine the efficacy of combining mastery imagery with hypnosis to facilitate performance on a motor task, and to identify the variables which are responsible for such an effect. 99 students were pretested on the Pursuit Rotor Task and screened for hypnotic susceptibility. From this screening, 40 high susceptibility Ss were randomly assigned to one of four conditions: (1) hypnosis and mastery imagery, (2) hypnosis, (3) mastery imagery (H) and (4) no-treatment control. Ten low susceptibility Ss were directly assigned to a second mastery imagery (L) condition which served as a special comparison group. Following the treatment intervention, Ss were posttested on the Pursuit-Rotor Task and were asked to complete a questionnaire regarding their experience in the experiment. ANOVA found no significant differences among the five groups" (p. 2368).

Salzberg, H. C.; DePiano, F. A. (1980). Hypnotizability and task motivating suggestions: A further look at how they affect performance. International Journal of Clinical and Experimental Hypnosis, 28 (3), 261-271.

An attempt was made to ferret out the separate effects on cognitive performance of hypnotic susceptibility, task motivating suggestions, and the hypnotic trance state. An equal number of susceptible and unsusceptible Ss were given 3 cognitive tasks, first to ascertain their baseline performances, and then again following either a traditional hypnotic induction, an alert trance induction or a short interview. All Ss were given task motivating suggestions prior to administering the alternate form of the 3 tasks. An additional control group of Ss was used to assess practice effects. Results indicated that task motivating suggestions were effective in enhancing performance for all groups on the digit symbol and abstract reasoning tasks but not on the memory task. Waking suggestion Ss performed as well as hypnotized SWs when both groups of Ss were given task motivating suggestions. It was concluded that when the experimental design of a study incorporates necessary controls, hypnosis does not facilitate performance.

This paper reviews a long term research project relating hypnotic susceptibility to performance and personality variables. Several experiments indicated that people who are low in hypnotic susceptibility try harder than high susceptibles for maximum performances on strength, endurance, psychomotor coordination, and cognitive tests, though high susceptibles are generally more pleased with their own performances. Other experiments indicated that people of high hypnotic susceptibility have slower brain-wave patterns under relaxed, nonhypnotic conditions, than do low susceptibles. These findings, together with a third set of

findings on the developmental character of hypnotic susceptibility, led to the theory that hypnotic susceptibility and brain-wave patterns are both inversely correlated with achievement motivation and with its developmental roots in childhood independence training. An elaborate research program was initiated to investigate the hypothesized relationships.

**1974**

**Bloom, Richard F. (1974). Validation of suggestion-induced stress.**

Sixty college men, divided into three equal groups, each attended two induced stress sessions in which their physiological, psychological and performance reactions were measured. Their responses were compared to determine if valid stress reactions could be induced through suggestion in an altered state (in this case, hypnosis), and also to determine the validity of such reactions if the subject had never before experienced that stress situation. It was demonstrated that valid stress reactions can be induced in an individual with the aid of suggestions, especially if the real stress situation has been experienced before. If no previous experience with that real situation exists, the subject still exhibits stressful reactions; however, the closest resemblance to real stress is found in the subjective or psychological measures, less similarity is found in the physiological measures, and the least similarity is found in the performance measures.

**1970**

**Sakata, Kenneth I.; Anderson, John P. (1970). The effects of posthypnotic suggestion on test performance. International Journal of Clinical and Experimental Hypnosis, 18 (1), 61-71.**

Tested 45 undergraduates preselected for hypnotizability on 2 learning tasks by E and retested on the tasks by other Es a mo. later. Before being retested Ss were randomly assigned to 1 of 3 treatment conditions: (a) a posthypnotic suggestion condition, (b) a waking suggestion condition, and (c) a hypnosis-no-suggestion condition in which Ss were merely dehypnotized without exhortative instructions. Es were blind to the experimental design. Analyses of covariance indicate that the posthypnotic suggestion group performed more rapidly and accurately on a Rational Learning Test (RLT), but not on a Digit Symbol Test (DST), than the waking suggestion group. The posthypnotic suggestion group did not differ from the hypnosis-no-suggestion group, which also performed more accurately but not more rapidly than the waking suggestion group on the RLT. There were indications that posthypnotic suggestions had interfered with performance on the DST, which involved motor manipulations. Findings supported previous studies indicating differences between a posthypnotic and waking suggestion group in task performance. No definite conclusions to account for the differences could be offered. (Spanish & German summaries) (18 ref.) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

**1965**

Evans, Frederick J.; Orne, Martin T. (1965). Motivation, performance, and susceptibility to hypnosis. International Journal of Clinical and Experimental Hypnosis, 13 (2), 103-116.

Earlier reports found that the waking base level performance of Ss who are relatively insusceptible to hypnosis is higher than the waking base level of highly susceptible Ss on tasks of muscular strength, endurance, coordination, and verbal learning and that any increment in performance under hypnosis tends to be at least as great with insusceptible Ss as with highly susceptible Ss. These previous studies were carefully replicated, but the results were not confirmed. No differences in base level or hypnosis performance were found, except for poorer hypnosis performance of Ss of medium susceptibility to hypnosis, arising in part from the emphasis on relaxation in the induction procedure, and in part because of subtle demand characteristics present in the counterbalanced experimental design. McCord, Hallack (1965). Trance induction under unusual circumstances. International Journal of Clinical and Experimental Hypnosis, 13, 96-102.

In order to obtain a test under naturalistic field conditions of the possible facilitory or inhibitory effects of ongoing tasks on hypnotizability and the interaction of such effects with S's set either to oppose or not oppose entering hypnosis, a series of Ss were hypnotized either singly or in groups while they were performing a variety of tasks typical of those encountered in office or factory situations. Included were such tasks as typewriting, reading a book, engaging in creative writing, performing the Bennett Hand Tool Dexterity and the Minnesota Rate of Manipulation tests, and performing the Pennsylvania Bi-Manual Worksample. In many cases, it was found that hypnosis could be induced under these conditions. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Naruse, Gosaku (1965). The hypnotic treatment of stage fright in champion athletes. International Journal of Clinical and Experimental Hypnosis, 13 (2), 63-70.

The use of direct hypnotic suggestion, posthypnotically produced autohypnosis, and self-hypnosis in conjunction with autogenic training and progressive relaxation in the treatment of "stage fright" in athletes is discussed. Illustrative case histories drawn from a sample of athletes participating in the 1960 Olympic Games are presented. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Levitt, Eugene E.; Brady, J. P. (1964). Muscular endurance under hypnosis and in the motivated waking state. International Journal of Clinical and Experimental Hypnosis, 12, 21-27.

8 female Ss scoring at least 10 on the Stanford Hypnotic Susceptibility Scale were required to hold a weight in the outstretched hand in 3 states: (a) under hypnosis,

(b) under hypnosis with the upper arm and shoulder anesthetized hypnotically, and (c) in the waking state with motivation provided by a verbal exhortation and monetary payment. Order of performance in the 3 states was varied. No significant differences among states were found. The interaction between states and orders was significant, but it appears more likely to be the result of intersubject variability rather than of position or fatigue effects. Ss' expectancies and estimates of performance time, obtained postexperimentally, did not appear to be related to performance itself. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

states and orders was significant, but it appears more likely to be the result of intersubject variability rather than of position or fatigue effects. Personality Disorder

2002

McNeal, Shirley A. (2002). A character in search of character: Narcissistic personality disorder and ego state therapy. American Journal of Clinical Hypnosis, 45 (3), 233-243.

The individual diagnosed with narcissistic personality disorder presents with grandiosity, extreme self-involvement, and lack of interest in and empathy for others. This paper reviews current theories concerning the development and treatment of this disorder, and presents a case study in which ego state therapy was successfully utilized and integrated into hypnotically facilitated psychotherapy with a 48-year-old man diagnosed with narcissistic personality disorder. The ego state model of treatment is described and demonstrated with case material. Initially ego states that reveal the grandiosity are accessed. As therapy progresses, ego states that hold the underlying feelings of emptiness, rage, and depression are able to emerge. With further treatment, transformation and maturation of the ego states occur, reflecting the changes in internal structure and dynamics as well as improvement in external interpersonal relationships. Issues concerning ego state therapy as utilized with personality disorders are discussed and contrasted with more traditional methods of treatment. 1998

Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm,

accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . Fink, D.; Golinkoff, M. (1990). Multiple personality disorder, borderline personality disorder, and schizophrenia: A comparative study of clinical features. Dissociation, 3, 127-134

Found that MPD was differentiated from schizophrenia on the great majority of test measures. MPD could not be distinguished from borderline personality on the MMPI or MCMI but differed in many clinical features, severity of abuse, and dissociative symptoms

1988

Kemp, Kristen; Gilbertson, Alan D.; Torem, Moshe (1988). The differential diagnosis of multiple personality disorder from borderline personality disorder. Dissociation, 1 (4), 41-46.

Considerable controversy [sic] surrounds the relationship between multiple personality disorder (MPD) and borderline personality disorder (BPD). Some authors argue that MPD is a variant of BPD, and most agree that the differential diagnosis of the two is often very difficult. In this article data are presented from a study comparing historical, demographic and psychological testing variables between the two groups. No statistically significant differences were found between the two groups on these variables. However, certain trends emerged which may serve as a catalyst for further research. The relationship between the disorders may be complex; clinicians may need to use more sophisticated research techniques and develop more sensitive diagnostic criteria before it is understood.

-ians may need to use more sophisticated research techniques and develop more sensitive diagnostic criteria before it is understood.

1987

Fromm, Erika (1987). Significant developments in clinical hypnosis during the past 25 years. International Journal of Clinical and Experimental Hypnosis, 35 (4), 215-230.

In the past 25 years, important changes have taken place in clinical hypnosis. It has become scientifically respectable as the field has moved from publishing anecdotal case reports to testing hypotheses on significant samples of patient populations. In addition, new treatment approaches have been introduced, foremost among them hypnoanalysis of psychotic, borderline, narcissistic, and post-traumatic stress disorders, as well as hypno-behavioral methods for the treatment of habit disorders and somatic and psychosomatic diseases. The former treatment approaches combine hypnotic techniques with the newer psychoanalytic methods derived from object relations and self-theories; the latter combine hypnosis with the methods of behavioral medicine and attempt to teach the patient voluntary control over ordinarily involuntary somatic processes. In general, while formerly the therapeutic use of hypnosis involved mainly direct and indirect suggestion, in the last 25 years hypnotherapists of all persuasions have become more and more convinced of the important role imagery plays in the application of hypnosis for therapeutic purposes. Several areas of clinical application are described.

Kluft, Richard P. (1987). Unsuspected multiple personality disorder: An uncommon source of protracted resistance, interruption, and failure in psychoanalysis. Hillside Journal of Clinical Psychiatry, 9 (1), 100-115.

Multiple personality disorder (MPD) is being recognized with increasing frequency. A great imitator, it may be encountered among patients who appear to have a wide range of other diagnoses, and have been in treatment for years without the presence

of MPD being discovered. Nine of 241 MPD patients interviewed by the author, 3.7%, had been accepted for psychoanalysis. In only one case had the diagnosis been appreciated by the analyst prior to his accepting the patient for analytic treatment. Four patients were profoundly resistant and/or inaccessible to analysis for protracted periods. In one of these cases the diagnosis became clear and successful analysis was concluded, but three analyses ended unsuccessfully with the diagnosis still unknown. Two patients' analyses ended unsuccessfully with the diagnosis still unknown. Two patients' analyses were interrupted due to abrupt regressive events initially perceived to indicate severe ego weakness incompatible with sustaining an analytic process, but later appreciated as signs of MPD. In three cases it appeared that the patients' being accepted for analysis triggered the emergence of the dissociative process, and either the patient or the analyst decided to pursue a different form of therapy. Unsuspected MPD appears to account for a small percentage of stalemates, failures, interruptions, and early flights from analysis.

"In most other literatures, dissociation is considered reflective of a capacity for hypnotizability, without any connotation of a particular level of psychopathology. There is solid evidence that hypnotizability is intrinsic to MPD (Bliss, 1980, 1983, 1984; Lipman, Frischholz, and Braun, 1984), and a borderline level of organization is not (Horevitz and Braun, 1984).

It is more parsimonious and consistent with clinical experience and research findings to infer that the splitting noted in pregenital pathologies and the splitting found in MPD are different although enticingly similar phenomena, and that in some patients they coexist in such a way that one could easily agree that a patient was both MPD and borderline. The linguistic confusion is to be deplored, and hopefully to be remedied in the near future" (p. 111).

Malon, Don W.; Berardi, Deborah (1987). Hypnosis with self-cutters. American Journal of Psychotherapy, 41 (4), 531-541.

Contends that hypnotic techniques can add to effective therapy with self-cutting patients in the context of a strong, communicative, and flexible relationship. "Neutral hypnosis" (i.e., the trance state in which specific suggestions are avoided so that physiological arousal is minimized) and relaxation techniques can be employed to counteract the frightening depersonalization that leads to the cutting. Techniques of uncovering and controlled regression are also possible. Hypnotic relaxation techniques, such as breath counting, positive imagery, and clinical vignettes are provided as illustrations.

1986

Copeland, Donna R. (1986). The application of object relations theory to the hypnotherapy of developmental arrests: The borderline patient. International Journal of Clinical and Experimental Hypnosis, 34 (3), 157-168.

The present paper reviews the literature on object relations theory with respect to the borderline patient and, within this perspective, discusses its application to

hypnotherapy. Emphasis is placed on developmental aspects of the attachment-separation-individuation process that relate to certain characteristics of the hypnotic experience and the therapeutic relationship, including transference, regression, and the internalization of positive aspects of the therapeutic alliance. The therapeutic process as described parallels normal developmental phases. Specific techniques to facilitate therapeutic integration are outlined and illustrated with case examples. These help to structure the internalization of the therapeutic relationship as a foundation to restructuralization of the patient's representational world.

1984

Jensen, Peter S. (1984). Case report of conversion catatonia: Indication for hypnosis. American Journal of Psychotherapy, 38 (4), 566-570.

Describes the successful hypnotic treatment of a 25-yr-old Black male who displayed symptoms of suicidal ideation, insomnia, and feelings of depression alternating with emptiness and boredom that led to an acute catatonic reaction. S met DSM-III criteria for borderline personality disorder. It is contended that since conversion mechanisms may underlie some presentations of catatonia, hypnosis may assist clinicians in the differential diagnosis of acute catatonic conditions.

Stava, L. (1984). The use of hypnotic uncovering techniques in the treatment of pedophilia: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32 (4), 350-355.

This case study describes the use of the hypnotic uncovering techniques of induced dreams (Sacerdote, 1967) and the affect bridge (Watkins, 1971) in reducing inappropriate sexual arousal in a male pedophile. Treatment effects were examined through the use of both psychophysiological measures of penile tumescence and psychological tests. The hypnotherapeutic treatment regime consisted of 25 sessions over approximately 9 months. At the end of treatment, psychophysiological measures revealed a definite reduction of sexual excitation to slides of prepubescent children. Psychological testing indicated reduced defensiveness as well as reduced sexual anxiety to adult women. Various hypnotherapeutic experiences which may have contributed to the treatment effects are discussed.

Watkins, John G. (1984). The Bianchi (L.A. hillside strangler) Case: Sociopath or multiple personality?. International Journal of Clinical and Experimental Hypnosis, 32 (2), 67-101.

The case of Kenneth Bianchi (the Los Angeles "Hillside Strangler") has been controversial ever since he was first arrested in January, 1979. This contributor saw Bianchi as a consultant on March 21st and 22nd, 1979. Under hypnosis, he manifested what appeared to be a multiple personality. An underlying personality, "Steve," whose existence was apparently unknown to Bianchi, claimed responsibility for the 2 murders in Bellingham and those in Los Angeles. As a

consequence, the court appointed 5 other consultants to examine the defendant. On April 20, 1979, I activated the Steve personality without a hypnotic induction. It described many murders in Los Angeles, indicating which ones he (Steve) had done and which ones Bianchi's cousin (Angelo Buono) did. The major personality (Ken) appeared to be amnesic to all this. 2 additional "personalities" were elicited by Martin Orne, another consultant. However, Orne would not accept the diagnosis of multiple personality. He diagnosed Bianchi as an "Antisocial Personality" (Sociopath) and claimed that he was a clever malingerer. He also asserted that Bianchi had never been hypnotized. The evidence, Rorschach tests, intelligence tests, handwriting samples, art creations, plus recorded sessions by Watkins, Orne and others, are analyzed. This writer concludes that the diagnosis of multiple personality is strongly supported.

1983

Baker, Elgan L. (1983). Resistance in hypnotherapy of primitive states: Its meaning and management. International Journal of Clinical and Experimental Hypnosis, 31 (2), 82-89.

This paper examines various aspects of resistance that become manifest in hypnotherapy with borderline, narcissistic, and psychotic patients. Specific clinical presentations are described and contrasted with forms of resistance encountered in work with neurotic patients. An ego psychology theoretical perspective is presented to conceptualize these more primitive resistance phenomena in terms of transference issues and dynamics relating to separation/attachment conflicts, and specific suggestions for management are outlined. 2 case examples are presented to demonstrate both conceptual and technical aspects of this approach.

Baker, Elgan L. (1983). The use of hypnotic dreaming in the treatment of the borderline patient: Some thoughts on resistance and transitional phenomena. International Journal of Clinical and Experimental Hypnosis, 31 (1), 19-27

This paper examines some phenomena of resistance to learning and utilizing self-hypnosis which may occur in the treatment of patients with borderline level ego organization and pathology. Conflicts around separation, individuation, and the constancy of self/other representations are highlighted as significant dynamic factors central to this resistance. The use of hypnotic dreams and the facilitation of transitional relatedness through dream processes and symbols are suggested and discussed as avenues for the clinical management of resistance to auto-hypnosis in hypnotherapy with these patients.

Epstein, S. J.; Deyoub, P. L. (1983). Hypnotherapeutic control of exhibitionism: A brief communication. International Journal of Clinical and Experimental Hypnosis, 31 (2), 63-66.

Hypnotherapy was used to treat a 30-year-old exhibitionist in 8 sessions. Under hypnosis, he explored causes for his behavior, developed tension reducing techniques, and learned a posthypnotic emergency response. If he felt exposure

imminent, his fists would clench, precluding the possibility of exposure. At 2-year follow-up, there were no known exposures.

Polk, W. M. (1983). Treatment of exhibitionism in a 38-year-old male by hypnotically assisted covert sensitization. International Journal of Clinical and Experimental Hypnosis, 31 (3), 132-138.

This case study reports the successful treatment of a 38-year-old male with a 14 year history of exhibitionism. A multifaceted treatment program was used, involving hypnotically assisted covert sensitization and brief marital therapy. Hypnosis was used to develop psychic aversive and reinforcing stimuli from the patient's past experience. The value of hypnosis in enhancing imagery in cognitive treatment approaches and the need for only experienced clinicians to utilize the present intervention strategy is discussed.

1981

Kellerman, J. (1981). Hypnosis as an adjunct to thought stopping and covert reinforcement in the treatment of homicidal obsessions in a twelve-year-old boy. International Journal of Clinical and Experimental Hypnosis, 29 (2), 128-135.

A combined cognitive behavioral approach was used to successfully treat matricidal obsessions in an otherwise psychologically well-adjusted 12-year-old boy. The primary problem was conceptualized as anxiety over loss of control. Therapeutic techniques included re-defining of symptoms, thought-stopping, hypnotic enhancement of imagery in order to facilitate cognitive restructuring, covert reinforcement, home practice, and paradoxical instructions to produce the symptom. A decline in obsessions began after 3 sessions and total remission was observed after 6 sessions (10 weeks). 2-year follow-up revealed no recurrence of symptoms. The value of hypnosis as an adjunct to behavior therapy with children is discussed.

Scrignar, C. B. (1981). Rapid treatment of contamination phobia with hand-washing compulsion by flooding with hypnosis. American Journal of Clinical Hypnosis, 23, 252-257.

Two obsessive-compulsive patients with contamination phobias and hand-washing compulsions are presented. Psychoanalytic psychotherapy had resulted in little change. Behavior therapy techniques of thought-stopping, systematic desensitization, progressive muscle relaxation, cognitive restructuring and self-imposed response prevention were first used, resulting in some subjective improvement, but no change in the hand-washing rate. Hypnosis, emphasizing relaxation, positive suggestion and corrective information provided further temporary subjective improvement but little change in compulsive rituals. Hypnosis, combined with the behavioral technique of flooding, produced rapid improvement. The patients maintained improvement at seven years and two years. Flooding under hypnosis may afford obsessive-compulsive patients a rapid and economical therapeutic procedure.

**Bauer, Rudolph (1979). The use of trance in working with the borderline personality. Psychotherapy: Theory, Research and Practice, 16 (4), 371-375.**

**Describes in detail those aspects of trance that facilitate the ongoing therapy process with the borderline personality and discusses the utilization of trance phenomena to work directly with the borderline person's experience and particular ego deficits. The discussion is developed from an object relations viewpoint, and 2 representative cases are presented.**

**1975**

**Spear, J. E. (1975). The utilization of non-drug induced altered states of consciousness in borderline recidivists. American Journal of Clinical Hypnosis, 18, 111-126.**

**Utilizing non-drug induced altered states of consciousness, various modes of interior reflection, behavior modification and reprogramming of conscious attitudes and values were utilized with 49 borderline recidivists. Such offenders were so determined by the Department of Corrections, Probation and Parole Office, District II. No coercion was used to induce such individuals to enter the program and there was no reprisal for stopping therapy at any time. Over a two and one-half year period the recidivist rate among this group was less than 5%. It is suggested that non-drug induced altered states of consciousness combined with indirect as well as symbolic techniques may prove to be the most effective means of criminal rehabilitation.**

**Berderline recidivists were "individuals, who, in the opinion of the P.O. [probation officer] were, in all probability, to be returned to prison within a few months, or less, if there wasn't a major change in attitude and actions" (p. 111). Therapy employed closed circuit TV with bi-directional audio and induction of altered state of consciousness using an ophthalmology-type rotary prism. Therapy involved (s) recall of relaxed state when under stress, (2) exploration of early conditioning events, (3) self evaluation during the ASC, (4) use of symbolic mental exercises and mental practice for similar circumstances in normal waking state, (5) suggestions for setting goals and ideals, (7) a type of logotherapy, (7) 'nudging' the person to examine their relationship with their concept of God. The author noted in the parolees: (1) low levels of self esteem, (2) depression, (3) going into deep levels of altered states once trust was established with the therapist.**

1954

Bowers, Margaretta; Berkowitz, Bernard; Brecher, Sylvia (1954). Hypnosis in severely dependent states. Journal of Clinical and Experimental Hypnosis, 2, 2-12.

[From the Introduction] "The patient with deep dependency needs, usually the schizophrenic or borderline case, presents difficult treatment problems, which make great demands on the personality of the therapist. A good therapeutic result in these cases requires a dependable positive transference. Yet the presence in the patient of ungratified infantile needs occasions severe hostility, which initially impedes the positive transference and continually renders its management difficult. We have found in hypnosis a procedure equal to these difficulties and offering, with reasonable consistency, a means of significantly improving the status of a patient group, until quite recently considered beyond the reach of psychotherapy. We consider in this paper, why and how hypnosis helps these patients, and some of the psychological hazards it presents for the therapist" (p. 2).

[From the section titled "Implications"] "Hypnosis affords real advantages, but it is also hard work, demanding far more from the therapist in skill and activity, especially in the hypnotic training of fragmented, distracted subjects. Consequently, where the patient could be reached by other means, hypnosis was not attempted" (p. 12). "There is evidence that hypnosis provides a respite, a holding operation, which permits the marshalling of positive forces within the patient. There are also indications that through hypnosis the patient is more quickly brought to a point of social remission, although the over-all time required in treatment is not materially lessened" (p. 12).

## Personality

1994

Csoli, Karen; Ramsay, Jason T.; Spanos, Nicholas P. (1994, August). Psychological correlates of the out-of-body experiences--a reexamination. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

12% of population reports an out-of-body experience (OBE) sometime in their lives. They leave their body and can see self from the outside. Awareness is confined to the new point of view, not fragmented; there is unimpaired intellectual ability; feelings of detachment, completeness, well being, and profound relaxation. Can occur under stress or deep relaxation; not while driving a car.

Psychological correlates aren't known. Studies are inconclusive with respect to belief systems (religious, death anxiety, etc.); measures of absorption, hypnosis, imaginative ability, imagery controls. Recent Carlton study with 87 Ss (33 had OBE) got results we didn't expect. They completed questionnaires, were tested for hypnotizability, had an interview re OBE experience.

This study found the OBE-experiencing people had higher levels of anxiety, psychosomatic symptoms, and panic attacks. They were also higher on magical

thinking, perceptual aberration, and Schizophrenia scores. They didn't differ on mysticism, levels of drug or alcohol use, or level of self esteem.

1993

Council, James R.; Grant, Debora L. (1993, October). Context effects: They're not just for hypnosis anymore. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Context effects in Absorption research are found in correlations, not in mean differences. Original paper has been replicated and yet results are not always significant. Now we are trying to generalize the effect to other areas: an individually administered measure will influence other measures made in the same session.

Other tests that correlate with hypnosis are studied with 2 x 2 design, enabling order effects and same vs separate contexts to be studied. Or two tests are administered at two points in time, with "bridges" between the two sessions (e.g. same experimenter, same consent forms, etc.) As one adds more and more bridging cues, the correlation of Absorption with other Tellegen MPQ subscales increases.

Same context assessment increases correlation between hypnotizability and 6-8 other scales; with childhood trauma scale when trauma scale is administered first; with beliefs in paranormal phenomena when the measure is related to an adjustment scale. The same inflation of correlations was found in Beck Depression scale research.

These results are of concern because we may have to re-do a lot of personality research that suggested correlation between personality test variables, as the correlations may be inflated by the effects of testing in the same context.

Glisky, Martha L.; Kihlstrom, John F. (1993). Hypnotizability and facets of openness. International Journal of Clinical and Experimental Hypnosis, 41 (2), 112-123.

Absorption, a correlate of hypnotizability, is related to a broader dimension of openness to experience, one construal of the "Big Five" structure of personality. But openness itself is very heterogeneous, and some of its facets may be unrelated to hypnotizability. A total of 651 subjects completed a questionnaire measuring three different aspects of openness -- absorption, intellectance, and liberalism -- before receiving the Harvard Group Scale of Hypnotic Susceptibility, Form A. The three dimensions were only modestly related to each other, and only absorption was significantly related to hypnotizability. Adding intellectance and liberalism to absorption did not enhance the prediction of hypnotizability. The results indicate that the various facets of openness are rather different from each other and that the "Big Five" structure may need to be expanded. Absorption and hypnosis share a kind of imaginative involvement that is not necessarily part of other kinds of openness, such as intellectance and liberalism.

1992

Barrett, Deidre (1992). Fantasizers and dissociaters: Data on two distinct subgroups of deep trance subjects. Psychological Reports, 71, 1011-1014.

The study delineated two subgroups of highly hypnotizable subjects. The first subgroup (fantasizers) entered trance rapidly, scored high on absorption (mean of 34 on the 37-item Absorption Scale), and described hypnosis as much like their rich, vivid, and very realistic waking fantasy life. None of the fantasizers experienced unsuggested amnesia, and 5/19 failed to produce suggested amnesia. Only 2/19 fantasizers described hypnosis as very different from their other experiences. The earliest memories of fantasizers were all identified as occurring before age 3, and before age 2 for 11 of 19. The second subgroup (dissociaters) took time to achieve a deep trance (unlike Wilson and Barber's fantasy-prone subjects, but they did achieve as deep a trance as fantasizers), experienced hypnosis as different from any prior experiences, and were more likely to exhibit amnesia for both hypnotic experience and waking fantasies. None of the dissociaters described their waking imagery as entirely realistic, and the earliest memories in this group were all over the age of 3 (mean age - 5). Of the 15 dissociaters, 7 scored below the norm on the Absorption Scale (Mean - 26).

Lynn, Steven Jay; Sivec, Harry (1992). The hypnotizable subject as creative problem-solving agent. In Fromm, Erika; Nash, Michael R. (Ed.), Contemporary hypnosis research (pp. 292-333). Guilford Press.

These notes are taken only from the section of this chapter that deals with Hypnotic Responding, Imaginative Activity, and Expectancies, and they treat of the concept of nonvoluntary responding (pp 315-316). Other topics covered in the chapter include: Imagination, Fantasy, and Hypnosis Theories; The Hypnotizable Subject as Creative Problem-Solving Agent; Hypnosis and Subjects' Capability for Imaginative Activity; Goal-Directed Fantasy: Patterns of Imaginative Activity during Hypnosis; Hypnosis and Creativity; and a Conclusion.

Several studies manipulated expectancies re the relationship between imagination and involuntariness. When Ss were told that "good" hypnotic subjects could (or could not) resist suggestions, "this information affected their ability to resist the hypnotist and tended to affect subjects' report of suggestion-related involuntariness ... [Lynn, Nash, Rhue, Frauman, & Sweeney, 1984]. Furthermore, subjects who successfully resisted suggestions and subjects who failed to do so reported comparable levels of hypnotic depth and imaginative involvement in suggestions.

"Spanos, Cobb, and Gorassini (1985) conducted a similar experiment in which they found that hypnotizable subjects who were instructed that they could become deeply involved in suggestions and yet resist them successfully resisted 95% of the suggestions and rated themselves as maintaining voluntary control over their behavior. Thus, subjects are able to resist nearly all of the suggestions when resistance is facilitated by situational demands. It is worth noting that subjects in this research who resisted hypnotic suggestions rated themselves as just as deeply

involved in the suggestions as Ss who failed to resist suggestions after being informed that deeply hypnotized subjects were incapable of resisting suggestions" (pp. 315-316).

Lynn, Snodgrass, et al. (1987). showed that hypnotizable Ss who were just "imagining" along with suggestions but instructed to resist responding to motoric suggestions acted the way hypnotized Ss did in their earlier countersuggestion research: imagining subjects tended to move in response to suggestion (that "good" Ss responded in certain ways), despite being instructed to resist. In this study, with instructions designed to increase the use of goal directed fantasies (GDFs), low and high hypnotizable subjects reported equivalent GDF absorption and frequency of GDFs. However, highs responded more and reported greater involuntariness than lows, even when their GDFs were equivalent.

"A number of other studies have examined the effects of expectancies on imaginings and hypnotic behavior. Spanos, Weekes, and de Groh (1984) informed subjects that deeply hypnotized individuals could imagine an arm movement in one direction while their unconscious caused the arm to move in the opposite direction. Even though subjects so informed moved in the opposite direction, they imagined suggested effects and described their countersuggestion behavior as involuntary" (p. 317).

**1990**

Avants, S. Kelly; Margolin, Arthur; Salovey, Peter (1990-91). Stress management techniques: Anxiety reduction, appeal, and individual differences. Imagination, Cognition and Personality, 10, 3-23.

Four stress management techniques were evaluated for their general appeal, their immediate benefits, and the subjective experiences they evoke. One hundred undergraduates were randomly assigned to one of five treatment groups: (1) progressive muscle relaxation (PMR); (2) distraction imagery; (3) focused imagery; (4) listening to music; (5) sitting quietly (control). Distraction imagery and listening to music were the only techniques found to reduce anxiety to a greater extent than simply sitting quietly. The techniques differed in the way they made subjects feel, but not in their general appeal. Individuals with a 'blunting' coping style were more likely to find all five techniques appealing.

Tests used included the Miller Behavioral Style Scale, Cognitive-Somatic Anxiety Questionnaire of Schwartz, Davidson & Golman, Life Orientation Test of Scheier & Carver, Somatic Perception Questionnaire of Landy and Stern, Body Consciousness Questionnaire of L. C. Miller, Murphy, & Buss, Betts' Questionnaire Upon Mental Imagery, Shortened Form, State-Trait Anxiety Inventory, and Technique Evaluation Questionnaire of the authors.

Progressive muscle relaxation was according to Bernstein & Borkovec. Distraction imagery involved successively imagining a walk along a beach, a stroll across a flower filled meadow, sitting by a stream, a walk into the woods, sitting in a cabin in the woods listening to the rain against the windowpane, all including images in a variety of sense modalities. Focused imagery involved creating an image of a stressor, then through symbolic imagery experiences Ss were guided through a

typical day's events that might lead up to the stressor, reinterpreting cues associated with the stressor as signals that they are in control, visualizing encountering the stressor feeling strong and determined, and any physical sensations reinterpreted as 'energy' that would help them to cope, visualizing enjoying their success (from Crits-Cristoph & Singer. Music was a 20-min tape (10 min of music used in the distraction imagery tape--Natural Light by Steve Halpern & David Smith) and 10 min of music used in background of the focused imagery tape (Structures of Silence by Michael Lanz). A 5th group, Control, was instructed to sit quietly with eyes closed.

This data can be used in support of imagery-suggestion types of hypnosis (as in surgery study) reducing anxiety. It shows particularly strong effects for people high in cognitive anxiety or low in optimism, pre-treatment.

Discussion: "... we feel confident that our distraction techniques were more effective for the immediate relief of anxiety than was PMR. This conclusion is consistent with the Suls and Fletcher meta-analysis (29) that suggested that 'avoidance' is an effective short-term coping strategy. That distraction (positive) imagery may be a more useful clinical technique than focused (active involvement) imagery was concluded in a study comparing these two techniques in the treatment of phobias (24)" (p. 19. [Ref #24 is Crits-Cristoph & Singer (1983) in *Imagination, Cognition, and Personality*.]

"Pessimism and cognitive anxiety emerged as the only individual difference variables to influence anxiety reduction. Pessimism as measured by the LOT is cognitive in nature, with most of the items relating to expectations of negative outcomes; similarly, cognitive anxiety is characterized by worry and an inability to control negative thoughts and images. That individuals who perceive their world somewhat negatively should have entered the study more anxious than individuals who do not is hardly surprising. What is surprising is that despite an inverse relation between cognitive anxiety and the ability to relax, these individuals were able to benefit from whatever technique they performed to a greater extent than were individuals with a more positive outlook. In fact, after performing the technique, pessimists had reduced their anxiety to the level of optimists" (p. 19).

"The stress management techniques used in the current study did not differ in their appeal" (p. 20). "Our finding that PMR produced more somatic effects than did focused imagery and less cognitive effects than did distraction imagery, listening to music, or sitting quietly is consistent with the model of anxiety proposed by Davidson and Schwartz (17). Our findings are also generally consistent with a conclusion reached by Woolfolk and Lehrer (4): that although various techniques are generally stress reducing, they seem to have highly specific effects. However, we found no support for the hypothesis that individuals who express anxiety cognitively (or somatically) prefer and benefit most from techniques that produce cognitive (or somatic) effects. In fact, the extremely high correlation found between the cognitive and somatic anxiety subscales of the Schwartz et al. measure (5) casts some doubt on the usefulness of a cognitive-somatic distinction, as does the corr between the experience of physical symptoms under stress (the Somatic Perception Questionnaire) with the cognitive, as well as the somatic, anxiety subscale.

-fects. In fact, the extremely high correlation found between the cognitive and somatic anxiety subscales of the Schwartz et al. measure (5) casts some doubt on the usefulness of a cognitive-somatic distinction, as does the correlation between the experience of physical symptoms under stress (the Somatic Perception Questionnaire) with the cognitive, as well as the somatic, anxiety subscale.

"The finding that blunTERS experiences more 'somatic effects' regardless of the technique they were assigned may have been the result of a single response--'how much did mind-wandering interfere with performing the technique'--which was the only Factor 2 item that was highly inversely related to blunting. Since blunTERS are more likely to perceive mind wandering as the essence of stress management rather than as 'interference,' we do not view this main effect as particularly illuminating" (p. 20). "However, our finding that blunTERS experienced all techniques as appealing is consistent with the results of Martelli et al. (1) who found that individuals with low information-preference benefitted from what the authors labeled an 'emotion-focused' intervention, but which, in fact, included many of the quite diverse stress management techniques that we compared in the current study. That 'avoiders' failed to benefit from any intervention in the Scott and Clum study (11) may be due to the nature of the stressor [postsurgical pain]. Our undergraduates may have been more like the Martelli dental patients in terms of their level of distress than were the Scott and Clum subjects who were patients undergoing major surgery (hysterectomy or cholecystectomy). Future research needs to examine possible three-way, technique by patient by stressor-type, interactions (cf. 19)" pp 20-21.

Biasutti, M. (1990). Music ability and altered states of consciousness: An experimental study. International Journal of Psychosomatics, 37, 82-85.

The relationship between music and altered states of consciousness was studied with 30 subjects divided into hypnosis and control groups. The "Test di abilita musicale" was applied. The hypnosis group did the retest after posthypnotic suggestions and the second in waking conditions. The hypnosis group had better results than the control group, especially in the rhythm test ( $p < 0.0001$ ).

Council, James R.; Huff, Kenneth D. (1990). Hypnosis, fantasy activity, and reports of paranormal experiences in high, medium and low fantasizers. British Journal of Experimental and Clinical Hypnosis, 7 (3), 9-15

The personality construct "fantasy-proneness" (Wilson and Barber, 1983a) has important implications for theories of hypnosis, imagination, and paranormal phenomena. The present study compared characteristics of persons who received high, medium or low scores on a self-report measure of fantasy-proneness. Results revealed that the three groups differed significantly on measures of absorption, daydreaming styles, and reports of paranormal experiences. However, although high fantasizers were significantly more hypnotizable than low fantasizers, they did not differ from the middle group. These results are used to further characterize fantasy-prone persons, and implications of extremely low fantasy-proneness are discussed.

Lombard, Lisa S.; Kahn, Stephen P.; Fromm, Erika (1990). The role of imagery in self-hypnosis: Its relationship to personality characteristics and gender. International Journal of Clinical and Experimental Hypnosis, 38 (1), 25-38.

30 volunteer Ss practiced self-hypnosis for approximately 4 weeks and wrote a record of their experiences in a diary following each session. Imagery produced during self-hypnosis was coded in 2 ways: the imagery was either reality oriented or it was fantastic and had primary process qualities. Levels of imagery production remained virtually the same over a 4-week period. Self-hypnotic imagery was significantly greater for the female Ss than for the male Ss, particularly primary process imagery. Verbal expressivity (measured as the average number of words per page of each S diary) was calculated to control for the effects of verbal production on Ss' imagery scores. When imagery scores were standardized based on verbal expressivity, female Ss still produced significantly more primary process imagery than male Ss. Personality characteristics (assessed by standardized personality inventories) were examined in relation to self-hypnotic imagery. "Impulse Expression" was positively related to primary process imagery for the female Ss. "Outgoingness" was positively related to primary process imagery for the entire sample, but especially for the female Ss.

1989

Buss, A. H. (1989). Personality as traits. American Psychologist, 44, 1378-1388.

Personality traits have been challenged as unimportant determinants of behavior, but evidence suggests that traits may carry as much variance as experimental manipulations. Asking whether traits or manipulations control more variance is useless because researchers can plan paradigms that favor one or the other. When traits and manipulations complement each other there are several major kinds of interaction. The trait-manipulation dichotomy is analogous to the person-environment dichotomy, and both are related to active versus passive models of behavior. Trait variance is increased by aggregating across responses, situations, and time. Underlying aggregation are the issues of units and classes of behavior. Individual responses are on a continuum of breadth that extends successively upward to response classes, personality traits, and higher order traits. Broad and narrow traits each have advantages and disadvantages. Recent research has led to novel personality traits and to knowledge about the origin and maintenance of traits. If there is to be a specialty called personality, its unique and therefore defining characteristic is traits.

Friswell, Rena; McConkey, Kevin M. (1989). Hypnotically induced mood. Cognition and Emotion, 3 (1), 1-26

This article addresses theoretical and methodological issues that are central to an understanding of hypnotically induced mood. Initially, the hypnotic procedures that are typically used to induce moods are examined. Then the empirical research that has employed hypnotic moods is reviewed; specifically, the impact of hypnotic

moods on physiological responses, behavioural performance, perceptual and cognitive responses, and personality, and clinical processes is examined. Finally, major theoretical and methodological issues are highlighted, and the research directions that will lead to a greater understanding of hypnotic mood are specified.

Hoyt, Irene P.; Nadon, Robert; Register, Patricia A.; Chorny, Joseph; Fleeson, William; Grigorian, Ellen M.; Otto, Laura; Kihlstrom, John F. (1989). Daydreaming, absorption and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 37, 332-342.

It appears that the consistent correlation between hypnotizability and positive-constructive daydreaming is carried largely by three subscales--Acceptance of Daydreaming, Positive Reactions to Daydreaming, and Problem-Solving. Number other subscales consistently correlated with hypnotizability.

When absorption was taken into account, daydreaming activity made no independent contribution to the prediction of hypnotizability. "The present results differ from Crawford's (1982) somewhat, however, in terms of the specific aspects of daydreaming activity that are associated with hypnosis. Crawford found that hypnotizability correlated consistently (i.e., in both men and women) with three subscales tapping imagery variables: the presence of visual and auditory imagery in daydreams and the hallucinatory vividness of daydream imagery. In the present study, the imagery subscale, including both visual and auditory items, did not correlate significantly with hypnotizability; unfortunately, the hallucinatory vividness subscale is not represented on the short form (SIPI) of the daydreaming questionnaire used in this study. Crawford (1982) did not find consistent correlations between hypnotizability and scales measuring acceptance, positive reactions, and problem solving--the subscales that consistently yielded significant correlations in the present study. Not too much interpretive weight should be given to any of the correlations between hypnotizability and daydreaming subscales, until a full replication with reliable subscale measurements (such as those provided by the long, original IPI) has been completed. The important point made by Crawford (1982), and confirmed in the present study, is that hypnotizability is related to positive-constructive rather than guilty-dysphoric daydreaming" (p. 338). The two studies agree that absorption and hypnosis are not correlated with daydreaming scales reflecting poor attentional control. Given the theoretical emphasis in both domains on the narrowing of attention and exclusion of potentially distracting input, negative correlations with this aspect of daydreaming might have been expected.

Kahn, Stephen P.; Fromm, Erika; Lombard, Lisa S.; Sossi, Michael (1989). The relation of self-reports of hypnotic depth in self-hypnosis to hypnotizability and imagery production. International Journal of Clinical and Experimental Hypnosis, 37, 290-304.

Studied multidimensional nature of self-hypnotic depth in 22 high hypnotizables who volunteered for self hypnosis research. On personality scales, they were

distinguished from the population at large by: strong theoretical orientation, high level of curiosity, disregard for opinions of others, and high Mf scale on the MMPI. Used the Stanford Profile Scale, SHSS:C and HGSHS:A, which measure the entire range of phenomena ordinarily used in experimental studies of hypnosis, including ideomotor phenomena, hypnotic fantasy and dreams, hypermnasias and age regressions, analgesias, negative and positive hallucinations, amnesias, posthypnotic phenomena, and cognitive and affective distortions. They asked Subjects to experience self hypnosis for 60 minutes/day for 4 weeks. Journals were coded for imagery production by scoring for both reality-oriented and primary process imagery. Subject had been taught to monitor their hypnotic depth using a slightly revised version of the Extended North Carolina Scale (ENCS) of Tart (1979). Previously, ENCS has been used only with hetero-hypnotic Subjects. The self-reports of depth using ENCS correlated highly with hypnotizability as measured by the Revised Stanford Profile Scale of Hypnotic Susceptibility... and with imagery production. Results demonstrate that ENCS scores are also a valid indicator of self-hypnotic depth among highly hypnotizable Subjects. Furthermore, they indicate that both hetero- hypnotizability and imagery production are related to self-hypnotic depth, but that the association between imagery and hypnotizability is due to their individual relationships to self-hypnotic depth. and hypnotizability is due to their individual relationships to self-hypnotic depth.

Malott, James M.; Bourg, Audrey L.; Crawford, Helen J. (1989). The effects of hypnosis upon cognitive responses to persuasive communication. International Journal of Clinical and Experimental Hypnosis, 37, 31-40.

Several writers have suggested that hypnotic responsiveness is directly related to the content of S's covert self-statements. To test this notion, low and high hypnotizable subjects in either hypnosis or waking conditions were exposed to a recorded message advocating that college seniors be required to pass a comprehensive exam in order to graduate. Following message presentation, subjects listed all of the thoughts which occurred to them while listening to the message; these thoughts were later coded as counterarguments, favorable thoughts, or neutral thoughts. Hypnotized subjects generated significantly fewer counterarguments and agreed more with the message than waking subjects. In addition, high hypnotizable subjects (in both waking and hypnosis conditions) produced significantly more favorable thoughts and agreed more with the message than low hypnotizability subjects. Results, therefore, provided a demonstration of the differential impact of context (induction) and trait (hypnotizability level) upon different cognitive phenomena. Implications for the occurrence of hypersuggestible behavior are discussed.

N = 48 (24 highs, 24 lows, blocked on sex and hypnotizability level, then randomly assigned to one of two conditions).

Hypnosis subjects generated significantly fewer counterarguments than waking subjects (12% vs 45%). Main effect for hypnotizability level was nonsignificant, as was the condition x hypnotizability interaction.

High hypnotizable subjects generated significantly more favorable thoughts than low hypnotizable subjects (28% vs 12%). The main effect for condition was nonsignificant, as was the condition x hypnotizability interaction.

Unexpectedly, hypnosis subjects produced a significantly greater number of neutral thoughts. The main effect for hypnotizability level did not reach significance, nor did the condition x hypnotizability interaction.

"Thus, as suggested by McConkey (1984), it may be the hypnotic context, rather than a hypnotic "state" which is responsible for reduced levels of counterarguing. ... the data indicate that an induction decreases counterarguing among high and low hypnotizable subjects alike; on the other hand, the incidence of favorable thoughts is related only to hypnotizability level and not to the hypnosis context. ... the present findings suggest that both context and trait play a role in the occurrence of hypnotic behavior, although each may do so by impacting upon different cognitive responses.

There appears to be a relationship between counterarguing and acceptance of the persuasive communication in the present study. First, there was a significant negative correlation between those two measures (collapsing across conditions), indicating that higher levels of counterarguing were associated with lower levels of communication acceptance. Second, subjects in the hypnosis condition who counterargued less than waking subjects, also indicated significantly higher levels of communication acceptance than waking subjects.

In a similar fashion, there appears to be a relationship between favorable thought production and communication acceptance. There was a significant positive correlation between the two measures, and high hypnotizable subjects who generated significantly more favorable thoughts than low hypnotizables, also produced higher scores on the attitude measure.

measures, and high hypnotizable subjects who generated significantly more favorable thoughts than low hypnotizables, also produced higher scores on the attitude measure.

They attribute the greater number of neutral thoughts for hypnosis subjects to minor differences in the instructions (p. 38).

1988

Council, James R.; Greyson, Bruce; Huff, Kenneth D. (1988, November). Reports of paranormal experiences as a function of imaginative and hypnotic ability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

Wilson and Barber (1983) have suggested that some excellent hypnotic subjects ("fantasy prone" persons) may be more likely to report paranormal experiences than the rest of the population. Council and Greyson (1985), studying a sample of subjects who had reported near-death experiences (NDEs), found a significant relationship between fantasy-proneness and NDEs, and a much stronger relationship between fantasy-proneness and reports of paranormal experiences in general. This paper presents new data from the study of NDE reporters and a

replication and extension of those findings with a sample not selected for NDEs. These data indicate a strong association between fantasy-proneness and reports of paranormal experiences. Hypnotic susceptibility bears a weaker relationship with such reports that appears dependent upon variance shared with measures of fantasy-proneness. Other data from these studies suggests that both imaginative ability and reports of paranormal experiences may be related to a history of stressful or traumatic childhood experiences.

Gudjonsson, Gisli (1988). Interrogative suggestibility: Its relationship with assertiveness, social-evaluative anxiety, state anxiety and method of coping. British Journal of Clinical Psychology, 27 (2), 159-166.

Investigated in 30 adults some of the theoretical components related to individual differences thought by the present author and R. Clark (1986) to mediate interrogative suggestibility as measured by a scale developed by the present author (1984). The variables studied were assertiveness, social-evaluative anxiety, state anxiety, and the coping methods generated and implemented during interrogation. Low assertiveness and high evaluative anxiety correlated moderately with suggestibility, but no significant correlations emerged for social avoidance and distress. State anxiety correlated significantly with suggestibility, particularly after negative feedback had been administered. Coping methods (active-cognitive/behavioral vs. avoidance) significantly predicted suggestibility scores. The findings give strong support to the present author's theoretical model.

Hines, Larry; Handler, Leonard (1988, November). Hypnotizability and ego functions. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

Researchers employed Bellak's Ego Functions Test (based on the clinical interview). Ss were 47 students and 1 non-student, some of whom had previously experienced hypnosis. They were all volunteers. Studied 12 ego functions. Used plateau hypnotizability which was defined as no improvement in Stanford Hypnotic Susceptibility Scale Form C after two hypnotic inductions; if they did not reach a plateau by Session 4, the highest score was used. Stanford Hypnotic Susceptibility Scale scores ranged 4-12. High 10-12, Medium 6-9, Low 4-5.  $\bar{x}=9.04$ ,  $SD=2.21$ .

On the Bellak Test, High 12-13, Medium 10-11 (average functioning.), Low 1-9. Range 5-13; widest range was in Adaptive Regression in Service of Ego Highest Mean = reality testing Lowest Mean = ARISE Majority fell into the medium range on all 12 ego functions measured.

A significant difference was found between High and Low hypnotizables on the following ego functions. [N.B. There may be transcription errors in the figures that follow.] 1. ARISE  $p<.02$   $r = .31$  Highs have greater ability to experience pleasure in regression. 2. Stimulus Barrier  $p<.003$  Highs are more flexible in their ability to separate from stimuli in their environment, Lows experienced stimulus overload. 3.

Autonomous Functioning  $p < .01$  Primary acct./ in attention, learning, memory, motor function. 4. Objective Relativity  $p < .07$  5. Regulating control of drive  $p < .06$  Multiple regression accounted for 33% of variance in 12 ego functions. Stimulus Barrier alone accounted for 14% ( $p < .005$ ); ARISE accounted for 5% ( $p < .01$ ). 47% of Ss were High hypnotizables, 42% were in the Medium range.

LeBaron, Samuel; Zeltzer, Lonnie K. (1988). Imaginative involvement and hypnotizability in childhood. International Journal of Clinical and Experimental Hypnosis, 36, 284-295.

2 pilot studies assessed the relationship between hypnotizability in children and extent of involvement in fantasy-related activities during early childhood. The Stanford Hypnotic Clinical Scale for Children and a structured interview questionnaire regarding fantasy activities based on previous work by Singer (1973) were given to 30 medical patients aged 6-18 years in the first study and to 37 healthy children aged 6-12 years from a school population in the second study. In both studies, hypnotizability correlated moderately (.42 and .39, respectively) with extent of involvement in fantasy-related activities. Results support Hilgard's (1979) findings that hypnotizability is related in part to the development of imaginative involvement in childhood.

Lynn, Steven Jay; Rhue, Judith W. (1988). Fantasy proneness: Hypnosis, developmental antecedents, and psychopathology. American Psychologist, 43 (1), 35-44.

This article presents a summary of the findings of our ongoing research program on the fantasy-prone person. In seven studies, nearly 6,000 college students were screened in order to obtain five samples of 156 fantasy-prone subjects. Fantasy-prone subjects (fantasizers) were selected from the upper 2%-4% of the college population on a measure of imaginative involvement and contrasted with nonfantasizers (lower 2%-4%), and medium fantasy-prone subjects (middle range). General support was secured for Wilson and Barber's construct of fantasy proneness: Fantasizers were found to differ from nonfantasizers, and in many cases also from medium-range subjects, on measures of hypnotizability, imagination, waking suggestibility, hallucinatory ability, creativity, psychopathology, and childhood experiences. Differences in hypnotizability were most reliable when subjects participated in a multisession study and were screened not only with the screening inventory, but also with an interview that substantiated their fantasy-prone status. However, our findings indicated that less correspondence between fantasy proneness and hypnotizability exists than Wilson and Barber suggested. Hypnotic responsiveness is possible even in the absence of well-developed imaginative abilities, and not all fantasizers were highly hypnotizable. Fantasizers recollected being physically abused and punished to a greater degree than other subjects did and reported experiencing greater loneliness and isolation as children. Many fantasizers appeared to be relatively well-adjusted; however, a subset of fantasizers were clearly maladjusted based on self-report, Minnesota Multiphasic

Personality Inventory (MMPI), and Rorschach test data. Because of the diversity inherent in the fantasy-prone population, it is misleading to think of individuals at the extreme end of the fantasy-proneness continuum as conforming to a unitary personality type.

Lytle, Richard A.; Lundy, Richard M. (1988). Hypnosis and the recall of visually presented material: A failure to replicate Stager and Lundy. International Journal of Clinical and Experimental Hypnosis, 36, 327-335.

Stager and Lundy (1985) found hypnotic hypermnesia without increased memory errors. The present study, an attempted partial replication of Stager and Lundy (1985), presented Ss with free recall and multiple choice questions about a short movie they had seen a week earlier. The experimental Ss, who were hypnotized, given hypermnesia suggestions, and retested, did not generally increase their accurate memory scores on posttest; the Stager and Lundy (1985) findings were thus not confirmed. An increase in memory scores did occur, however, but only with high hypnotizable Ss, whether they were hypnotized or not, and only with multiple choice questions. The high hypnotizable Ss had the greatest increase in inaccurate memory scores on the free recall questions.

This study provides data on response tendencies by using two forms of question: recall (as in Stager & Lundy (1985) and recognition, from a 4-choice multiple choice format.

120 Ss were screened with Harvard Scale to yield 24 high (10-12) and 24 low (0- 4) hypnotizable Ss. They were randomly assigned to four groups (two recall conditions and two test form conditions).

Ss saw a 15-minute movie, "Posters," and a week later were tested: oral presentation of questions (on audiotape), alternating multiple-choice and recall formats, ABBA for 50% and BAAB for 50% of Ss. After 40 pretest questions they were hypnotized (or given attention-focusing awake instructions to count randomly occurring clicks barely audible over white noise for 15 minutes--described as a very important task). Then all Ss were told they would again hear 40 questions about the movie, that they would find the answers "coming more easily" than before, and that they should give the best answers that they could. They received the same test form as before (post-test).

**RESULTS.** Total Scores were analyzed with a 4-way ANOVA (hypnotizability; recall condition = hypnosis or attention control; question format = multiple choice or free recall; and pretest-posttest). The ANOVA yielded 3 main effects: 1. Posttest

scores were greater than pretest scores. 2. Multiple choice scores were greater than free recall scores. 3. High hypnotizable scores were greater than low hypnotizable scores.

Also they found a 2-way interaction between hypnotizability and pre- vs. postadministration. There was an increase from pretest to posttest for the high hypnotizable Ss and the highs had greater scores relative to the lows in the posttest administration.

Correct Scores analysis showed two main effects: 1. Posttest scores were greater than pretest scores. 2. Multiple choice scores were greater than free recall scores.

Also there was a two-way interaction between hypnotizability and pre-postadministration, such that the scores of highs relative to the scores of lows increased more from pre- to posttest.

Also there was a three-way interaction for hypnotizability, question format, and pre-postadministration was significant. There was an increase from pre- to posttest in the scores of the high hypnotizable Ss on the multiple choice format, with no increase for the low hypnotizables or on the free recall format.

that the scores of highs relative to the scores of lows increased more from pre- to posttest.

Also there was a three-way interaction for hypnotizability, question format, and pre-postadministration was significant. There was an increase from pre- to posttest in the scores of the high hypnotizable Ss on the multiple choice format, with no increase for the low hypnotizables or on the free recall format.

Incorrect Scores showed three main effects: 1. Posttest scores were greater than pretest scores. 2. Free recall scores were greater than multiple choice scores. 3. High hypnotizable scores were greater than low hypnotizable scores.

A three-way interaction also was found: the pretest to posttest increase was only for the free recall questions with high hypnotizable Ss, and free recall posttest scores for highs was greater than those same scores for lows. Pretest differences between hypnotizability groups and pre- postdifferences for the low hypnotizable Ss were not found.

In the Discussion, the authors note that this study did not confirm Stager and Lundy. "Although the high hypnotizable Ss in the hypnosis condition did increase their free recall correct scores, this increase was not significant or different from the general increase made by all Ss. Further, the increase of the incorrect scores in free recall ...[was] greater, though not significantly, for the high hypnotizable Ss in the hypnosis condition than for any other group" (p. 331). The differences in results may be due to different question format. On the other hand, reviews such as those by Shields and Knox (1986) usually find little, or at best modest, improvement of memory with hypnosis. In the present study, as with Stager and Lundy (1985) the memory increase observed was with the highly hypnotizable Ss. But those Ss are also the ones who increase their incorrect scores. "When the correct response is available to Ss (the multiple choice format), the high hypnotizables increase their correct scores. When the correct response, or any other alternative, is unavailable to Ss (the free recall format), the high hypnotizables increase their incorrect scores" (p. 332).

"The high hypnotizable Ss gave more incorrect responses than the low hypnotizables on both pre- and posttest and in both test formats. Although this tendency to respond incorrectly is most apparent in the posttest free recall condition, Table 3 also shows that even in the multiple choice form, the high hypnotizable Ss appear to be responding more incorrectly. Thus, the high hypnotizables not only incorporate more incorrect information presented to them, as found by Sheehan (1985, 1988), but they also make more errors in test situations which supply them with no information and which supply them with the correct information. Also, high hypnotizable Ss have been found by Laurence, Nadon, Nogrady, and Perry (1986) to believe that hypnotically suggested pseudomemories are in fact veridical" (pp. 332-333).

The authors suggest that the increase in both correct and incorrect scores (for both question formats) may be due to a decrease in the 'don't know' or no response category. This suggests that high hypnotizable Ss may be more willing to guess in the posttest. Perhaps it is a criterion shift. If so, the shift occurs whether or not they are hypnotized, and it leads to increased accuracy sometimes but also decreased accuracy sometimes. "When the correct answer is available, as in the multiple choice format, the high hypnotizable Ss can increase their correct responses significantly, but when the correct response is not available, as in free recall, they increase their incorrect responses significantly" (p. 333).

The authors present a cautionary note. "Although the statistical analysis confirms hypnotizability as a significant effect, it must be remembered that this study, and the others reported above, took place in a hypnotic context. ... The results suggest, however, that the personality characteristics underlying measured hypnotizability may be important factors in memory enhancement and memory distortion and that studies directed toward tapping those characteristics will be fruitful in future research efforts" (pp. 333-334).

Re forensic application, "changes in memory that occur in the hypnotic context probably occur as a result of witnesses' decreased reticence, that is, as a result of their belief that they can now answer questions that they previously could not answer" (p. 334).

1987

Lynn, Steven Jay; Rhue, Judith W. (1987). Hypnosis, imagination, and fantasy. Journal of Mental Imagery, 11, 101-112.

Considers three questions pertaining to the relationship between hypnotic responsiveness and imaginative processes: Are subjects' nonhypnotic imaginative involvements related to hypnotic susceptibility? Do some fantasy prone subjects share a unique constellation of personality attributes and experiences, including an ability to respond to hypnotic suggestions? What are the childhood developmental antecedents of persons who score at the extremes of hypnotic ability and measures of fantasy and imagination? Reviews literature.

Monteiro, Kenneth P.; Zimbardo, Philip G. (1987). The path from classroom seating to hypnotizability--a dead end: A brief communication. International Journal of Clinical and Experimental Hypnosis, 35, 83-86.

It has been proposed that classroom seating behavior predicts brain functioning involved in hypnotizability and in other cognitive processes. The present authors attempted to test this hypothesis and to replicate some earlier findings. The relationships between classroom seating preference, actual seating location, and hypnotizability in male and female students were investigated. No relationship was found between any of the seating measures and hypnotizability. These findings lend no support for the hypothesis that classroom seating predicts hypnotizability. This failure to replicate is discussed in relationship to the lack of theoretical grounding for the seating-hypnosis connection.

The authors review the literature, then present and test specific hypotheses that right-side seating preferences would be correlated with hypnotizability for males, while actual seating on the right side of the class would be associated with higher hypnotizability scores for females. This pattern should be more robust for right-handed than for left-handed students. They found no support for these hypotheses. They suggest that other measures of cognitive processing may correlate with a social behavior such as classroom seating. Monteiro & Zimbardo (unpublished ms.) found that the variables of field independence and field sensitivity predicted actual seating behavior in males and seating preference in females.

1986

Belicki, Kathryn; Belicki, Denis (1986). Predisposition for nightmares: A study of hypnotic ability, vividness of imagery, and absorption. Journal of Clinical Psychology, 42 (5), 714-718.

The relationships of nightmare frequency to hypnotic ability, vividness of visual imagery, and the tendency to become absorbed in fantasy-like experiences were examined. Subjects were 841 undergraduate university students who participated in group tests of hypnotic ability, after which they estimated the number of nightmares that they had experienced in the prior year. In addition, 406 of the subjects completed Marks' Vividness of Visual Imagery Questionnaire, and Rotenberg and Bowers' Absorption scale. Of the subjects, 76% reported experiencing at least one nightmare in the prior year; 8.3% indicated one or more per month. Individuals with frequent nightmares scored higher on hypnotizability, vividness of visual imagery, and absorption.

620, Belicki & Bowers, 1982 ABSTRACT: Investigated the role of demand characteristics in dream change by comparing dream report change following pre- and postsleep administrations of instructions to pay attention to specific dream content. This design was based on the assumption that if presleep instructions merely distort dream reports rather than influence actual dreams, report change should be observable following a postsleep instruction. 42 undergraduates were prescreened with the Harvard Group Scale of Hypnotic Susceptibility (Form A),

which allowed experimenters to examine the role of hypnotizability in dream change. Significant differences were observed only following the presleep instructions. It is concluded that report distortion as a result of paying attention to a dimension of dream content was insufficient to account for dream report change following presleep instructions. Hypnotic ability correlated significantly with the amount of dream change.

Lynn, Steven Jay; Rhue, Judith W. (1986). The fantasy-prone person: Hypnosis, imagination, and creativity. Journal of Personality and Social Psychology, 51, 404-408.

Experimenters selected subjects who ranged along the continuum of fantasy proneness and assessed hypnotizability, absorption, vividness of mental imagery (QMI; Sheehan, 1967), response to waking suggestion (Creative Imagination Scale), creativity, and social desirability (Crowne & Marlowe). Fantasy-proneness was evaluated with the Inventory of Childhood Memories and Imaginings (Wilson & Barber, 1981). Strong support was secured for J. R. Hilgard's construct of imaginative involvement and Wilson and Barber's contention that fantasy prone persons can be distinguished from others in terms of fantasy and related cognitive processes. Fantasizers were found to outscore subjects in both comparison groups on all of the measures of fantasy, imagination, and creativity, with social desirability used as a covariate. Low fantasy-prone subjects were no less creative or less responsive to hypnosis than their medium fantasy-prone counterparts.

Mitchell, George P.; Lundy, Richard M. (1986). The effects of relaxation and imagery inductions on responses to suggestions. International Journal of Clinical and Experimental Hypnosis, 34, 98-109.

Theoretical attempts to understand the meaning and importance of induction procedures in producing hypnotic phenomena suggest that 2 critical components, relaxation and imagery, should be isolated and their relative effect on hypnotic responding studied. Objectively and subjectively scored responses to 12 hypnotic suggestions, which had followed relaxation, imaginal, or combined inductions, were obtained from 59 Ss, divided into 3 levels of hypnotizability. Regardless of hypnotizability level, the combined induction led to a greater subjective report of hypnotic response than hypnotic response than did either the relaxation or the imagery inductions; and the relaxation led to a greater subjective report than the imagery induction. It may follow that the subjective experience of hypnosis is facilitated by inductions which include relaxation. The inductions were equally effective in producing objectively measured behavioral responses. There were no significant interactions found between induction type and hypnotizability level.

(From the Discussion Section). As suggested by Sacerdote (1970), the combination procedure was the most generally effective in producing hypnotic responses. The difference between combined and imagery inductions reached statistical significance

on four dependent variables, and the difference between combined and relaxation reached significance on three. It may also be of interest that Ss receiving the combined procedure scored consistently higher on all nine dependent variables.

A somewhat unexpected finding was that the relaxation induction produced scores on four of the dependent variables that were statistically higher than the imagery induction scores. Considering the difficulty of isolating relaxation and imagery components, it is quite noteworthy that these differences between inductions were found.

The four variables in which the combination and relaxation conditions produced significantly higher scores than the imagery condition were subjective reports--subjective score, degree hypnotized, response volition, and Field Inventory. In contrast to Ss in the imagery induction, Ss in the other two induction conditions believed that they were responding more, felt that their responses were more nonvolitional, and felt that they were more deeply hypnotized.

The fact that relaxation instructions were present in both conditions that were superior to the imagery condition would appear to support Edmonston's (1981) position which posits relaxation as essential for the production of the state of neutral hypnosis. For Edmonston the condition of neutral hypnosis is defined as the relaxed state and precedes other phenomena, such as dissociation and increased suggestibility, which other theoreticians may include in the definition of hypnosis.

However, the statistically significant superior effect of the combined over the relaxation induction on three measures casts doubt on Edmonston's position. The S believes that he or she is more deeply hypnotized and is responding less volitionally when an imagery component is combined with relaxation. The Ss also responded more to the Field Inventory when the combined induction was used.

Another explanation for imagery's relatively poor showing may lie in Ss' differential expectations. The Ss, especially those with previous experience with a traditional hypnotic induction, as was the case in the present study, may not expect to be hypnotized when presented with an imagery alone induction. Such expectations, of course, might reduce responses. On the other hand, there is no reason to believe that the reduced expectation in the imagery condition would not affect the behavioral responses as well, and such was not the case.

Thus, we may be left with the explanation that relaxation adds to the subjective experience of hypnosis. This is in keeping with Edmonston's (1981) position as well as with previous research, such as that by Hilgard and Tart (1966), which finds traditional inductions, with their relaxation components, superior to nontraditional inductions, such as fantasy or task-motivational. If future research should find that bodily involvements such as the physical exertion or repetitive motor behavior (Banyai and Hilgard, 1976) lead to the same level of subjective experience as relaxation did, then we may need to broaden the concept of the somatic component beyond relaxation alone.

In terms of the behavioral compliance of Ss, the results of the present study are in accord with some previous studies in finding all procedures equally effective. Neither imagery, relaxation, nor the combined procedure was superior for the behavioral measure.

Personality factors (social desirability, internality/externality, and absorption) did not affect the basic findings. To the degree that the Tellegen scales measure the ability to engage in imagery there seems to be little basis for believing that imagery ability is related to the general findings.

Sarbin (1983) would call the inductions studied here 'entrance rituals,' and he has recently asked in his review of Edmonston's book, "Which ritual is more suitable... [p. 58]' for preparing S to respond in various hypnotic ways? One answer from the present results is that an entrance ritual should include muscular relaxation if one wants a better subjective response from S. From Sarbin's point of view, the relaxation component may be more ego-involving, producing more subjective experience and meaning for S.

If one wants to produce only a behavioral response, either a relaxation or imagery ritual

In terms of the behavioral compliance of Ss, the results of the present study are in accord with some previous studies in finding all procedures equally effective. Neither imagery, relaxation, nor the combined procedure was superior for the behavioral measure.

Personality factors (social desirability, internality/externality, and absorption) did not affect the basic findings. To the degree that the Tellegen scales measure the ability to engage in imagery there seems to be little basis for believing that imagery ability is related to the general findings.

Sarbin (1983) would call the inductions studied here 'entrance rituals,' and he has recently asked in his review of Edmonston's book, "Which ritual is more suitable... [p. 58]' for preparing S to respond in various hypnotic ways? One answer from the present results is that an entrance ritual should include muscular relaxation if one wants a better subjective response from S. From Sarbin's point of view, the relaxation component may be more ego-involving, producing more subjective experience and meaning for S.

If one wants to produce only a behavioral response, either a relaxation or imagery ritual will serve.

**1985**

**Kerry Buhk; Rhue, Judith; Henry, Stephanie; Lynn, Steven Jay (1985, November). Fantasy proneness: Are their word associations richer?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.**

Experimenters screened 7000 students to get 6 samples of fantasy prone Ss (top 2.4% on Wilson and Barber's ICMI). They found less association between fantasy proneness and hypnotizability than did Wilson and Barber.

They had fantasizers hallucinate a second cup next to a first styrofoam cup. Results were that 87% of High fantasizers, < 50% Medium fantasizers, < 25% Low fantasizers could do it, but they didn't describe seeing the hallucinated cup "as real as real" as Wilson and Barber said they did.

Experimenters were concerned about context effects (expectancy) because the Creativity and Fantasy Proneness tests were run proximal in time, so they separated

in time the administration of Fantasy Prone and Creativity tests and also looked at word associations.

23 High and 20 Low fantasy prone students selected by ICMI, which was administered to Subjects 18 mos before the creativity study. At the time of the creativity study, Ss were informed they were randomly picked. There were two 90' sessions, counterbalanced.

Sessions: 1. Hallucinate image of R.A. and of styrofoam cup. Other tests were administered for intelligence and personality: Shipley-Hartford, MMPI, Crowne-Marlowe, etc. 2. Creativity tests (Revised Art Scale, Hilgard's Alternate Uses; story production which was scored on detail, imagery and fantasy and on imagery nouns.) Results of this study which was independent of context (i.e. the tests being correlated were administered independently of each other, separated by time). 1. Fantasizers were more creative than low fantasizers on both Creativity Scales. 2. Fantasizers show more divergent thinking on Hilgard Alternate Uses test, but relationship between fantasy proneness and creativity were not strong,  $r = .30$ . 3. Fantasizers and non fantasizers did not differ on the story measures! This diverges from Wilson and Barber's results. Fantasizers may have more vivid images, but storytelling does not capture that.

Kunzendorf, Robert G.; Benoit, Michelle (1985-86). Spontaneous post-hypnotic amnesia and spontaneous rehypnotic recovery in repressors. Imagination, Cognition and Personality, 5 (4), 303-310.

The Salpatriere school of hypnosis posited that true hypnotic effects occur spontaneously in people with repressive tendencies. Consistent with this early position, the current study indicates that both spontaneous amnesia after hypnosis and spontaneous recovery during rehypnosis are statistically associated with repression (but not with hypnotic suggestibility). In contrast, both suggested forgetting and suggested recovery are statistically associated with hypnotic suggestibility (but not with repression). Whereas the latter effects of suggestibility are attributable to the demand characteristics of hypnotic suggestions, the spontaneous effects of hypnosis on repressors' memories are not reducible to social psychological principles.

1982

Hilgard, Josephine R.; LeBaron, Samuel (1982). Relief of anxiety and pain in children and adolescents with cancer: Quantitative measures and clinical observations. International Journal of Clinical and Experimental Hypnosis, 30, 417-442.

Children and adolescents with cancer, chiefly forms of leukemia, aged 6 to 19 years, underwent medical treatments which required repeated bone marrow aspirations, normally a painful and anxiety-provoking experience. Data were obtained in baseline bone marrow observations on 63 patients, who were then offered the opportunity to volunteer for hypnotic help in pain control. Of the 24 patients who accepted hypnosis, 9 were highly hypnotizable. 10 of the 19 reduced self-reported pain substantially by the first hypnotic treatment (the prompt pain reducers) and 5

more reduced self-reported pain by the second treatment (the delayed pain reducers) while none of the 5 less hypnotizable patients accomplished this. The latter benefitted by reducing anxiety. Short case reports illustrate the variety of experiences.

Analysis of baseline observations before any therapeutic intervention revealed age and sex differences. The difference between self-reported and observed pain was not statistically significant for patients under age 10 but was significant for the patients age 10 and older ( $p < .001$ ). There were minor but significant sex differences both in observed pain ( $p < .01$ ) and in self-reported pain ( $p < .05$ ), with the females reporting more pain.

**1981**

Fromm, Erika; Brown, Daniel P.; Hurt, Stephen W.; Oberlander, Joab Z; Boxer, Andrew M.; Pfeifer, Gary (1981). The phenomena and characteristics of self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 189-247.

Self-hypnosis and hetero-hypnosis were compared, and self-hypnosis was studied longitudinally. Results indicated that absorption and the fading of the general reality orientation are characteristics of both hetero-hypnosis and self-hypnosis. The differentiating characteristics lie in the areas of attention and ego receptivity. Expansive, free-floating attention and ego receptivity to stimuli coming from within are state-specific for self-hypnosis, while concentrative attention and receptivity to stimuli coming from one outside source--the hypnotist on whom the subject concentrates his attention--are state-specific for laboratory defined hetero-hypnosis.

Attempts to produce age regression and positive or negative hallucinations are markedly more successful in hetero-hypnosis. Imagery is much richer in self-hypnosis than in hetero-hypnosis. Self-hypnosis requires adaptation to the state: in the beginning of self-hypnosis there is a good deal of anxiety and self-doubt. As the subject feels more comfortable in the self-hypnotic state, he spends less time worrying about failures in self-suggestion, his ability to enter trance quickly and easily increases, as does the fading of the general reality orientation, trance depth, and absorption. An attempt was also made in the present study to find personality characteristics related to the ability to experience self-hypnosis.

**1978**

Hiscock, Merrill (1978). Imagery assessment through self-report: What do imagery questionnaires measure?. Journal of Consulting and Clinical Psychology, 46, 223-229.

Four studies examined imagery questionnaires and addressed issues of reliability, agreement among different questionnaires, social desirability, and construct validity. The Betts, Paivio, and Gordon scales were examined. In two studies the Betts and Paivio correlated .45-.50, but correlations involving the Gordon were inconsistent from one study to the next. Imagery measures generally were not

influenced by social desirability. Factor analysis indicated that subjective and objective measures of visualization are independent. Concludes that imagery is not a unitary construct and that criteria other than visuospatial tests may be appropriate for validating imagery questionnaires.

1977

Grant, Guy (1977). The psychophysiology and hypnotherapeutic management of cancer. Australian Journal of Clinical Hypnosis, 5, 35-49.

Reviews research on psychophysiology of cancer, effect of stress on host resistance, cancer prediction from personality traits, psychological theories of cancer aetiology, and psychological characteristics of patients with different types of neoplasms. The hypnotherapy of cancer patients is outlined in terms of its effect upon the malignancy, relief of discomfort, and psyche of the cancer patient. Recommends direction of hypnotherapeutic treatment of cancer patients.

1976

Cooper, Leslie M.; London, Perry (1976). Children's hypnotic susceptibility, personality, and EEG patterns. International Journal of Clinical and Experimental Hypnosis, 24, 140-148.

19 boys and 16 girls, aged 7 to 16, were given the EEG and then the Children's Hypnotic Susceptibility Scale, while a parent watched. About 1 week later, after some separate tests and interviews, each child was given a puzzle to solve in the parent's presence, while Es recorded offers and requests for help. Hypnotic susceptibility was positively correlated with the alpha duration with eyes open, but not with eyes closed. Both susceptibility and alpha duration tended to be negatively correlated with age. Highly susceptible children tended to wait longer than low susceptibles before asking parents for help with the puzzle, and their parents tended to be more strict, anxious, and impatient than did the parents of low susceptible children.

King, Dennis R.; McDonald, Roy D. (1976). Hypnotic susceptibility and verbal conditioning. International Journal of Clinical and Experimental Hypnosis, 24, 29-37.

18 Subjects highly susceptible to hypnosis and 18 Subjects refractory to hypnosis were studied in a verbal conditioning task modeled after the one used by Taffel (1955). Results indicated that the highly susceptible group showed significantly greater conditioning than the low group. Awareness of the reinforcement contingency by S was not related to the learning task nor to hypnotic susceptibility. A measure of S's attitude toward the reinforcement cue during learning showed that the highly susceptible group had a more positive set toward the cue, whereas the low group tended to respond to it in a neutral or negative manner. Results were interpreted in terms of the theoretical nature of hypnotic susceptibility

They review literature on attempts to correlate hypnotizability with verbal conditioning ability.

Volunteer students participated; screened by HGSHS:A: highs 10-12, lows 0-4.

Verbal conditioning procedure: S viewed 100 3x5 cards on which were a two-syllable, past tense verb, below which typed in upper case letters on one line were the pronouns I, WE, HE, SHE, THEY, and YOU (randomly assigned to different orders). E was blind to hypnotizability. E instructed S to make up a sentence using the verb and a pronoun; gave no response for first 20 trials; said "good" to usage of I or WE during conditioning.

Afterwards, S filled in an Awareness Questionnaire (What was purpose? If E gave cues, what were they? If you noticed cues, what do you think they indicated?) and attitude toward the reinforcement cue (Did you notice that I did anything special? What? Did I say "good" for a special reason? What was the reason for my saying "good"? How did hearing the word "good" affect you during the experiment? IN a positive, negative, or neutral way?

Results. Groups did not differ at baseline but did differ at Blocks 2 (highs 9.7 vs lows 6.3;  $p < .05$ ) and 3 (highs 10.4 vs lows 6.3;  $p < .05$ ). Although the High group continued to maintain a somewhat higher level of responding than the Low group during extinction (9.8 vs 7.6), this difference did not reach statistical significance. (The graph shows an increase for Lows during extinction!)

Using a liberal definition of awareness and a learning index computed for each S by subtracting his operant level of response from the mean number of correct responses shown during the 3 blocks of acquisition trials, Subjects were ordered and a median test applied; contingency coefficient of .28 not significant ( $p < .10$ ).

Attitude significantly differentiated High and Low hypnotizability groups (see Table 2) with Highs more often responding in positive manner to reinforcement cue and Lows giving a neutral rating. Awareness of reinforcement contingency was equally represented in High and Low groups. The Aware High Positive groups learning index differed significantly from Aware Low Neutral group ( $p < .01$ ); the Unaware Low Positive group ( $p < .05$ ); and the Unaware Low Neutral group ( $p < .001$ ).

Thus, the Aware High Positive group's learning index score was significantly higher than that of the 3 Low groups. Also, the Unaware High Positive group differed significantly from the Unaware Low Neutral group ( $p < .05$ ). No other High groups differed from the Low groups and none of the High groups differed among themselves.

Among the Low groups, only the Unaware Low Positive group differed significantly from the Unaware Low Neutral group ( $p < .05$ ).

Discussion. Data show that hypnotizability is important in response to verbal conditioning, extending findings of Das (1958) by showing that primary suggestibility is associated with operant as well as classical conditioning but also those of Weiss et al. (1960) in illustrating that higher hypnotic susceptibility leads to enhanced verbal conditioning, using an improved measure of hypnotic susceptibility.

Awareness of reinforcement contingencies is not sufficient to account for subject differences in verbal conditioning; the characteristics tapped by HGSHS:A produce conditioning which cannot be accounted for by awareness alone.

extending findings of Das (1958) by showing that primary suggestibility is associated with operant as well as classical conditioning but also those of Weiss et al. (1960) in illustrating that higher hypnotic susceptibility leads to enhanced verbal conditioning, using an improved measure of hypnotic susceptibility.

Awareness of reinforcement contingencies is not sufficient to account for subject differences in verbal conditioning; the characteristics tapped by HGSHS:A produce conditioning which cannot be accounted for by awareness alone.

The fact that high susceptible Subjects here rated E's cue more positively than low susceptible Subjects is further consistent with some of the personological descriptions associated with hypnotic susceptibility which have been offered by Hilgard (1968). In addition, Cairns and Lewis (1962) and Spielberger et al. (1962) found that persons who assigned more positive value to the kind of reinforcement present in verbal conditioning experiments produced greater conditioning than Subjects whose attitudes were less favorable or non-committal toward the reinforcement. This relationship is not clear-cut in the present data in that although the High groups had an overall more positive attitude regarding reinforcement, only the Aware High Positive group learned better than all the Low groups, while the only other High group learning better than a Low group was the Unaware High Positive which had a significantly better learning index score than the Unaware Low Neutral group. Moreover, positive attitude did not differentiate learning within the High groups or the Low groups. Thus, the present data are unclear regarding the role attitude plays in the acquisition of verbally conditioned responses.

The roles of awareness and attitude could probably be better defined in future research using larger experimental groups. The attitude measure employed here was a gross one and a more sophisticated assessment of the valence characteristics of reinforcement cues could reveal more complex relationships in subsequent research. In addition, a more careful assessment than was done here of the role of cooperation and demand characteristics would contribute substantially to understanding more completely the effect of awareness on these phenomena.

The general indications regarding attitude may in part account for the increased interest in production of conditioned responses in Figure 1 shown by the Low group (graph) during the extinction phase of this experiment. Although highly susceptible Subjects show a decrease in the correct response with nonreinforcement, low susceptible Subjects begin to evidence an increase in the correct response. The attitude measure indicates that Subjects in the Low group did not respond positively to the reinforcement cue, and one of these Subjects reported in the interview that he did not like being told what to do by the E. It can be speculated that these Subjects were aware of the reinforcement contingency but did not "cooperate" until the reinforcement was absent. This follows the interpretation of Farber (1963) who found that aware Subjects who conformed to the demand characteristics of the experimental situation showed greater verbal conditioning than those who were aware and nonconforming. It thus appears that a willingness to go along with E's expectations and a positive, cooperative attitude are common features in individuals who make good hypnotic Subjects and who evidence an enhanced propensity for verbal conditioning.

Lenox, J. R.; Bonny, H. (1976). The hypnotizability of chronic alcoholics. International Journal of Clinical and Experimental Hypnosis, 24, 419-425.

Research on the hypnotizability of alcoholics is rare, contradictory, and fails to consider the age of alcoholic samples, who are much older than college norm groups. 36 male chronic alcoholics were given the Harvard Group Scale of Hypnotic Susceptibility, Forms A and B of Shor and E. Orne (1962, 1963a), administered individually and then averaged. Alcoholics scored lower, but not significantly so, than controls matched for age and sex. An expected negative correlation of age with hypnotizability was not found. The implications of these results for past studies are discussed.

Miller, Lawrence J. (1976). A comparison of hypnotic susceptibility for internal and external locus of control subjects in hetero- and self-hypnotic treatments (Dissertation). Dissertation Abstracts International, 37, 978-979.

"This study investigated the use of self- and hetero-hypnosis with internal and external locus of control subjects. Fifty-eight subjects, matched on hypnotic susceptibility and internal-external locus of control, were randomly assigned to the self- or hetero-hypnotic treatments. Self reports of their hypnotic behavioral scores and hypnotic subjective responses were obtained for each subject. "The statistical analyses showed there were no significant differences between the internal and external locus of control groups or within groups in regard to self- and hetero-hypnosis total behavioral scores, "challenge" or "non-challenge" items, ... their reported subjective experiences. The results supported the similarity of hetero- and self- hypnosis. Various findings from past research in regard to I-E subjects were also challenged in terms of their generalizability to hypnotic settings" (pp. 978-979).

1970

Fromm, Erika; Oberlander, Mark I.; Gruenewald, Doris (1970). Perceptual and cognitive processes in different states of consciousness: The waking state and hypnosis. Journal of Projective Techniques and Personality Assessment, 34, 375-387.

Hypnosis was assumed to influence perceptual and cognitive functioning in the direction of increased primary process ideation and adaptive regression. The Rorschach test was administered to 32 Ss in the waking state and under hypnosis in counterbalanced order. Hypnosis was induced by a standardized procedure. Ss received identical instructions for the Rorschach in both conditions. Protocols were scored according to Holt's system for manifestations and control of primary process. Hypnotic Rorschachs showed an increase in primary process manifestations, but no changes in defensive and coping functioning, and no overall changes in the Adaptive Regression Score. However, the nature of the data was found to be influenced by Ss' sex and level of adjustment.

Faw, Volney; Sellers, David J.; Wilcox, Warren W. (1968). Psychopathological effects of hypnosis. International Journal of Clinical and Experimental Hypnosis, 16, 26-37.

The probability that hypnotic induction produces psychopathological effects has not been experimentally determined. The present study hypothesizes various negative effects following hypnosis such as increased signs of personality disturbances, increased need for medical attention, greater tendencies toward suicide, and negative effects among the more maladjusted persons of the population sample. 107 college students were assigned at random to experimental and control groups. The experimental group was hypnotized 3 times in successive weeks. A comparison between control and experimental groups in respect to pre- and post-MMPI score differences plus a follow-up with the college counseling center and infirmary for a 90-day period following induction led to the rejection of the hypotheses. A comparison of measures yielded some significant differences in favor of the experimental group. It is concluded that there are nondetrimental effects when hypnosis is used with a normal college population.

Cooper, Leslie M.; Pedersen, Darhl M. (1965). A note on the failure to find personality differences between volunteers and nonvolunteers for hypnotic research. International Journal of Clinical and Experimental Hypnosis, 13 (4), 274-278.

Personality measures were administered to 136 students in an introductory psychology class at Brigham Young University. 30 Ss subsequently volunteered to have their hypnotic susceptibility assessed. There were no significant differences found between the means of the resulting 23 variables for the 30 volunteers and 106 nonvolunteers. 2 variables (age and ego strength) showed significantly different

variances for the 2 groups, but these may be attributed to chance because of the number of significance tests made. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

**1964**

Cooper, G. W.; Dana, R. H. (1964). Hypnotizability and the Maudsley Personality Inventory. International Journal of Clinical and Experimental Hypnosis, *12*, 28-33.

The Maudsley Personality Inventory was administered to 349 male college students. 9 male Ss were chosen to represent each of the 4 possible combinations (total N = 36) of extreme high and low extraversion and introversion scores. An attempt was made to hypnotize each S by means of the Stanford Hypnotic Susceptibility Scale, Form C. Analysis of variance indicated no significant relationship between either extraversion or neuroticism and hypnotizability, although the relationship between extraversion and hypnotizability approached significance. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Deckert, G. H.; West, L. J. (1963). The problem of hypnotizability: A review. International Journal of Clinical and Experimental Hypnosis, *11*, 205-235.

This paper summarizes the relatively unsuccessful effort to relate hypnotizability to sex, age, psychiatric diagnoses, suggestibility, and various personality traits. The problems of measurement, subject selection, controls, and experimenter bias are reviewed. Comparison of data is difficult and replication of studies infrequent. This might be attributed to incomplete reporting of methodology, defects in experimental design, and various conceptual problems. Concepts which view hypnotizability as "something" universal, "something" unique, or "nothing" are briefly appraised. Finally, hypnotizability is seen as a "term" describing a relationship between a "route" and a "state"--each identifiable by measurable criteria. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Evans, Frederick J. (1963). The Maudsley Personality Inventory, suggestibility and hypnosis. International Journal of Clinical and Experimental Hypnosis, *11*, 187-200.

An attempt to replicate the claim of Furneaux and Gibson (1961) that stable extraverts and neurotic introverts were more susceptible to hypnotic suggestion than neurotic extraverts and stable introverts, using the MPI dimensions, was unsuccessful. Some "trends" are discussed. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Furneaux, W. D. (1963). Neuroticism, Extraversion, answer suggestibility: A comment. International Journal of Clinical and Experimental Hypnosis, *11*, 201-202.

Author develops hypotheses about the relationships between scores on the Maudsley Personality Inventory (MPI) and suggestibility.

"(a) The effective-drive experienced by a S in a suggestibility test, or hypnosis situation, is positively correlated with both neuroticism and with extraversion, as measured by the MPI.

(b) Effective-drive is also a function of the "press" of the test situation, and of the S's previous experience.

(c) Within the range of values of effective-drive lower than the Yerkes-Dodson optimum for the test being studied, the magnitude of response to a suggestibility test (or hypnosis) is a positive function of drive.

(d) For values of effective-drive greater than the Yerkes-Dodson optimum, response is a negative function of drive" (p. 201).

Levitt, Eugene E.; Lubin, B. (1963). TAT card '12MF' and hypnosis themes in females. International Journal of Clinical and Experimental Hypnosis, 11, 241-244. Modification of TAT Card 12M, so that the supine figure was a female, did not increase the frequency of hypnosis themes among sophomore student nurses. The hypothesis that difficulty in identifying with a male figure accounted for the card's inability to predict attitudes towards hypnosis in females was, therefore, not supported. The modified card did elicit significantly more identifications of the standing figure as a professional person. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Levitt, Eugene E.; Brady, J. P.; Lubin, B. (1963). Correlates of hypnotizability in young women: Anxiety and dependency. Journal of Personality, 31, 52-57.

"2 measures of anxiety and 1 of dependency distinguished between groups of hypnotizable and refractory student nurses, according to the hypothesis that low anxiety and high dependency are associated with hypnotizability . . . . Sign analyses of all 6 possible combinations of anxiety and dependency variables were carried out. For all combinations, the frequency of Ss whose reactions to hypnosis were predictable according to the hypothesis significantly exceeded chance expectation." 1962

As, Arvid; Lauer, Lillian W. (1962). A factor analytic study of hypnotizability and related personal experiences. International Journal of Clinical and Experimental Hypnosis, 10 (3), 169-181.

To throw further light on the exclusivity of "primary suggestibility" as reported by other investigators, a factor analysis was performed in a sample of 102 female college students on the basis of the intercorrelations of 23 items of personal experiences earlier shown to be related to hypnotizability, and 19 items from 2 hypnosis scales. No simple factor structure emerged. 2 factors were interpreted: the 1st as a hypnotic factor with special emphasis on the capability to sustain the effect

of suggestion over time, and the 2nd as a combination of psychological changeableness and social influencibility. A brief discussion was given of the composite picture of hypnotic susceptibility emerging from the fact that many hypnotic items loaded on both factors. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Gibson, H. B. (1962). Furneaux's discussion of extroversion and neuroticism with regard to suggestibility. International Journal of Clinical and Experimental Hypnosis, 10, 281-287. (Abstracted in Index Medicus, 63, March, S-676)

Hypotheses suggested by Furneaux (see 36: 4II95F) are criticized on the grounds that his basic assumption that extraverts attend more closely in the interpersonal situation is unwarranted. It is maintained on the contrary that introverts are the less distractible and it is shown that the data published earlier by Furneaux and Gibson (see 36: 3II67F) accord with a theoretical model derived from Spence. The results are also discussed in terms of an alternative interpretation. It is further contended that Furneaux's treatment of the data leads to other inconsistencies. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Kuhner, Arthur (1962). Hypnosis without hypnosis. International Journal of Clinical and Experimental Hypnosis, 10 (2), 93-99.

The traditional concept of hypnosis that seeks a "sleep" state through employment of formal induction techniques seriously limits its general clinical applicability. It fails to fit the special needs of the patient. An approach designed to counteract this shortcoming manipulates the interpersonal relationship factor. Case illustrations from dental practice support the viewpoint that the proper relationship is akin to the hypnotic one and comparable results obtain without resort to ritualistic induction methods. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Levitt, Eugene E.; Lubin, Bernard; Brady, J. P. (1962). On the use of TAT Card 12M as an indicator of attitude toward hypnosis. International Journal of Clinical and Experimental Hypnosis, 10 (3), 145-150. (Abstracted in Psychological Abstracts, 63: 5233)

This investigation indicates that responses to TAT Card 12M do not predict attitude toward hypnosis in female Ss, though such predictiveness has been reported for male respondents. The basis for this differential predictiveness may be that the latter give a significantly greater proportion of themes involving hypnosis. An explanatory hypothesis, based on perceptual theory and the stimulus properties of the card, is advanced. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

London, Perry; Cooper, Leslie M.; Johnson, Harold J. (1962). Subject characteristics in hypnosis research. International Journal of Clinical and Experimental Hypnosis, 13-21.

Items of experiences, interests, and attitudes, in London's Survey, tended to cluster among themselves, suggesting a separate factor for each. The items were compared to several objective tests, but correlations were low. The Survey and Shor's Personal Experiences Questionnaire combined, correlated .64 with Stanford Scale A, suggesting the possible development of a paper-and-pencil predictor of hypnotic suggestibility. 1961

Furneau, W. D.; Gibson, H. B. (1961). The Maudsley Personality Inventory as a predictor of susceptibility to hypnosis. International Journal of Clinical and Experimental Hypnosis, 9, 167-177.

99 Ss were tested on the MPI, Body-Sway, and reaction to hypnotic induction. The Extraversion and Neuroticism scales when used in conjunction were efficient predictors of susceptibility, though the relationships were not simple linear and additive. The most susceptible Ss were the Stable Extraverts, while those scoring high on the Lie scale tended to be insusceptible to hypnosis. From Psyc Abstracts 36:01:3II67F. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Furneau, W. D. (1961). Neuroticism, extroversion, drive, and suggestibility. International Journal of Clinical and Experimental Hypnosis, 9, 195-214. (Abstracted in Psychological Abstracts, 62: 4 II 95F)

In the group studied, the body-sway scores of stable extraverts and neurotic introverts tended to be large, whereas they were smaller for stable introverts and neurotic extraverts. This result was explained in terms of a theoretical model in which the effective drive produced in a S by a test-situation is a function of both his neuroticism and his extraversion. The author believes that the theoretical model generates a number of predictions and suggestions which can serve to guide future experimental work in this field. From Psyc Abstracts 36:04:4II95F. Hilgard, Josephine R.; Hilgard, Ernest R.; Newman, Martha (1961). Sequelae to hypnotic induction with special reference to earlier chemical anesthesia. Journal of Nervous and Mental Disease, 133, 461-478.

Although a review of relevant literature turned up little in the way of statistical studies, some case studies were located in which unintended or unexpected results of hypnosis were observed. The authors located 15 cases in which the symptoms that developed subsequent to symptom removal using hypnosis were more disturbing than the original symptom. This type of response occurred in patients with extensive psychiatric history, prior to the hypnosis experience. However, it could not be determined whether the undesired response was due to hypnosis or to the psychotherapy that was provided to these patients.

In order to avoid the complications introduced by studying undesired sequelae in psychiatric patients receiving posthypnotic suggestions for therapeutic purposes, this investigation used a sample of non-patient university students (114 male and

106 female) who volunteered for research. Subjects were asked about "aftereffects" in followup interviews. Aftereffects that might be considered sequelae are exemplified by statements such as, "I was 'in a fog' for one hour" and "Things were hazy and vague for four hours."

Of the 220 Subjects, 17 (7.7%) reported sequelae, many of them "minor and fleeting." None of the sequelae was of psychotic proportions. Only 2.3% of the sample experienced sequelae that lasted as long as a few hours. Although the relationship of sequelae to hypnotizability was slight, there seemed to be a relationship to having had a difficult experience with chemical anesthesia in early childhood. They present six case studies, three who had difficulty with chemical anesthesia and three for whom the sequelae appeared to relate to a different kind of childhood experience.

The investigators concluded that "a routine experience of hypnosis is generally harmless in a student population, but E (or therapist) should be alert for possible aftereffects, and provisions should be at hand for occasional brief psychotherapy, even though the experiments themselves are not oriented toward therapy" (p. 477).

The authors present a psychodynamic explanation for the sequelae observed. "It is conjectured that the conflicts within the induction phase of hypnosis that produce either immediate or delayed symptoms are primarily those having to do with the exercise of power and the reaction to authority, hence, conflicts between the conscious willingness to be hypnotized and the unconscious resistance to or fear of the submissive role required. The individual forms that such conflicts take are highly varied.

"The conflicts within the established state differ, in that the state is not reached unless the conflicts of the induction are at least temporarily resolved. The new state, which has regressive characteristics, makes S vulnerable to conflicts based on reality distortions (as in suggested hallucinations) or ethical-social issues (as in suggested behavior violating his moral code or superego demands). Sometimes specific suggestions revive early experiences that were traumatic or provocative of fear.

Sometimes specific suggestions revive early experiences that were traumatic or provocative of fear.

"While the language of psychodynamics is appropriate in the discussion of these cases, the many redintegrative factors also suggest that learning theory can have much to say in explanation of them. Because learning theory has ways of dealing with conflict and conflict resolution, it can also encompass some of the problems discussed as conflicts over authority, commonly treated in psychodynamics as transference problems.

"The many reflections of earlier childhood experiences in the sequelae, including some of the dreams, suggest the promise of a developmental theory of hypnosis" (p. 477).

London, Perry (1961). Subject characteristics in hypnosis research: Part I. A survey of experience, interest, and opinion. International Journal of Clinical and Experimental Hypnosis, 151-161.

Questionnaire measuring (a) direct and observational experience with hypnosis, and (b) stereotyped attitudes towards hypnosis was administered to 645 undergraduate students of psychology. Results indicate hypnosis considered in generally favorable light. Girls were less willing than boys to be hypnotic Ss. Items regarding the nature of hypnosis reflected a rather sophisticated attitude. From *Psyc Abstracts* 36:01:3II51L. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1958

Faw, Volney; Wilcox, Warren W. (1958). Personality characteristics of susceptible and unsusceptible hypnotic subjects. *Journal of Clinical and Experimental Hypnosis*, 6 (2), 83-94.

"1. The Ss for this study of hypnosis were a cross section of a college population, 44 women and 36 men. A group or mass induction technique was used; the Ss were divided into three sections for ease in administering the hypnotic suggestions which were read.

1. A susceptibility scale was developed on which trained Os rated the Ss and Ss rated themselves. The susceptible were defined as those above the median and the unsusceptible as those below the median. The r between the self and O ratings was .68 which indicates a substantial though not high relationship.

3. When the susceptible are compared with the unsusceptible, the susceptible had better over-all adjustment scores on the MMPI, the group Rorschach and the clinical assessment of diaries, which indicates that susceptibility is a characteristic possessed in greater degree by the better adjusted.

4. However, there were among the more poorly adjusted of the susceptible, a small group with high Hy scores indicating that they had responses similar to clinic patients who had developed conversion hysteria. Their susceptibility was attributed to two factors: first, on the psychic items of the Hy scale their responses indicate rather optimistic cooperative attitudes which would make their initial responses to hypnotic suggestions favorable; second, their tendencies to translate psychological stress into bodily symptoms which have a great similarity to the criteria of hypnotic behavior would indicate a common response mechanism for the expression of symptomatology and hypnotic behavior.

5. The unsusceptible tended to have poorer over-all adjustment scores on the MMPI, the Rorschach and the clinical evaluation of diaries. They had significantly poorer scores on the D, Mf and Sc scales indicating a greater tendency toward depression, less security in regard to sex status and more distraction in the form of bizarre thoughts and feelings than do the susceptible.

6. Neither the profiles of the susceptible nor those of the unsusceptible correspond to the three generalized patterns of the MMPI: the neurotic, the behavior problem or the psychotic.

7. Our general conclusion is that while susceptibility is associated predominately with the well adjusted personality save for those with high Hy scores on the MMPI, the unsusceptible belong to a deviant group not easily classified by a term in general use in abnormal or clinical psychology" (pp. 93-94).

Barber, Theodore Xenophon (1956). A note on 'hypnotizability' and personality traits. Journal of Clinical and Experimental Hypnosis, 4, 109-114. (Abstracted in Psychological Abstracts 58: 3288)

1. Eighteen 'typical students' were ranked on a scale of hypnotizability and on the ten traits measured by the Guilford-Zimmerman Temperament Survey. The ranks on the hypnotizability scale were determined by the subjects' responses -- after twenty minutes of standard hypnotic induction -- on five standard tests of suggestibility.

2. The coefficients of correlation between hypnotizability and 'ascendance,' 'sociability,' 'emotional stability,' and 'objectivity' ranged between +0.47 and +0.70. There was a negative coefficient of -0.45 between hypnotizability and 'restrain' [sic].

3. This investigation tends to confirm the studies that find a relationship between hypnotizability and 'desirable character traits' and the studies that find no relationship between hypnotizability and maladjustment.

4. If these results are confirmed on a larger and more representative sample we may be able to accept a 'good guy' theory of hypnotizability -- at least for college students. The more hypnotizable students tend to confirm [sic] to our cultural definition of a 'good guy' -- sociable, emotionally stable, non-submissive, non-hypersensitive, happy-go-lucky, and interested in overt activity" (p. 113).

Kupfer, David (1954). Hypnotherapy in a case of functional heart disorder. Journal of Clinical and Experimental Hypnosis, 2 (3), 186-190.

"Summary. A young soldier with functional cardiac complaints was treated with hypnosis in a total of 4 interviews. The dynamics were bypassed and the therapeutic suggestions attached to 2 significant events in the patient's childhood, dealing intimately with the oedipal conflict and castration fears. Follow-up studies of 3 weeks duration revealed that significant changes had been produced in the patient's attitudes towards himself and towards his role in the military service" (p. 190).

Kline, Milton V.; Haggerty, Arthur D. (1953). An hypnotic experimental approach to the genesis of occupational interests and choice. III. Hypnotic age regression and

the Thematic Apperception Test -- a clinical case study in occupational identification. Journal of Clinical and Experimental Hypnosis, 3, 18-31.

**"1. Hypnotic age regression responses to TAT cards in reference to occupational identifications appear quantitatively and qualitatively different from waking simulation responses.**

**2. A quantitative analysis of the hypnotic age regression protocols points strongly in the direction of further confirmation of the neuropsychological validity of hypnotic age regression.**

**3. TAT cards suitable for children are significantly more productive as psychological stimuli in the hypnotic regression state than in waking simulation.**

**4. Adult TAT cards fail to elicit the ratio of productivity in hypnotic age regression that they do in waking simulation.**

**5. Hypnotic age regression appears to involve perceptual alterations of ego functions and related neuropsychological activity.**

**6. Simulation behavior appears to be primarily projective behavior with recall and role-playing characteristics interspersed within a behavior pattern which retains its adult perceptual orientation.**

**7. The utilization of a language usage quotient technique adds to the holistic validity of neuropsychological age regression and sharply differentiates hypnotic behavior from role-playing simulation.**

**8. The technique of hypnotic age regression described in this paper would appear to be a valid and useful method for the systematic study of occupational interests and choice within the framework of ego functions and developmental psychology.**

**9. Hypnosis would appear to produce empathizing and identifying processes more productively than the waking state" (pp. 30-31).**

**Author's Summary - "This paper is a further report on the use of varied hypnotic methods and techniques for the investigation of the origins of occupational interests and vocational choices. As an experimental means for studying the development of such interests and attitudes, hypnotic age regression would appear to have considerable validity and value. As a clinical technique in certain cases of vocational maladjustment it would seem to have considerable value" (p. 31).**

**Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)**

**This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment**

strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

1998

Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

Brown, Gail W.; Riddell, Rodney; Summers, David; Coffman, Brent (1994, August). Use of hypnosis by practitioners in the school setting. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

## NOTES

Hypnosis is a therapeutic procedure that is appropriate for some school-age clients. Through the use of hypnosis that utilizes metaphors and imagery, children can be empowered to find unique solutions to their problems. Children enjoy the feeling of power and mastery that they have when able to perform hypnotic phenomena. They like to play magic and can be told that a finger or other body part will become numb. Because a major goal of hypnotherapy is to teach a child to be an active participant in his or her own behalf, the focus is on creating solutions and mastering the situation rather than enduring the problems. Four case studies demonstrate the utility of hypnosis in the treatment of phantom pain and nausea, sleep terror disorder, school phobia, and spider phobia. In each case, treatment goals were realized. Because the solutions were self-generated, the behavioral changes maintained over time and situation.

Case #1: Hypnosis was used to help alleviate phantom limb pain and nausea during chemotherapy following amputation of the right leg at the knee due to cancer in a thirteen-year-old male. The client had indicated that he loved nature and enjoyed the mountains. The metaphor described a young tree that has just begun to grow small silvery leaves. The spring floods tear the limbs and branches from the stump. The deep roots and stump of the tree are all that remain. The tree is not the same as before the flood. Its roots are stronger, its base more sturdy compared to the branches and limbs. The young tree has withstood the catastrophe of the torrent of waters and is even stronger than before. To counter the nausea and vomiting associated with chemotherapy a switch mechanism metaphor was used. The client was adroit with computers and had no difficulty picturing a switch located in his brain which could "turn off" the nausea from chemotherapy. A room contained all the unpleasant feelings that were being experienced. In this room is a light of a particular color that represents all the unpleasant sensations. Press the key on the computer that controls the switch to turn off the colored light in that room. Suggestions for healing were also given. Your body has known for years how to heal. Visualize the battle between good and bad cells and the victory of the good cells.

Case #2: Hypnosis was used to alleviate sleep terror disorder in a ten-year-old female. The onset of the subject's parasomnic symptomatology appeared to coincide with her starting kindergarten and her family's relocation shortly before. The initial treatment consisted of progressive relaxation, deep breathing, and the visual image

of her "secret safe place." An induction utilizing a variety of images was presented. Hiking barefoot on a cool moss covered mountain trail, sitting in an alpine meadow on a warm summer afternoon, and flying proved most effective in facilitating trance. The participant was told to "Visualize all your anxiety and tension as hard grey rocks. Pick up these rocks and place them in your pockets. Go to the front porch of your "secret safe place and on the porch is a "magic hefty bag." Place your hard grey rocks that contain all your anxiety and tension in the magic bag. Once in the bag, the rocks will no longer weight you down, you will be free of any feelings of stress or tension. Your bed is magic; it is covered with a special glue which will keep you in a reclining position until you are fully rested and ready to awaken."

**Case #3:** Hypnosis was used in the treatment of school phobia in a nine-year-old male. The student experienced intense anxiety whenever separation from the primary caretaker occurred. The teacher stated that this boy experienced frequent absences and crying spells that were only relieved by phone calls to his mother or the presence of his mother next to him in class. In preparation for the intervention, the student was asked to draw a picture of how he felt inside during a panic attack. He drew a fire. He also said that only his mother could put that fire out. This information was utilized in creating a metaphor that described a house in a small town. "The mother had left, and a young boy was left alone. While at home, the boy looked out the window and saw several boys trying to burn a neighbor's yard! Acting quickly, he called the fire department, grabbed the fire extinguisher and unraveled the garden hose. He was able to extinguish the fire. The neighbors and friends were very happy and praised the boy's performance. When his mother heard the good news, she quickly returned home and held a celebration in his honor." Following the metaphor, hypnotherapy continued with suggestions about fire extinguishers that the subject could use to put out emotional fires.

**Case #4:** Hypnosis was used in the treatment of spider phobia. Diagnosis of phobia was made in this eleven-year-old female when the fear or avoidance behavior was distressing. The child's strained facial expressions occurred even at the thought of seeing what she described as "a creepy, crawly creature with 8 legs." Preparatory to her first induction the participant was read the story of Charlotte's Web (White, 1980) to facilitate the imagery for future hypnotic work. In the following session systematic desensitization was accomplished using characters from the story of Charlotte's Web. During the third session the subject was age regressed to the first time she remembered seeing a spider. She recalled playing in the woods outside her family home on an island and seeing a large web stretched between two trees with a very large spider in the center of its web. She was then asked to remain at that place to look closely at that spider as it was most likely Charlotte or one of Charlotte's family. Upon closer investigation she saw not only Charlotte but "teeny-tiny babies." The event was reconstructed as a happy experience. The imagery provided by Charlotte's Web permitted the subject to fantasize her previous frightful experience and reframe spiders as cute little "teeny-tiny" babies with admirable human qualities.

grey rocks. Pick up these rocks and place them in your pockets. Go to the front porch of your "secret safe place and on the porch is a "magic hefty bag." Place your hard grey rocks that contain all your anxiety and tension in the magic bag. Once in the bag, the rocks will no longer weight you down, you will be free of any feelings of stress or tension. Your bed is magic; it is covered with a special glue which will keep you in a reclining position until you are fully rested and ready to awaken."

Case #3: Hypnosis was used in the treatment of school phobia in a nine-year-old male. The student experienced intense anxiety whenever separation from the primary caretaker occurred. The teacher stated that this boy experienced frequent absences and crying spells that were only relieved by phone calls to his mother or the presence of his mother next to him in class. In preparation for the intervention, the student was asked to draw a picture of how he felt inside during a panic attack. He drew a fire. He also said that only his mother could put that fire out. This information was utilized in creating a metaphor that described a house in a small town. "The mother had left, and a young boy was left alone. While at home, the boy looked out the window and saw several boys trying to burn a neighbor's yard! Acting quickly, he called the fire department, grabbed the fire extinguisher and unraveled the garden hose. He was able to extinguish the fire. The neighbors and friends were very happy and praised the boy's performance. When his mother heard the good news, she quickly returned home and held a celebration in his honor." Following the metaphor, hypnotherapy continued with suggestions about fire extinguishers that the subject could use to put out emotional fires.

Case #4: Hypnosis was used in the treatment of spider phobia. Diagnosis of phobia was made in this eleven-year-old female when the fear or avoidance behavior was distressing. The child's strained facial expressions occurred even at the thought of seeing what she described as "a creepy, crawly creature with 8 legs." Preparatory to her first induction the participant was read the story of Charlotte's Web (White, 1980) to facilitate the imagery for future hypnotic work. ## Philosophy

1998

Chapman, C. Richard; Nakamura, Yoshio (1998). Hypnotic analgesia: A constructivist framework. International Journal of Clinical and Experimental Hypnosis, 46 (1), 6-27.

Hypnotic analgesia remains an enigma. Recent neuroscience studies demonstrate that widespread distributed processing occurs in the brains of individuals experiencing pain. Emerging research and theory on the mechanisms of consciousness, along with this evidence, suggest that a constructivist framework may facilitate both pain research and the study of hypnosis. The authors propose that the brain constructs elements of pain experience (pain schemata) and embeds them in ongoing consciousness. The contents of immediate consciousness feed back to nonconscious, parallel distributed processes to help shape the character of future moments of consciousness. Hypnotic suggestion may interact with such processing through feedback mechanisms that prime associations and memories and thus shape the formation of future experience.

#### NOTES

1:

The authors suggest that emerging paradigms for the study of consciousness may be useful in bridging research on hypnotic analgesia with advances in research on pain control. The constructivist framework emphasizes central processing of nociceptive signals, and consciousness as "an emergent property of a self-organizing process in a distributed neural network" (p. 14). The Dennett & Kinsbourne (1992) 'multiple drafts model' of consciousness and the authors' constructivist framework provide a way of understanding phantom limb pain, which classical models of pain cannot do. Pain is experienced as the brain blends schemata reflecting current stimuli, memories, associations formed by conditioning, emotions, and cognitions. "Hypnotic suggestions can engender temporally dominant schemata that influence ongoing consciousness construction of the subject" (p. 20). They suggest that "hypnotic analgesia depends heavily on the formation of suggestion-related schemata and subsequent priming effects, that somatosensory imagery is the key element in the contents consciousness [sic], and that the mechanisms behind hypnotic analgesia phenomena are largely related to the competition among schemata for a dominant position within the contents of consciousness" (p. 23). Jean Holroyd

1997

Covino, Nicholas (1997). The integration of clinical and experimental work. International Journal of Clinical and Experimental Hypnosis, 45 (2), 109-125.

The work and the professional relationships of clinicians who use hypnosis and their research counterparts always contain a certain degree of tension. This is especially true when one group or the other claims to have a purchase on truth. A review of the strengths and limitations of each subspecialty is provided along with an understanding of some of the subspecialty is provided along with an understanding of some of the differences between the clinical and experimental perspectives. The author raises a number of points with the hope that this article will promote discussion among those who are engaged in clinical and experimental work and those few who are active in both.

Several suggestions for integration and collaboration are offered for consideration by both groups. -- Journal Abstract

1996

Rosenbaum, Robert & Dyckman, John (1996). No self? No problem! Actualizing empty self in psychotherapy . In Hoyt , Michael F. (Ed.), Constructive therapies (2, pp. 238-274). New York NY: Guilford.

NOTES

1:

In this book chapter, Rosenbaum and Dyckman (1996) argue that self has no permanently fixed, defining, thing-like characteristics (p. 270). They thus dispute the classical notion--commensurate with the position of philosophical realism --that the self is a substance, with fixed qualities and measurable qualities. The authors refer to this classical self as a full self, contained inside the skin and delimited by its participation in linear time. Instead, they propose an empty self, not to be construed as a void, but as a fluid, connected, relational self that overflows the traditional boundaries of the skin and is open to greater possibilities for change. To support their view of an empty self, the authors include several case examples of working with hypnosis and strategic/narrative therapy with clients experiencing a variety of psychological and physical symptoms. The authors further contend that self is not unitary, but the product of multiple drafts (p. 248)[Editor note: See Dennett, 1991, in this database]. In the narrative-constructivist tradition, they argue, if we speak in terms of multiple contextual selves for us all...[then, people diagnosed with MPD/DID] are not so different from the rest of us (p. 249). The chapter draws from western & Buddhist philosophy, strategic/systemic and narrative therapies, Ericksonian hypnosis, and, cognitive science theories regarding memory, consciousness, embodiment, and language, to support their alternative view of, and treatment for, the self.

1994

Walsh, Roger (1994, August). Transpersonal psychology--the state of the art. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

NOTES

Twenty-five years ago a group formed that was called transpersonal psychology, following after humanistic psychology (e.g. Maslow). Some of the humanistic psychologists came into transpersonal psychology. Maslow was interested in healthy people, and in peak experiences that were transpersonal in nature--experiences encompassing wider aspects of life, including mystical experiences.

that were transpersonal in nature--experiences encompassing wider aspects of life, including mystical experiences.

Peak experiences were thought to be positive, but also overwhelming. When psychologists looked Eastward, they found that there were whole families of these types of experiences, and that they could be induced by will and could be stabilized into not only peak but plateau experiences. There was a reservoir of wisdom in the

world's religions that could be drawn upon. This wisdom is being integrated with Western science to create the discipline of transpersonal psychology.

There is a broad spectrum of altered states of consciousness. Traditionally, altered states of consciousness were thought to be few in number, and usually pathological. Our society has been resistant toward studying them. For example, Esdaile's use of hypnosis in surgery was not welcomed, even though he was lowering morbidity and mortality because he controlled shock. His paper was turned down for publication. He amputated a leg in front of colleagues in Britain, who commented that he "must have hired a very hard rogue" to have his leg cut off under hypnosis.

Our culture is monophasic, deriving its world view almost exclusively from the waking state; other cultures are polyphasic and also draw their world view from dreams, meditative, or yogic contemplative states, etc. Recently we can apply more sophisticated analyses, to compare states of consciousness and map these out, phenomenologically. There are several key dimensions of experience for mapping the states: 1. Control 2. Awareness of Environment 3. Concentration 4. Mental Energy/Arousal 5. Emotion 6. Identity or Self Sense 7. Out-of-Body Experience 8. Content of Experience

Using these dimensions, we could compare shamanic, yogic, and Buddhist practices. A Nepalese shaman drums himself into a trance state, demonstrating: 1. Ability to enter and leave an altered state of consciousness and partly control experience 2. Decreased awareness of his environment 3. Increased concentration, fluid attention 4. Increased mental energy/arousal 5. Either pleasurable or not [pleasurable] emotion 6. Separate self sense: may be experienced as a non-physical "spirit" or "soul" 7. Controlled ecstasy (Out of Body experience)

Buddhist meditation is training awareness to examine experience as minutely as possible, in effect a heightened awareness (Vipassana).

A yogic practitioner engages in concentration, focusing on a fixed stimulus and holding it unwaveringly, till it dissolves a sense of separation into a unity with the object, ultimately with the Self.

[Author showed a slide comparing the three.] All three approaches have increased control and concentration. (The Yogi's is unshakable.) An awareness of the environment is increased for the Buddhist; the Yogi may lose awareness entirely. Others have ecstatic experience; the yogi has enstatic experience. Identity for the shaman is separate (a soul); for the Buddhist awareness is so precise that what was "I" is deconstructed into evanescent flux, into thoughts, images, emotions (like a movie with solitary frames); the yogi dissolves the self sense, but because of fixed concentration the separate self disappears and yogis feel like merging with larger Self.

So now for first time in history we can compare and map both similarities and differences. Now we have new possibilities for understanding and contrasting different practices. We can now differentiate the many states of consciousness that are available. But there are an awful lot of states. Can we find an over-arching framework? For the first time, we can say yes--due to the work of Ken Wilber. This is Developmental Structuralism (looking for common deep structures).

For example, you can identify millions of different faces, and they are surface structures; but they all have a common deep structure. Likewise, if we see that a

Hindu creates images of [devas] and a Christian sees saints, they are seeing archetypal images. Likewise, Buddhists experience nirvana in which all phenomena disappear, and so does another group. This [sense of all phenomena disappearing] is common to both, but different from those who see archetypal images. We may be able to come up with a typology of altered states.

Wilber also says that these deep structures and corresponding states may develop in a developmental sequence, with common stages. Three transpersonal stages are subtle, causal, and non-dual. In meditation, first you learn how out of control the mind is, then gradually it quiets and you discover subtle experiences that you usually overlooked. Going further, all thoughts cease to arise, and there is only pure consciousness. Beyond that, images re-arise but are now recognized as projections of consciousness.

Subtle images may be formless (as in pure light, pure sound). The person may pay attention to more and more subtle sounds. Or the images may have form (as in shamanic power animals).

At the casual stage, the person may be aware of consciousness itself, only consciousness, with no objects: pure consciousness, void, the Atman of Vedanta, abyss of gnosticism.

At the non-dual stage, objects arise again: everything is recognized as expressions of consciousness--e.g., Zen's "one mind." Consciousness now has awoken and sees itself in all things, unbounded by space and time and limits because consciousness is what creates space, time, and limits. This is Moksha, Enlightenment, etc.

This is not the final task, because the final task is bringing the awakening to the world (Plato's re-entering the cave, to educate others; Zen oxherder entering the marketplace with help-bestowing hands; Christianity's "fruitfulness of the soul"). For Joseph Campbell, this was the hero's return. Toynbee observed that each great contributor had withdrawn and then returned to the world to offer what they had found.

[It is a process of] transforming a peak into plateau experience; an altered state into a trait; stabilized into enduring understanding, and then bringing it back into the world.

Is there evidence for enlightenment? There now is analogical and laboratory support for this. Analogical support is lucid dreaming. Until 20 years ago, Western psychology thought lucid dreaming was impossible, but now LaBerge at Stanford University has shown physiological evidence. We know from every night's experience that we can create worlds and bodies on which our lives seem to depend. The claim of spiritual traditions is that there is a state of consciousness that bears a relationship to the ordinary [waking] state as lucid dreaming has to nonlucid dreaming. The Dalai Lama said they train yogis to be aware during dreams, not to lose awareness 24 hours a day; then to be aware of dreaming while in a waking period. A Tibetan dream yoga aim is the "great realization," that everything in existence is like a dream.

Laboratory studies have been done on enlightened people. The EEG data obtained while they are sleeping is consistent with lucidity during their dreams and between dreams. Rorschach tests have been done on advanced Buddhist meditators; at the penultimate of enlightenment, they show no evidence of conflicts around sexuality

and aggression. The 2000 year old Buddhist texts say that at this stage these issues are resolved.

The implications for our usual state are that normality is not the peak of human development; normality is arrested development. The link between apes and civilization is us! We experience a consensus trance, a collective psychosis, society's hypnosis. We live in the biggest cult of all: CULTURE. The answer is, "Wake up." A most important question is, if it is true that our conventional state of development is suboptimal, how do we develop other states? The classic answer is: take up a discipline, a practice (e.g., meditation, service, being in nature). One problem is that spiritual traditions are usually couched in archaic language, and have accumulated nonsense around them over the years. It is desirable to abstract out the essential elements. That is a recent thrust of transpersonal research.

There are six common elements: 1. Ethics: the moment you sit down to meditate, what emerges is all the unethical stuff you've done and what was done to you. Ethical behavior (not conventional morality) is a tool for mind training. 2. Attentional training: ordinarily we cannot sustain attention. (William James said the maximum is 3 seconds.) The aim is to be able to maintain attention on what one wants. It leads to the stabilization of mind, calming. 3. Emotional training: destroying negative emotions (well developed in Western psychology, maybe better than in the Eastern traditions, because we recognize the problem with repression); cultivating positive emotions (where contemplative practices do well, because they offer tools for unwavering, unconditional, and all-encompassing [positive regard]; what is known as agape in Christianity). 4. Redirection of motivation: changing what you want, etc. 5. Perceptual refinement: we mistake shadows for realities; according to St. Paul we "see through a glass darkly." This enhances sensitivity, accuracy, and subtlety of perception. 6. Wisdom: actually the first element, playing a role all through the path. Initial motivation sees suffering of the world; provides motivation for realizing that there must be another way of living, culminates with deep insight into nature of the world, mind, consciousness, reality (prajna; Christian's gnosis). When the mind is trained, stabilized, and clarified, the mind has a heightened capacity for understanding.

So for the first time we can recognize the common elements in religions; we can see that the contemplative core contain practices and road maps. This approach recognizes multi-state psychologies and philosophies.

APPLICATION. Many areas of research are developing in transpersonal psychology. These studies have implications for the state of the world. It is only 25 years since the founding of transpersonal psychology. The world's population has developed to the extent that every four months we are losing as many people from malnutrition as from a Holocaust. Our problems are still solvable. The best population explosion control is to make education available to women in the Third World. The transpersonal vision gives a frame to recognize that we are all connected.

For a fuller account of transpersonal psychology, see R. Walsh & F. Vaughan (Eds). (1993) *\_Paths Beyond Ego: The Transpersonal Vision.\_* New York: Tarcher/Putnam.

**Brown, Jason W. (1991). Self and process: Brain states and the conscious present. New York: Springer-Verlag**

## **NOTES**

**Author, from the Department of Neurology at New York University Medical School, presents a theory about the genetic unfolding of mental content (mind) through stages, from mental state into consciousness or into behavior. He relates the genesis of mind to brain development but avoids assuming that there is a straightforward correlation between brain development (e.g. myelination) and cognitive development or perception. To some degree, the theory is based on subjective report data and psychological symptoms. The author discusses issues that bear on the phenomena of nonvoluntary responding and dissociation that are reported or described by hypnotized persons.**

**"The nature of the mental state will determine the relation between self and world, and thus the interpretation given to agency and choice. ... The crossing of the boundary from self to world is a shift from one level in mind to another" (pp. 10-11).**

**"... if we begin with mind as primary and seek to explain objects from inner states and private experience, the discontinuity between inner and outer evaporates: mind is everywhere, a universe. ... Whereas before we thought to perceive objects, now we understand that we think them" (p. 19).**

**"The concept of a stratified cognition is central to the notion of a mental state ... This entails an unfolding from depth to surface, not from one surface to the next, a direction crucial to agency and the causal or decisional properties of consciousness" (p. 52). By unfolding from depth to surface, he means from Core, through Subconscious, then Conscious Private Events, and finally Extra-Personal Space.**

**He goes on to provide a definition of mental states. "A mental state is the minimal state of a mind, an absolute unit from the standpoint of its spatial and temporal structure. ... The state also has to include the prehistory of the organism. ... The concept of a mental state implies a fundamental unit that has gestalt-like properties, in that specific contents-- words, thoughts, percepts--appear in the context of mind as a whole (p. 53).**

**"The entire multitiered system arborizes like a tree, with levels in each component linked to corresponding levels in other components. For example, an early (e.g., limbic) state in language (e.g., word meaning) is linked to an early stage in action (e.g., drive, proximal motility) and perception (e.g., hallucination, personal memory) ... In sum, a description of the spatial and temporal features of a single unfolding series amounts to a description of the minimal unit of mind, the absolute mental state" (p. 54).**

**The author's discussion of an individual's physical movement relates to the concept of nonvoluntary movement (or movement without awareness of volition) in hypnosis. "More precisely, levels in the brain state constitute the action structure. As it unfolds, this structure generates the conviction that a self-initiated act has occurred. This structure--the action representation--does not elaborate content in consciousness. ... As with the sensory-perceptual interface, the transition to**

movement occurs across an abrupt boundary. In some manner, perhaps through a translation of cognitive rhythms in the action to kinetic patterns in the movement, levels in the emerging act discharge into motor (physical) events" (p. 57).

"The self has the nature of a global image or early representation within which objects-to-be are embedded. ... The self is the accumulation of all the momentary cognitions developing in a brain configured by heredity and experience in a particular way (p. 70).

"The deposition of a holistic representation ... creates the deception of a self that stands behind and propagates events. The feeling of the self as an agent is reinforced by the forward thrust of the process and the deeper locus of the self in relation to surface objects. The self appears to be an instigator of acts and images when in fact it is given up in their formation. The self does not cause or initiate, it only anticipates (p. 70).

The foregoing notes cover only the first five chapters, less than half the book. Other chapters relevant to hypnosis would be those titled 'The Nature of Voluntary Action,' 'Psychology of Time Awareness,' 'From Will to Compassion,' and 'Mind and Brain.'

Dennett, Daniel C. (1991). Consciousness explained. Boston: Little, Brown & Co..

## NOTES

Material in this book is relevant to discussions about 'nonvoluntary' behavior and (un)conscious experiencing. It combines information from cognitive neuroscience with the philosophy of mind. The author presents a view that consciousness (the 'mind') is the consequence of the brain's activities which give rise to illusions about their own properties. He presents the Multiple Drafts model of consciousness, which reformulates the concept of a 'stream of consciousness.' This provides a basis for consideration of concepts central to cognitive neuroscience and phenomena associated with hypnosis, e.g. experiential states and the nature of the self.

The author gives various examples of phenomenology and notes that although these examples are familiar to us, they are totally inaccessible to materialistic science; e.g. the way the sunset looks to someone. He treats people's descriptions of what they experience as a record of speech acts. Thus, observing and interpreting speech acts, inferring from them the speaker's inner states, is like a reader who is interpreting a work of fiction. He gives as examples of how one can scientifically study what does not 'exist' (a) literary theorists who describe fictional entities, (b) anthropologists who study cultural artifacts like gods and witches, and (c) physicists who study a center of gravity.

In Dennett's theory, multitrack processes of interpretation of sensory inputs and elaboration of those inputs amounts to a kind of 'editorial revision' by the brain. For example in the phi phenomenon a red dot is displayed, followed by a green dot in a different location; the first spot seems to begin moving and then change color in the middle of its illusory passage toward the second location. He points out that awareness of the change in color must occur after seeing the green spot, but one consciously experiences a single spot first red, then red-turning-to-green, finally green. In an example that relates directly to the words used for his theory, he cites

contemporary publishing practices, in which several different drafts of an article are in circulation even while the author is revising it. Deciding on some specific moment of brain processing as the moment of consciousness is arbitrary, according to his Multiple Drafts model.

"Visual stimuli evoke trains of events in the cortex that gradually yield discriminations of greater and greater specificity. At different times and different places, various 'decisions' or 'judgments' are made; more literally, parts of the brain are caused to go into states that discriminate different features, e.g., first mere onset of stimulus, then location, then shape, later color (in a different pathway), later still (apparent) motion, and eventually object recognition. These localized discriminative states transmit effects to other places, contributing to further discriminations, and so forth. The natural but naive question to ask is: 'Where does it all come together'? The answer is: Nowhere. Some of these distributed contentful states soon die out, leaving no further traces. Others do leave traces, on subsequent verbal reports of experience and memory, on 'semantic readiness' and other varieties of perceptual set, on emotional state, behavioral proclivities, and so forth. Some of these effects--for instance, influences on subsequent verbal reports--are at least symptomatic of consciousness. But there is no one place in the brain through which all these causal trains must pass in order to deposit their content 'in consciousness'" (pp. 134-135).

The author describes the evolution of the brain, along Darwinian lines, and introduces the idea of culture as a repository and transmission medium for innovations (including innovations of consciousness) as a medium of evolution. Through learning, we humans evolve an American or a Japanese brain. Once we have evolved the 'entrance and exit pathways' for language, they become 'parasitized' by memes (entities that have evolved to thrive in such a niche).

Richard Dawkins coined the term memes to describe the smallest idea elements that replicate themselves reliably (e.g. wheel, alphabet, wearing clothes, right triangle). "The transformation of a human brain by infestations of memes is a major alteration in the competence of that organ" (p. 209).

Dennett discusses the similarities and dissimilarities of brains and computers. He suggests that human minds are like serial virtual machines implemented on parallel processing hardware. The stream of consciousness results from our rehearsal of brief experiences, to commit them to memory; language then permits us to describe to ourselves the process of thinking which leads to judgement and action.

The author's discussion of how a verbal expression evolves and becomes manifest is related to how so-called intentional action occurs. [This relates to discussions of nonvoluntary actions in hypnosis.] We assume that because our actions make sense, they are the product of serial reasoning. However, there are multiple channels "in which specialist circuits try, in parallel pandemoniums, to do their various things ... (pp. 253- 254). Bernard Baars has suggested "that consciousness is accomplished by a 'distributed society of specialists that is equipped with a working memory, called a global workspace, whose contents can be broadcast to the system as a whole (p. 42)'" (p. 257). Dennett states that there is no line dividing the events that are definitely in consciousness from those that are outside consciousness. He urges scientists to forgo the concept of the 'inner observer' implied by Cartesian materialism.

of a human brain by infestations of memes is a major alteration in the competence of that organ" (p. 209).

Dennett discusses the similarities and dissimilarities of brains and computers. He suggests that human minds are like serial virtual machines implemented on parallel processing hardware. The stream of consciousness results from our rehearsal of brief experiences, to commit them to memory; language then permits us to describe to ourselves the process of thinking which leads to judgement and action.

The author's discussion of how a verbal expression evolves and becomes manifest is related to how so-called intentional action occurs. [This relates to discussions of nonvoluntary actions in hypnosis.] We assume that because our actions make sense, they are the product of serial reasoning. However, there are multiple channels "in which specialist circuits try, in parallel pandemoniums, to do their various things ... (pp. 253- 254). Bernard Baars has suggested "that consciousness is accomplished by a 'distributed society of specialists that is equipped with a working memory, called a global workspace, whose contents can be broadcast to the system as a whole (p. 42)'" (p. 257). Dennett states that there is no line dividing the events that are definitely in consciousness from those that are outside consciousness. He urges scientists to forgo the concept of the 'inner observer' implied by Cartesian materialism.

Examples of perception that is unaccompanied by consciousness include blindsight (in which the subject does better than chance on visual tests but denies consciousness, and the denials are given credence by neurological evidence of brain damage) and hysterical blindness, which is given less credence because subjects often use the visually provided information in ways blindsight Ss do not. Other behaviors not controlled by conscious thought include blinking when things approach the eye, walking without falling over, regulating our body temperature, adjusting our metabolism, etc. "If I am trying to see a bird that I hear, and stare at the spot but do not distinguish the bird from its background, can I say that it is present in the background of my (visual) consciousness or not?" (p. 336).

The author maintains that if an event doesn't linger and the person is unable to identify and reidentify the effect, it cannot be reported. But such reportability can be improved, as with training the palate of wine tasters. Often, however, we continue disregarding stimuli that impinge on us. There are minor oversights, such as our 'blind spots' or proof reading errors, and major oversights such as a brain-damaged patient's hemi-neglect. In the Multiple Drafts theory, the Observer is replaced by 'coalitions of specialists' that are distributed around in the brain, distributed in both time and space.

Though discrimination or discernment happens, there is no one Discerner doing the work. However, Dennett takes the middle ground on the question of whether a self exists: it is simply a creation like the nest of the Bower bird, or the organized colony of termite ants. "So wonderful is the organization of a termite colony that it seemed to some observers that each termite colony had to have a soul (Marais, 1937). We now understand that its organization is simply the result of a million semi-independent little agents, each itself an automaton, doing its thing. So wonderful is the organization of a human self that to many observers it has seemed that each

human being had a soul, too: a benevolent Dictator ruling from Headquarters" (p. 416). The sense of self is a creation, like a physicist's center of gravity.

Thus, multiple personality disorder is viewed as a self that has gaps; and our sense of self might include different aspects from one year to the other. Hence, "selves are not independently existing soul-pearls, but artifacts of the social processes that create us, and, like other such artifacts, subject to sudden shifts in status. The only 'momentum' that accrues to the trajectory of a self, or a club, is the stability imparted to it by the web of beliefs that constitute it, and when those beliefs lapse, it lapses, either permanently or temporarily" (p. 423).

Finally, the author has an extensive discussion of the concepts of 'qualia' and of 'epiphenomena' and seems to have little use for either term in trying to understand Mind.

or a club, is the stability imparted to it by the web of beliefs that constitute it, and when those beliefs lapse, it lapses, either permanently or temporarily" (p. 423).

Finally, the author has an extensive discussion of the concepts of 'qualia' and of 'epiphenomena' and seems to have little use for either term in trying to understand Mind.

Zika, William (1991, January). Hidden observer in psychotherapy. [Lecture] Seminar in the UCLA Department of Psychiatry and Biobehavioral Sciences.

#### NOTES

Author has explored use of a "hidden observer" metaphor in psychotherapy. He distinguishes between two types of dissociation--that resulting from involvement in fantasy and imagery (separation from the Generalized Reality Orientation described by R. Shor) and that between the "I" and the Observer. He calls the latter nonattachment instead of dissociation, aligning it with meditation concepts. The observer, in the hypnotized patient, is objective and even more in touch with reality than the patient in the waking state. He likens the Observer to Erickson's Inner Self, noting that just as patients learn to allow the therapist to care for them, they can come to allow the Observer to care for them. During inductions he speaks of the Hidden Observer (H.O.) that always knows what is going on, giving a suggestion that the H.O. can be helpful. (This concept seemingly relates also to the observer in Multiple Personality Disorder, and to John Kihlstrom's discussion of William James and the self, as well as to amnesia/duality in age regression or duality (HO) in pain control.)

**Moon, T. (1985). Idiographic as well as nomothetic? Problems for Naish's 'Trance' described in signal detection terms. [Comment/Discussion] .**

**NOTES**

**1:**

**"Naish ... hypothesises that in an unselected sample, the more hypnotisable subjects will make larger criterion shifts in response to signal detection task conditions. In nomothetic/idiographic terms this hypothesis is ambiguous. Should the statement 'the more hypnotisable subjects will make larger criterion shifts' be taken as describing a generalised, group effect? Or should it be interpreted as saying something about each more hypnotisable subject? Both versions are consistent with the theory, but the latter is clearly the more fallible one, most sensitive to falsification" (pp. 144-145). The commentator concludes that "The proposition that the essence of hypnosis is perceptual distortion engendered by criterion shift remains untested by the experiments" (pp. 145-146).**

-tested by the experiments" (pp. 145-146).

NOTES

1:

Most of the chapter deals with brain neurology and the developmental psychology of morality (e.g. L. Kohlberg). The last part treats of hypnotherapy:

"Hypnopsychotherapy ... is a suggestion treatment and suggestion is a process of adopting a proposition in the absence of critical thought which would normally occur. This is achieved in hypnosis by gradual reduction of the tone of the central nervous system. This triggers off a chain reaction composed of four basic steps:

1. Inhibition of muscle tone leading to akinesia;
2. Reduction of autonomic activity seen in slowing down of pulse, lowering of blood pressure and so on;
3. Inhibition of cortical activity with diminished degree of alertness and therefore, volition;
4. Reduction of affective response characterized by detachment from emotional involvement;

The brain as a whole is involved in the induction of hypnotic trance and as a whole it must be involved in the therapeutic endeavour. Simple symptom removal without wholistic approach will have doubtful results" (0. 243).

NOTES: Contains papers presented by multidisciplinary group at a symposium. Covers broad areas of: 1. The mind and its integration. 2. The influence of drugs on the individual. 3. The mind and society 4. The effect of technology on the mind 5. Restrictions and freedom of the mind.

1948

MacCorquodale, Kenneth; Meehl, Paul E. (1948). On a distinction between hypothetical constructs and intervening variables. Psychological Review, 55, 95-107.

NOTES

Among other things, the authors distinguish between intervening variables and hypothetical constructs. Intervening variable is used for abstractions from a set of data that are not assumed to have existential status, whereas hypothetical construct pertains to entities that are assumed to have existential status. The description of hypothetical constructs consists of both data statements and "surplus meaning" which incorporates information about the way the hypothetical construct

exists. Generally, hypothetical constructs are portrayed as existing only in the sense of physiological entities.

**Ginandes, Carol (2002). Extended, strategic therapy for recalcitrant mind/body healing: An integrative model.. American Journal of Clinical Hypnosis, 45 (2), 91-102.**

The development of the power therapies, behavioral medicine, and short term interventions have reported such success even with trauma cases that it is relevant to question the justification for lengthy psychotherapy. Yet some patients with complex mind/body conditions impervious to medical treatment/hypnosis may require extended, multi-modal, integrative therapy. This paper details a single complex case of paruresis as a prototype for illustrating a holographic treatment model for recalcitrant conditions: Component features of the proposed model presented include: 1) the sequential utilization of hypnbehavioral and analytic approaches; 2) uncovering work providing access to the somatic ego state associated with the illness condition; 3) the extended treatment time frame required for deep psycho-physiological change; and 4) the stages of counter-transference expectably evoked by such patients (e.g. urgency, exuberant optimism, frustration, discouragement), and the transformation of such reactions to achieve maximum therapeutic efficacy.

## **NOTES**

**1:**

Paruresis is a social phobia involving urinary retention and "thought to affect some 17 million or 7% of the American population" (p. 92). Also known as "bashful bladder."

**Van Dyck, R.; Spinhoven, P. (1997). Depersonalization and derealization during panic and hypnosis in low and highly hypnotizable agoraphobics. International Journal of Clinical and Experimental Hypnosis, 45 (1), 41-54.**

The primary aim of the present study was to investigate the association between spontaneous experiences of depersonalization or derealization (D-D) during panic states and hypnosis in low and highly hypnotizable phobic individuals. Secondly, the association among level of hypnotizability, capacity for imaginative involvement, and severity of phobic complaints was also assessed. Sixty-four patients with panic disorder with agoraphobia according to the DSM-III-R (American Psychiatric Association, 1987) criteria participated in the study. Proneness to experience D-D during hypnosis was positively related to hypnotizability, but only for agoraphobic patients who had already experienced these perceptual distortions during panic episodes. Correlations of level of hypnotizability and capacity for imaginative involvement with severity of agoraphobic complaints were not significant. These

findings suggest that hypnotizability may be a mediating variable between two different, although phenotypically similar, perceptual distortions experienced during panic states and hypnosis. Implications for both theory and clinical practice are discussed. -- Journal Abstract

NOTES

1:

"This is a book for the thinking clinician" (p. 401). "The editors are to be congratulated for making this volume much more coherent than most edited books" (p. 402). "My impression is that the book is best suited for an intermediate or advanced course on hypnotherapy, or for people who are already using hypnosis in treatment. Although there is some material on the basics of hypnotic inductions and a few introductory sample scripts for inductions, a beginners" course should probably use a different book, or this book could be accompanied by an inductions manual. ... I recommend it very highly" (p. 403).

1994

Brown, Gail W.; Riddell, Rodney; Summers, David; Coffman, Brent (1994, August). Use of hypnosis by practitioners in the school setting. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

NOTES: Hypnosis is a therapeutic procedure that is appropriate for some school-age clients. Through the use of hypnosis that utilizes metaphors and imagery, children can be empowered to find unique solutions to their problems. Children enjoy the feeling of power and mastery that they have when able to perform hypnotic phenomena. They like to play magic and can be told that a finger or other body part will become numb. Because a major goal of hypnotherapy is to teach a child to be an active participant in his or her own behalf, the focus is on creating solutions and mastering the situation rather than enduring the problems. Four case studies demonstrate the utility of hypnosis in the treatment of phantom pain and nausea, sleep terror disorder, school phobia, and spider phobia. In each case, treatment goals were realized. Because the solutions were self-generated, the behavioral changes maintained over time and situation.

Case #1: Hypnosis was used to help alleviate phantom limb pain and nausea during chemotherapy following amputation of the right leg at the knee due to cancer in a thirteen-year-old male. The client had indicated that he loved nature and enjoyed the mountains. The metaphor described a young tree that has just begun to grow small silvery leaves. The spring floods tear the limbs and branches from the stump. The deep roots and stump of the tree are all that remain. The tree is not the same as before the flood. Its roots are stronger, its base more sturdy compared to the

branches and limbs. The young tree has withstood the catastrophe of the torrent of waters and is even stronger than before. To counter the nausea and vomiting associated with chemotherapy a switch mechanism metaphor was used. The client was adroit with computers and had no difficulty picturing a switch located in his brain which could "turn off" the nausea from chemotherapy. A room contained all the unpleasant feelings that were being experienced. In this room is a light of a particular color that represents all the unpleasant sensations. Press the key on the computer that controls the switch to turn off the colored light in that room. Suggestions for healing were also given. Your body has known for years how to heal. Visualize the battle between good and bad cells and the victory of the good cells.

**Case #2:** Hypnosis was used to alleviate sleep terror disorder in a ten-year-old female. The onset of the subject's parasomnic symptomatology appeared to coincide with her starting kindergarten and her family's relocation shortly before. The initial treatment consisted of progressive relaxation, deep breathing, and the visual image of her "secret safe place." An induction utilizing a variety of images was presented. Hiking barefoot on a cool moss covered mountain trail, sitting in a an alpine meadow on a warm summer afternoon, and flying proved most effective in facilitating trance. The participant was told to "Visualize all your anxiety and tension as hard grey rocks. Pick up these rocks and place them in your pockets. Go to the front porch of your "secret safe place and on the porch is a "magic hefty bag." Place your hard grey rocks that contain all your anxiety and tension in the magic bag. Once in the bag, the rocks will no longer weight you down, you will be free of any feelings of stress or tension. Your bed is magic; it is covered with a special glue which will keep you in a reclining position until you are fully rested and ready to awaken."

**Case #3:** Hypnosis was used in the treatment of school phobia in a nine-year-old male. The student experienced intense anxiety whenever separation from the primary caretaker occurred. The teacher stated that this boy experienced frequent absences and crying spells that were only relieved by phone calls to his mother or the presence of his mother next to him in class. In preparation for the intervention, the student was asked to draw a picture of how he felt inside during a panic attack. He drew a fire. He also said that only his mother could put that fire out. This information was utilized in creating a metaphor that described a house in a small town. "The mother had left, and a young boy was left alone. While at home, the boy looked out the window and saw several boys trying to burn a neighbor's yard! Acting quickly, he called the fire department, grabbed the fire extinguisher and unraveled the garden hose. He was able to extinguish the fire. The neighbors and friends were very happy and praised the boy's performance. When his mother heard the good news, she quickly returned home and held a celebration in his honor." Following the metaphor, hypnotherapy continued with suggestions about fire extinguishers that the subject could use to put out emotional fires.

The neighbors and friends were very happy and praised the boy's performance. When his mother heard the good news, she quickly returned home and held a celebration in his honor." Following the metaphor, hypnotherapy continued with suggestions about fire extinguishers that the subject could use to put out emotional fires.

**Case #4:** Hypnosis was used in the treatment of spider phobia. Diagnosis of phobia was made in this eleven-year-old female when the fear or avoidance behavior was distressing. The child's strained facial expressions occurred even at the thought of seeing what she described as "a creepy, crawly creature with 8 legs." Preparatory to her first induction the participant was read the story of Charlotte's Web (White, 1980) to facilitate the imagery for future hypnotic work. In the following session systematic desensitization was accomplished using characters from the story of Charlotte's Web. During the third session the subject was age regressed to the first time she remembered seeing a spider. She recalled playing in the woods outside her family home on an island and seeing a large web stretched between two trees with a very large spider in the center of its web. She was then asked to remain at that place to look closely at that spider as it was most likely Charlotte or one of Charlotte's family. Upon closer investigation she saw not only Charlotte but "teeny-tiny babies." The event was reconstructed as a happy experience. The imagery provided by Charlotte's Web permitted the subject to fantasize her previous frightful experience and reframe spiders as cute little "teeny-tiny" babies with admirable human qualities.

Culbert, Timothy P.; Reany, Judson B.; Kohen, Daniel P. (1994). Cyberphysiologic strategies for children: The clinical hypnosis/biofeedback interface. International Journal of Clinical and Experimental Hypnosis, 42 (2), 97-117

This article presents an in-depth discussion of the integrated use of self-hypnosis and biofeedback in the treatment of pediatric biobehavioral disorders. The rationale for integrating these techniques and their similarities and differences are discussed. The concepts of children's imaginative abilities, mastery, and self-regulation are examined as they pertain to these therapeutic strategies. Three case studies are presented that illustrate the integrated use of self-hypnosis and biofeedback in the treatment of children with psychophysiological disorders. The authors speculate on the specific aspects of these self-regulation or "cyberphysiologic" techniques that appear particularly relevant to positive therapeutic outcomes.

Stanton, Harry E. (1994). Self-hypnosis: One path to reduced test anxiety. Contemporary Hypnosis, 11, 14-18.

Describes a self-hypnosis technique and its efficacy in reducing test anxiety. Forty high school students were matched on sex and anxiety scores and randomly allocated to an experimental group (receiving two 50-minute sessions, a week apart, to learn the self-hypnosis technique), and a control group (receiving two 50-minute sessions focused on ways of reducing test anxiety). Students were retested after the two sessions, and 6 months later. Results showed a significant reduction in anxiety scores only for the hypnosis group, which was maintained at 6-month follow-up.

Wormnes, Bjorn (1994, October). Hypnosis in integrated treatment of dental fear. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Research reports from different countries estimate the proportion of adult dental phobic patients to be between 5% to 10%. It represents a large health problem. Helping patients to continue regular treatment by their local dentist and experience it as tolerable is the main treatment goal in our program. The main treatment method is a flexible and integrated exposure training. The psychotherapist works in cotherapy with the dentist. Using hypnosis in the dental chair is of great help, and patients are normally found to be very susceptible and easily hypnotized. Hypnosis helps the patient to experience increased tolerance of treatment and also to perform better than expected in the treatment situation.

1993

LaGrone, Randy G. (1993). Hypnobehavioral therapy to reduce gag and emesis with a 10-year-old pill swallower. American Journal of Clinical Hypnosis, 36, 132-136.

A 10-year-old child experienced severe nausea and psychogenic vomiting that resulted in refusal to take oral medication in pill form. The youngster was treated with hypnobehavioral therapy consisting of mental imagery, relaxation, direct suggestion, adaptive self-talk, self-monitoring, and self-reinforcement. The child's

parents were instructed to reinforce approximations of successful pill swallowing while withdrawing attention for avoidance, whining, gagging, and vomiting. A one-year follow-up revealed successful pill swallowing without significant distress. Distress.

1992

Somerville, Wayne R.; Jupp, James J. (1992). Experimental evaluation of a brief 'ideodynamic' hypnotherapy applied to phobias. Contemporary Hypnosis, 9, 85-96.

This study used a test-retest design to investigate the effectiveness of a brief 'ideodynamic' hypnotherapy which notionally located and reformulated memories in the treatment of simple phobia disorder. Subjects were 19 phobics randomly assigned to treatment (n = 10) and waiting control groups (n = 9). Rapid, significant, and sustained relief from phobic fear and avoidance was reported by 50% of treatment subjects. A number of symptoms and therapy process variables were correlated with treatment outcome. These included a negative association with hypnotizability and a positive association with hypnotic depth estimates. The ramifications of these and other associations are discussed and it is concluded that the 'ideodynamic approach' investigated may have contributed a therapeutic effect beyond the operation of treatment non-specific factors.

#### NOTES

Treatment consisted of: 1. Hypnotic induction. 2. Establishment of ideomotor signals described to clients as a means of communicating with the 'inner unconscious mind'. 3. Beyond the first therapy session, a review of work done in previous sessions. 4. Gaining signaled permission from clients to work on their problem and for the 'inner mind' to review relevant memories. 5. Location of the 'earliest critical event' by the 'inner mind'. 6. Review of the located memory by the 'inner mind'. 7. Establishing age at the occurrence of the 'critical' event. 8. Ideomotor signaling indicating suitability of a visual imagoic processing of the event.

If visual processing was chosen, the dissociated viewing procedure (step 9A) was used next, otherwise the ego-state procedure (step 9B) was employed.

The authors describe each treatment step in detail. Each subject received at least two sessions of therapy, or a maximum of three sessions if signaling indicated the presence of further unresolved memories after two sessions.

They present a case illustrating that the approach is possible with minimally hypnotizable subjects, in the apparent absence of imagoic experience, 'desensitization', catharsis, unpleasant affect, talking through or 'insight'.

"There was a positive correlation between changes in phobic fear and capacity for mental imagery which suggests that this may be one relevant variable in predicting response to memory reformulating therapy.

"There was a negative correlation between changes in fear and hypnotic responsiveness. So, successful therapeutic outcome was obviously not limited to highly hypnotizable subjects. Hypnotizability was assessed in a careful and standardized manner but testing was conducted 10 weeks following therapy. This

meant that subjects had a substantial experience in hypnotherapy at assessment. Furthermore, at the time of assessment subjects were aware of the outcome of therapy and of the kinds of memories located during therapy. It has been suggested that an association between level of hypnotizedness achieved during treatment and outcome rather than an association between degree of hypnotizability possible during therapy and outcome, taps an hypnotic effect (Spiegel & Spiegel, 1978).

"All therapy sessions were of equal duration and, as the inductions were standardized, all subjects had an approximately equal opportunity to engage in memory reformulation. However, there were individual differences in the number of memories located and a strong significant association was found between reduced fear and the number of these critical memories that were dealt with. This result suggests that the therapeutic effect may have derived either from factors specific to the therapy cycle or from differing levels of motivation among subjects to undertake the necessary 'work'.

"Maximum discomfort experienced during session two of treatment was negatively correlated with relief from phobic fears. This relationship may again reflect the influence of unresolved problematic memories on subjects who had not achieved relief by that time. It is clearly consistent with relief not being associated with painful abreaction.

"The therapy permitted a pervading privacy through the options of non-imaginative processing of recalled material (which was used by a substantial minority of subjects) and conscious withholding of the content of memories from the therapist (which was employed to a large extent by all subjects). Their reports indicated that this 'privacy' was seen as attractive by both successfully and unsuccessfully treated subjects. Taken with other results mentioned above these process findings suggest that the treatment studied stood up quite well against other brief but highly stressful exposure treatments for phobia currently in use (e.g. Ost, 1989).

"Further research needs to address the complex question as to what are the necessary and sufficient features of this procedure in producing therapeutic change. Unsolicited comments by subjects about their experience during treatment suggested that some of them were surprised by the 'involuntary' nature of their ideomotor signaling while others said that signaling was under their voluntary control. Some expressed surprise at the nature of the memories that came to them 'suddenly' during therapy. Some memories were of traumatic childhood experiences that were unexpected and considered to have 'nothing to do with my phobia'" (pp 93-94).

Stanton, Harry E. (1992). Brief therapy and the diagnostic trance: Three case studies. Contemporary Hypnosis, 9, 130-135.

## NOTES

He reviews very brief hypnotherapy, then writes, "A systematic way of encouraging people in the use of their inner resources to solve problems, the 'diagnostic trance', has been outlined by Havens and Walters (1989). People sit quietly, eyes closed, physically relaxed, concentrating upon the unpleasant sensations or feelings

associated with their problem. By turning inward in order to focus upon these internal events, they tend to drift into a trance state.

"While mentally observing these unpleasant sensations, they describe, in a somewhat detached manner, the thoughts and images which are present in their minds. They make no effort to control these in any way, simply allowing associated memories to surface quite spontaneously. Usually they reveal a pattern of thinking, a series of images, or even a specific memory which is creating the problem. Sometimes these are in the form of visual images of previously forgotten incidents, usually of a traumatic nature. On other occasions they may take the form of a voice repeating a particular negative statement.

"Once people have been able to identify the source or sources of their unpleasant feelings, they attempt to find a thought or image which is sufficiently powerful to remove or displace the negative material. On many occasions, people find that they have the inner resources needed to solve their problem but, until given the opportunity provided by the diagnostic trance, they were unaware that they possessed these resources. However, the diagnostic trance procedure appears to encourage the spontaneous emergence of creative solutions" (p. 131).

unaware that they possessed these resources. However, the diagnostic trance procedure appears to encourage the spontaneous emergence of creative solutions" (p. 131).

Of the 103 patients with whom he used the procedure, "approximately 70% reported that it had helped them resolve the specific problem for which they had sought therapeutic assistance. ... In addition to being effective, the diagnostic trance is enjoyable, even when used to process past experience of an unpleasant nature. In its simplicity lies its strength. Patients find it easy to learn and, once they have gained confidence in its value as a problem-solving tool, often teach it to family members and friends" (p. 134).

1991

Bodden, Jack L. (1991). Accessing state-bound memories in the treatment of phobias: Two case studies. American Journal of Clinical Hypnosis, 34, 24-28.

Two cases of simple phobia demonstrate the inadequacies of both behavioral and psychodynamic theories. These cases and their treatment outcomes provide support for the state-dependent memory and learning theory. Hypnosis and ideomotor signaling proved to be not only effective treatments but also useful means of illuminating the role and nature of symptom function. Issues of symptom removal and substitution are also discussed in relation to these cases

## NOTES

The authors state that Rossi and Cheek (1988) summarize a number of experimental studies on animal memory that demonstrate that different information substances are involved in different learning situations. For example, ACTH and cortisol are involved in avoidance learning while angiotensin is involved in operant conditioning. In hypnosis, state dependent memory seems to be implicated. "Hilgard (1977)

interpreted the state-dependent memory studies by Overton and others as entirely consistent with and supportive of his theory of hypnosis. Milton Erickson (1948) has also strongly suggested that it is the altered levels of arousal and affect that are responsible for the encoding and recall of stress-related problems with hypnosis" (p. 26).

"Affective experiences are apparently stored independently from their intellectual counterparts, or the emotional unit from one set may attach itself to a constellation of cues that make up a totally different cognitive set. Hypnosis may facilitate recall by providing relevant cues during an altered state of consciousness" (p. 27).

"In commenting upon [one of Erickson's cases], Rossi (1986) states that Erickson was effective because he helped the patient access state-bound memories by reviewing the context and sensory-perceptual cues that surrounded their original acquisition" (p. 27).

"When traditional behavior therapy fails it may be because the original fear stimulus is state bound or unconscious. What is conscious to the patient are those stimuli that are similar in some important respect to the original phobic stimulus and are acquired by stimulus generalization. Desensitization may reduce the patient's reactivity to the associated or acquired stimuli but cannot desensitize the original stimulus until it can be accessed consciously" (p. 27).

"The two main psychological explanations of phobic behavior are psychodynamic and behavioral. The psychodynamic approach is built upon the early writings of Freud (1956) on the traumatic basis of neurosis. Freud speculated that the intense anxiety (psychic pain) associated with the emotional trauma lead to dissociation, repression, and amnesia. Symptoms represented a dissociated or symbolic vestige of the repressed ('forgotten') trauma.

"Behavioral explanations (e.g., Rimm & Masters, 1974) are built upon classical and operant conditioning models of learning. Classical conditioning explains how a neutral stimulus (e.g., a bridge) can acquire reactivity and elicit a fear response. Avoidant behavior, which preserves the phobia, is acquired and maintained by operant conditioning. Treatment apparently involves gradual extinction of the fear response.

"Behavioral explanations (e.g., Rimm & Masters, 1974) are built upon classical and operant conditioning models of learning. Classical conditioning explains how a neutral stimulus (e.g., a bridge) can acquire reactivity and elicit a fear response. Avoidant behavior, which preserves the phobia, is acquired and maintained by operant conditioning. Treatment apparently involves gradual extinction of the fear response.

"These two divergent explanations have spawned quite different therapeutic approaches, with the behavioral approach (systematic desensitization) demonstrating greater empirical support for its effectiveness (Kaplan & Sadock, 1986). The problem is made complex theoretically by the fact that desensitization doesn't always work, even when applied in a competent fashion" (p. 25).

"Freud's early work on the traumatic basis of neurosis pointed to but offered an incorrect explanation of phobias whose origins were unconscious or state bound (i.e., not available to recall during the normal conscious state)" (p. 25).

Migaly, Peter, M. D. (1991). Hypnotic pain control and patient management in dentistry. Hypnos, 18 (3), 127-32.

#### NOTES

The value of brief psychological and hypnotic techniques in dentistry is discussed from the point of view of an anesthesiologist. The paper deals with three important areas in general and pediatric dentistry, namely the hypnotic pain control, the management of dental anxiety and phobia and the use of hypnosis as adjunct to chemoanesthesia. Two cases are also presented.

#### 1990

Clark, Duncan B.; Agras, W. Stewart (1990). The assessment and treatment of performance anxiety in musicians. American Journal of Psychiatry, 148 (5), 598-605.

94 adults with a performance anxiety problem were recruited by mass media announcements and were seen in a university-based outpatient psychiatric clinic. Assessments were questionnaires for all 94 ss, diagnostic interview of 50 ss, and laboratory performance of 34 ss. Treatment conditions were 6 weeks of buspirone, 6 weeks of placebo, a five-session group cognitive-behavior therapy program (CBTP) with buspirone, or the CBTP with placebo. All Ss fulfilled criteria for Diagnostic and Statistical Manual of Mental Disorders-III-Revised (DSM-III-R) social phobia. Of the 15 full-time professional musicians, 10 had tried propranolol and 3 had stopped performing. Most Ss had substantial anxiety and heart rate increases during lab speech and musical performances. CBTP resulted in significant reductions in subjective anxiety, improved quality of musical performance, and improved performance confidence.

#### 1989

Abelson, James L.; Curtis, George C. (1989). Cardiac and neuroendocrine responses to exposure therapy in height phobics: Desynchrony within the 'physiological response system'. Behaviour Research and Therapy, 27 (5), 561-567.

Monitored subjective, behavioral, cardiovascular and neuroendocrine responses in 2 men (aged 19 and 34 yrs) with height phobias over a full course of exposure therapy and at 6 and 8 month follow-up. Both Ss showed rising cortisol responses and stable, nonextinguishing norepinephrine responses to height exposure over the course of treatment, while

-rine responses to height exposure over the course of treatment, while improvement occurred in subjective and behavioral response systems. They had differing heart rate responses. Despite desynchrony among anxiety response systems and within the physiological system at treatment conclusion, Ss had successful outcomes with general measures of change (phobia rating scales, the Fear Survey Schedule, and the SCL-90) showing substantial improvement for both Ss. These outcomes were preserved at follow-up.

Owens, Mark E.; Bliss, Eugene L.; Koester, Peri; Jeppsen, E. Alan (1989). Phobias and hypnotizability: A reexamination. International Journal of Clinical and Experimental Hypnosis, 37 (3), 207-216.

25 phobic Ss were administered the Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) of Weitzenhoffer and E. R. Hilgard (1962). The mean SHSS:C score was 3.5 (S.D. = 2.6), which was lower than that obtained by comparison groups. The results are in direct opposition to previous results and the predictions of Frankel (1974; Frankel & M. T. Orne, 1976). Potential explanations for the discrepancy in results are discussed, including the possibility that previous studies used unrepresentative samples of phobics. It is suggested that hypnosis may sometimes play a role in the production of phobic symptoms but that other processes must be considered as well.

1986

LeBoeuf, Alan (1986). Relaxation-induced anxiety in an agoraphobic population. Perceptual and Motor Skills, 62, 910.

Two groups of 14 agoraphobic patients with anxiety attacks were randomly assigned to suggestion-imagery (like hypnosis) and progressive relaxation (with muscle tensing and release). The progressive relaxation group showed greater drop in subjective anxiety, but there was no different between groups with regard to heart rate. Following the experience, the suggestion-imagery group had more negative responses to : Did you experience anxiety? Did you ever fear losing control? Did you experience any strange sensations during the session? Was the session aversive?

1985

Domangue, Barbara B. (1985). Hypnotic regression and reframing in the treatment of insect phobias. American Journal of Psychotherapy, 39 (2), 206-214.

Presents the case histories of 2 women (aged 30 and 38 yrs) with insect phobias, who were treated with therapies that combined constructs and strategies from psychodynamic, cognitive, and behavioral approaches with hypnotic interventions. In one case, hypnotic regression to the original trauma resulted in reframing. In the other case, hypnotic regression was indirectly introduced through a childish story.

1984

Kelly, S. F. (1984). Measured hypnotic response and phobic behavior: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32 (1), 1-5.

A prospective replication of Frankel and M. T. Orne's (1976) finding that phobic patients scored higher on measures of hypnotic response than did patients wishing to use hypnosis to control smoking was carried out. 112 patients with a variety of

complaints were compared to 22 phobics. The latter scored significantly higher on hypnotizability.

**Nugent, William R.; Carden, Nick A.; Montgomery, Daniel J. (1984). Utilizing the creative unconscious in the treatment of hypodermic phobias and sleep disturbance. American Journal of Clinical Hypnosis, 26 (3), 201-205.**

An Ericksonian hypnotherapeutic procedure is designed to access and direct creative unconscious processes toward the creation and implementation of satisfactory solutions to recurrent problem behaviors. The use of the procedure is described in 3 cases. Two of the cases involve treatment of severe hypodermic needle phobias. The third case involves use of the procedure in treatment of a somnambulistic sleep disturbance. Possible curative forces tapped by the procedure, suggestions for its continued use, and suggestions for further investigation of the procedure are also discussed.

#### **NOTES**

The procedure involved: 1. Pretrance discussion of unconscious mental processes 2. Hypnosis, followed by "Now your unconscious mind can do what is necessary, in a manner fully meeting all your needs as a person, to insure that [desired therapeutic outcome], and as soon as your unconscious knows that you will [desired therapeutic outcome] it can signal by [appropriate ideomotor signal]" 3. Post-ratification.

Example: "Now your unconscious mind can do what is necessary, in a manner fully meeting all your needs as a person, to insure that you remain comfortably awake and alert anytime you receive an injection in the future, and as soon as your unconscious knows you will remain comfortably awake and alert when receiving an injection it can signal by lifting your right hand into the air off the chair.' This suggestion was [their] communicative effort to access and direct unconscious processes to the creation and implementation of altered behavioral responses to injections. Three minutes after the suggestion, B's right hand lifted jerkily into the air. She was then awakened and experienced a complete amnesia for the trance period" (p. 203).

"[They] then carried out a procedure to ratify the therapeutic change. This process presumably further develops expectancy of change, confirms change at the unconscious level, and puts doubt into any conscious beliefs contrary to positive change. This step is standardly carried out as was done with B. [They] had B sit with her hands resting on the arms of the chair. [They] told her they would ask her unconscious mind a question that only it would know the answer to. It could answer 'yes' to the question by lifting her left hand, 'no' by lifting her right hand, and 'I don't know' or 'I don't want to answer' by lifting both hands. Then the question was asked, 'In the future, will B remain comfortably awake and alert anytime she receives an injection or a blood test?' After a few minutes her left hand jerked momentarily into the air. After some discussion about the ideomotor response and her trance experience they dismissed her with the prescription to 'await the surprising results'" (p. 203).

The authors cite as a source for their work two books: Erickson, Rossi, and Rossi, *Hypnotic Realities*, 1976, pp. 226-230; also Erickson & Rossi, *Hypnotherapy*, 1979.

1983

Baker, S. R; Boaz, D. (1983). The partial reformulation of a traumatic memory of a dental phobia during trance: A case study. *International Journal of Clinical and Experimental Hypnosis*, 31 (1), 14-18.

A dental patient undertook hypnosis for the modification of a dental phobia. While she was in trance, the disturbing memory was replaced by a nontraumatic memory. After 2 sessions, the dental phobia was significantly reduced.

Flatt, Jennifer R. (1983). What makes therapy work? Thoughts provoked by a case study. *Australian Journal of Clinical and Experimental Hypnosis*, 11 (2), 63-72.

The case described is offered as illustrating the doubt common to introspective therapists: what did cure the patient? "Francesca's" presenting problem and the object of the short-term psychological intervention described here, was a fairly circumscribed set of fears related to enclosed spaces. The therapeutic approach adopted was primarily hypnobehavioural, with hypnotically-assisted systematic desensitization and "in vivo" exposure being the main components of the planned programme. However, at the client's suggestion, one hypnotic session with content planned by the therapist as age regression produced rather dramatic and unexpected results claimed by the patient to effect complete cure.

NOTES

1:

The therapist suggested that "her mind would take her back to a time that was important in understanding her fears and that she would be able to stay calm and relaxed while this past event was revealed to her" (p. 69). She subsequently imagined being in a cave, peaceful and calm. "On being roused from hypnosis, Francesca eagerly described her cave image. She was enthusiastic about the significance of this experience, claiming that it was evidence that in a previous life she had died from being locked into a cave as some sort of punishment and that this experience made her fear of enclosed places rational and comprehensible to her" (p. 69).

John, Rodney; Hollander, Barbara; Perry, Campbell (1983). Hypnotizability and phobic behavior: Further supporting data. *Journal of Abnormal Psychology*, 92 (3), 390-392.

Twenty women who were phobic to snakes, spiders, or rats were individually evaluated for hypnotic susceptibility using the standard audiotaped version of the Harvard Group Scale of Hypnotic Susceptibility, Form A. Consistent with the findings of three earlier studies using the Hypnotic Induction Profile (HIP), 55% of the present sample was found to be highly responsive to hypnosis. An item analysis comparing item pass percentages for the phobic subjects with item difficulties obtained from a normative sample of 357 female college students indicated that the

two samples were significantly correlated. The discrepancy between the findings of studies using standard measures of hypnotizability and studies using HIP is discussed.

1981

Epstein, S. J.; Deyoub, P. L. (1981). Hypnotherapy for fear of choking: Treatment implications of a case report. International Journal of Clinical and Experimental Hypnosis, 29 (2), 117-127.

An eclectic hypnotherapeutic approach consistent with Sacerdote's treatment model was utilized for overcoming the swallowing difficulty of an adult male. Traumatic onset followed an active fellatio experience. Cognitive restructuring preceded symptomatic improvement, and the client was nearly asymptomatic after 56 sessions. Further improvement was evidenced posttherapy on a 3-year follow-up study. The process of change is emphasized, highlighting the broader case management implications of this single case study. Clinical observations are supplemented with psychological test data, providing a richer framework for understanding client and therapy process.

Frutiger, A. Dewane (1981). Treatment of penetration phobia through the combined use of systematic desensitization and hypnosis: A case study. American Journal of Clinical Hypnosis, 23, 269-273.

Systematic desensitization and hypnosis were used in a client with long-standing penetration phobia. Glass test tubes were used in dilation exercises and masturbation instead of more expensive metal catheters. The client was able to have intercourse and adequate sexual adjustment.

Gustavson, John L.; Weight, David G. (1981). Hypnotherapy for a phobia of slugs. American Journal of Clinical Hypnosis, 23, 258-262.

Hypnotic procedures for treating phobias are reviewed. A case of a 21-year-old female with a long-standing phobia of slugs involved hypnotic techniques of dream elicitation, age regression, and directed imagery in therapy. The patient successfully overcame her fear of slugs as well as related problems.

O'Brien, Richard M.; Cooley, Lewis E.; Ciotti, Joseph; Henninger, Kathleen M. (1981). Augmentation of systematic desensitization of snake phobia through posthypnotic dream suggestion. American Journal of Clinical Hypnosis, 23, 231-238.

Nine snake phobics who had scored above eight on the SHSS (Form A) were given four desensitization sessions and five sessions in which a pleasant posthypnotic dream of the phobic object was suggested. These subjects were significantly superior to a desensitization-only control group on a behavioral avoidance test. Seven of the nine hypnosis subjects were able to touch a real snake. The two subjects who did not touch the snake reported dreams in which the snake was either absent or

threatening. Although conclusions are limited by differential attention and susceptibility, the technique seems promising.

Scrignar, C. B. (1981). Rapid treatment of contamination phobia with hand-washing compulsion by flooding with hypnosis. American Journal of Clinical Hypnosis, 23, 252-257.

Two obsessive-compulsive patients with contamination phobias and hand-washing compulsions are presented. Psychoanalytic psychotherapy had resulted in little change. Behavior therapy techniques of thought-stopping, systematic desensitization, progressive muscle relaxation, cognitive restructuring and self-imposed response prevention were first used, resulting in some subjective improvement, but no change in the hand-washing rate. Hypnosis, emphasizing relaxation, positive suggestion and corrective information provided further temporary subjective improvement but little change in compulsive rituals. Hypnosis, combined with the behavioral technique of flooding, produced rapid improvement. The patients maintained improvement at seven years and two years. Flooding under hypnosis may afford obsessive-compulsive patients a rapid and economical therapeutic procedure

Spiegel, David; Frischholz, Edward J.; Maruffi, Brian; Spiegel, Herbert (1981). Hypnotic responsivity and the treatment of flying phobia. American Journal of Clinical Hypnosis, 23, 239-247.

Systematic follow-up data are reported for 178 consecutive flying phobia patients treated with a single 45-minute session involving hypnosis and a problem restructuring strategy. One hundred fifty-eight (89%) of the patients completed follow-up questionnaires between six months and ten and one half years after treatment. Results showed that hypnotizable patients were over two and one half times more likely to report some positive treatment impact than those who were found to be nonhypnotizable on the Hypnotic Induction Profile. In addition, the patients' previous experiences with psychotherapy were found to be significantly associated with treatment outcome. The clinical implications of these findings are discussed.

1980

Kelly, S. F. (1980). Hypnotizability and the inadvertent experience of pain: A brief communication. International Journal of Clinical and Experimental Hypnosis, 28 (3), 189-191.

A clinical case of dental phobia similar to that reported by Frankel (1974, 1975) is presented that suggests a relationship between high hypnotizability and the genesis of phobic behavior. Further, the experience of pain despite anesthesia is speculatively linked to hypnosis and the mechanism for the development of the phobia.

1978

Dyckman, John M.; Cowan, Philip A. (1978). Imaging vividness and the outcome of in vivo and imagined scene desensitization. Journal of Consulting and Clinical Psychology, 46 (5), 1155-1156.

This study reexamined the role of imaging vividness in desensitization success. Scores on the Betts Questionnaire on Mental Imagery were used to divide 48 snake-phobic subjects into high, medium, and low vivid groups, who were assigned to imagined scene or in vivo desensitization treatments. Imaging vividness was assessed at scheduled points during therapy. Significant decreases in behavioral and self-reported fear were observed after both treatments, though in vivo desensitization produced significantly greater fear reduction. In therapy imaging vividness scores were significantly correlated with therapeutic success and were superior to pretherapy ratings as predictors of outcome.

Slutsky, Jeffrey; Allen, George J. (1978). Influence of contextual cues on the efficacy of desensitization and a credible placebo in alleviating public speaking anxiety. Journal of Consulting and Clinical Psychology, 46 (1), 119-125.

This investigation was designed to determine the extent to which contextual cues mediated the effectiveness of systematic desensitization and a plausible placebo in alleviating public speaking anxiety. After participating in a public speaking situation that allowed the collection of self-report, physiological, and behavioral manifestations of anxiety, 67 subjects were randomly assigned to receive five sessions of either desensitization, "T scope" therapy, or no treatment. Each of these conditions was conducted in a context that either stressed the clinical relevance of the procedure or presented the procedure as a laboratory investigation of fear without therapeutic implications. Analysis of changes both between groups and within individuals indicated that desensitization reduced public speaking anxiety in both contexts, whereas the placebo was effective only in the therapeutic setting. The superiority of desensitization was most pronounced on the physiological variables. The results are interpreted as indicating support for a counterconditioning, rather than an expectancy, interpretation of desensitization.

Weerts, Theodore C.; Lang, Peter J. (1978). Psychophysiology of fear imagery: Differences between focal phobia and social performance anxiety. Journal of Consulting and Clinical Psychology, 46 (5), 1157-1159.

Spider phobics and speech anxious subjects imaged fear scenes with spider and public-speaking content and a series of standard scenes that were constructed to vary in degree of emotional arousal and movement. Heart rate, skin conductance, and ocular activity were recorded. Spider phobics rated all imagery contents as more vivid and reported more scene movement than speech anxious subjects. Both groups responded to their own fear scenes with higher ratings of emotion and a greater physiological response than to the other group's fear scenes. The arousal response of spider phobics to relevant fear scenes was greater than that of speech

anxious subjects. The data suggest that the outcome of imagery-based therapies may be partly determined by type of fear.

1976

Lawlor, E. D. (1976). Hypnotic intervention with 'school phobic' children. International Journal of Clinical and Experimental Hypnosis, 24, 74-86.

Case studies are used to illustrate the use of hypnosis in working with children who exhibit symptoms of "school phobia." Responses obtained during and after hypnosis are utilized to uncover underlying conflicts and fears.

The literature (Ansbacher, 1956; Friedman, 1959; Johnson, 1957; Johnson, Falstein, Szurek, & Svendsen, 1941; Kessler, 1966; Waldfogel & Gardner, 1961) confirms the findings that a child through his symptoms has fears which he is unable to bring to consciousness and talk about. Typical are fears of abandonment by parents; fears of disaster befalling parents, especially the mother; fears based on destructive wishes toward siblings due to severe rivalry for the mother's love and attention; fears that exhibiting angry feelings will be punished by the parents; and fears of annihilation and starvation.

Hypnosis has aided in restoring these children to a school environment more quickly than more traditional methods. One case is reported with excerpts from a session. The perceptions uncovered through the use of hypnosis can be utilized with children in various school settings.

traditional methods. One case is reported with excerpts from a session. The perceptions uncovered through the use of hypnosis can be utilized with children in various school settings.

1975

Lick, John R. (1975). Expectancy, false galvanic skin response feedback, and systematic desensitization in the modification of phobic behavior. Journal of Consulting and Clinical Psychology, 43 (4), 557-567.

This study compared systematic desensitization and two pseudotherapy manipulations with and without false galvanic skin response feedback after every session suggesting improvement in the modification of intense snake and spider fear. The results indicated no consistent differences between the three treatment groups, although all treatments were significantly more effective than no treatment in modifying physiological, behavioral, and self-report measures of fear. A 4-month follow-up showed stability in fear reduction on self-report measures for the three treatment groups. Overall, the results of this experiment were interpreted as contradicting a traditional conditioning explanation of systematic desensitization. An alternate explanation for the operation of systematic desensitization emphasizing the motivational as opposed to conditioning aspects of the procedure is discussed.

1973

**Tori, Christopher; Worell, Leonard (1973). Reduction of human avoidant behavior: A comparison of counterconditioning, expectancy, and cognitive information approaches. Journal of Consulting and Clinical Psychology, 41 (2), 269-278.**

**This study was designed to compare the fear-reducing efficacy of procedures based on three major theories that have been proposed to account for the success of systematic desensitization therapy: (a) cognitive information storage and retrieval, (b) cognitive expectancy, and (c) counterconditioning. Predictions were confirmed in that the outcome measures of the high-expectancy placebo group and the two cognitive-coping groups were significantly superior to those of the counterconditioning and no-treatment groups. Thus, this experiment supports the supposition that changes in human avoidant behavior may be attributed to demand and expectancy variables rather than the conditioning of "antagonistic responses" as has been previously suggested.**

**McAmmond, D. M.; Davidson, P. O.; Kovitz, D. M. (1971). A comparison of the effects of hypnosis and relaxation training on stress reactions in a dental situation. American Journal of Clinical Hypnosis, 13, 233-242.**

#### **NOTES**

**Compared the effectiveness of relaxation, hypnosis, and a control condition in reducing in dental phobics the reaction to pressure-algometer stimulation and the injection of anesthesia. For subjects with high baseline skin-conductance levels, relaxation was most effective in reducing stress reactions. Hypnosis did not differ from the control condition. For subjects with a medium or low skin-conductance baseline, relaxation was not effective. The hypnosis group rated their treatment as most effective, and the controls rated their treatment as least effective. Five-month follow-up indicated that all subjects in the hypnosis group returned for dental treatment and that 5 of 10 in the control group and only 1 of the relaxation group returned for care.**

**1970**

**Davis, Daniel; McLemore, Clinton W.; London, Perry (1970). The role of visual imagery in desensitization. Behaviour Research and Therapy, 8 (1), 11-13.**

#### **NOTES**

**Summary: a measure of visual imagery ability was obtained for 33 females who and participated in desensitization therapy for snake phobia. Visual imagery was positively related to pretherapy performance (closeness of approach to a live snake), but not to improvement. On the basis of these results and the results of two other**

studies, it was hypothesized that the fear of good imagers tends to be based on imagination while that of poor imagers tends to be based on sensory experience. Most psychologists now recognize behavior therapy as effective in alleviating a wide variety of fears, but the nature of the processes underlying the various methods remains an open issue. Imagery has been of particular interest as a possible common denominator among various desensitization techniques. Lazarus (1961), for example, asserts that a "prerequisite for effective application of desensitization is the ability to conjure up reasonably vivid images," and Wolpe (1961) claims, "it is essential for visualizing to be at least moderately clear." London suggests that theoretically opposed treatments such as reciprocal inhibition (Wolpe, 1958) and implosion (Stampfl and Levis, 1967) may both be facilitated by repeated imagery which "produces a discrimination set such that the patient learns to distinguish between the imaginative, cognitive, affective aspects of experience, and the sensory and overt muscular aspects" (1964, p. 130). However, no systematic studies linking visual imagery to desensitization have been reported. This study examined the relationship between visual imagery and success in desensitization therapy.

Owens, Herbert E. (1970). Hypnosis and psychotherapy in dentistry: Five case histories. International Journal of Clinical and Experimental Hypnosis, 18, 181-193. (Abstracted in Current Contents, 2, 35, 21)

Used hypnosis to facilitate dental psychotherapy in resolving problems specific to the dental situation. Case histories illustrate the use of hypnosis in alleviating dentophobia and in the care and control of allergic responses. Formal induction procedures are not always necessary in achieving the desired result. Through the appropriate use of hypnosis, observable benefits can accrue to some dental patients in their ability to approach the dental situation and receive proper care. 1969

Marcia, James E.; Rubin, Barry M. (1969). Systematic desensitization: Expectancy change or counterconditioning?. Journal of Abnormal Psychology, 74 (3), 382-387. Forty-four snake and spider phobic Ss, selected from a large pool of undergraduates were exposed to either (a) a form of systematic desensitization treatment, (b) a technique, called T-scope therapy, which embodies most of the expectancy-manipulating features of desensitization, but does not contain the technical elements of the procedure (i.e., relaxation, visualization, and the construction of an anxiety hierarchy), (c) T-scope therapy, presented as an "incomplete" and probably ineffective form of treatment, or (d) no treatment. There were no significant differences (on self-rating, runway, or interview measures) between the effects of the systematic desensitization procedure and T-scope therapy, although Ss receiving either of these treatments improved significantly more than those who received no treatment or T-scope therapy administered under the "low-expectancy" condition.

**Schubot, Errol David (1967). The influence of hypnotic and muscular relaxation in systematic desensitization of phobias (Dissertation). Dissertation Abstracts, 27 (n10-B), 3681-3682.**

**"15 snake phobic subjects had desensitization treatment and 15 matched subjects had desensitization treatment with a hypnotic and muscular relaxation induction. Rate of moving through the fear hierarchy was based on three variables fear report, report of body tension, and time of signaling anxiety. Analysis of results took into consideration initial approach (to snake) level of subjects. Both treatments were effective. However, hypnotic relaxation was significantly important in desensitization for the most phobic subjects (those who couldn't approach closer than 5 feet, initially) though not for less fearful subjects. In fact, the most fearful subjects did not show improved approach behavior if they did not get the hypnosis relaxation treatment, though bodily tension and fear were reported as less while working on early items in the hierarchy. The Waking group, compared to the Relaxation hypnosis group, manifested significantly less improvement in approach and slower progress in desensitization. Hypnotizability was significantly correlated with improvement for the Relaxation subjects, as was vividness of imagery. In summary, hypnosis (a relaxation induction) facilitated desensitization treatment of highly anxiety snake-phobic subjects with the hypnotic relaxation induction, treatment outcome was related both to hypnotizability and to imagery vividness" (p. 3681- 3682).**

Levendula, Dezso (1961). Two case presentations: Treatment of central pain with reconstruction of the body-image -- hypnoanalysis of a travel phobia. International Journal of Clinical and Experimental Hypnosis, 9, 283-289.

## NOTES

Uses analogy of phantom limb (hallucinated pain which is a central pain) with a multiple sclerosis patient who had "excruciating" pain between her thighs despite paralysis from waist down due to multiple sclerosis. She valued her sex life though she couldn't feel sexual response, and felt that she "didn't have any legs" and her husband "had to carry her."

In giving her history the patient noted an increasing numbness and weakness in her legs five years earlier. At that time she also entered menopause and developed severe vaginitis. She became depressed when she became increasingly unable control her excretory functions. As the pain in the genital region increased, her ability to feel pleasant vaginal sensations diminished. Ultimately the pain was continually present.

The therapist attributed her problem to a faulty body image because she "denied the existence of her legs which were actually physically present, although, she could neither feel, nor see, nor move them" (p. 285). Secondly, it was most necessary for her to hold on to the myth [sic], that her vagina existed, because it made her feel wanted and needed by her husband. She was unconsciously afraid that by giving up her vagina she would lose the most important bond between herself and her husband" (p. 285).

The therapist speculated that "the pain, which was the last sensation perceived before the total sensory loss occurred, was fixated centrally. This "pain-image" served to maintain the pretense, unconsciously of course, that there was still feeling in the vagina even though it was only pain and not pleasure. The pain permitted her to avoid facing reality, just as in the case of an amputee who develops the fantasy of a phantom limb, because he cannot readjust his pre-existing body-image to the acceptance of mutilation" (p. 285). He offered the patient "the rather simple explanation... that because she really did not feel where her lower body ended or began, the pain served her need to know where the body halves were separated. If she could learn to imagine and to accept herself as a full, whole person, the pain probably would leave her. This theory seemed very logical and acceptable to the patient" (p. 285).

"Hypnosis was extensively utilized in the following sessions to regress the patient toward her youth. She went again for long walks with her boyfriend, now her husband. It was fun to re-experience the feeling of walking in her father's apple orchard and stretch up for a red apple. Autohypnosis was taught and [he] told her to exercise "walking" while hypnotized twice daily" (p. 285-286). He also tapped on the soles of her feet repeatedly, until she could localize the vibrations. "She finally learned that she did have legs and also that other sensations besides pain could originate below the waist... Gradually with the acceptance of her "wholeness and tallness" the pain became less and less. She was able to "forget" the pain for a longer

period of time. ... Occasionally she does call. She tells [the therapist] that in a stressful situation, such as moving into a new house and not knowing where things are, the pain comes back temporarily, but it is much less and after [they] talk an hour she is relieved" (p. 287). The patient had a total of 20 visits.

The author describes a second case, which is not described in these notes.

**Platonov, K. I. (1959). The word as a physiological and therapeutic factor: The theory and practice of psychotherapy according to I. P. Pavlov. ( 2nd). Moscow: Foreign Languages Publishing House.**

## **NOTES**

On pp. 75-76 the author discusses conditioning in hypnosis. Most of the theoretical material is in the first part of the book; the rest consists of case studies. He presents the position that the activity of the cortex and subcortex are different during states of waking and suggested sleep.

Note: Much of the Russian research done during "suggested sleep" involves subjects who are hypnotized for a long period of time--sometimes hours. Routinely, in treatment, they would give corrective suggestions and then tell the person to "sleep" and would leave them in the "sleep" for an hour or longer.

"Thus, it appears from the foregoing that the basic peculiarities of the activity of the cerebral cortex manifesting themselves in the state of suggested sleep are as follows: 1. In addition to the division of the cerebral hemispheres into sections of sleep and wakefulness typical of the hypnotic sleep of an animal, there is also a functional dissociation of the two signal systems and within the second signal system. 2. The activity of the second signal system under these conditions is not only confined to the narrow framework of the rapport zone, but is also frequently of a passive nature being directly dependent on the verbal influences of the hypnotist. Outside these influences there is no (or hardly any) activity. 3. A considerable increase in the coupling function with respect to the stimuli of the second signal system is noted at the same time in the rapport zone. This especially favours the formation of new cortical dynamic structures under the verbal influences of the hypnotist, these

structures representing the physiological basis for effectuating the suggested actions and states.

"The foregoing peculiarities manifest themselves in the fact that the entire external second signal activity of the subject is reduced only to direct answers to the questions of the hypnotist with no independent reactions to any influences, including verbal, coming from other people (so-called isolated rapport). This is understandable, since the activity of the second signal system lying outside the rapport zone is inhibited" (pp. 73-74).

"As to the problem of the peculiarities of the conditioned reflex activity during suggested sleep, it will be noted that this problem has not been very extensively studied as yet. Nevertheless, the data of various authors are of indubitable interest, since they have revealed a number of specific peculiarities in the state of the higher nervous activity under these conditions.

"According to these data the conditioned reflex activity in suggested sleep undergoes certain changes. Thus, S. Levin observed in his early studies (1931) that in children under conditions of suggested sleep the motor and secretory conditioned reflexes elaborated earlier in the waking state grew very much weaker and that there was a dissociation both between the motor and secretory conditioned reflexes and between the unconditioned reflexes of salivation and mastication; he also observed the transitional (phasic) states--paradoxical, ultraparadoxical and inhibitory phases, all the way to the onset of complete sleep" (pp. 74-75).

Platonov indicates that conditioned reflexes may disappear during suggested sleep (Povorinsky & Traugott, 1936). Arousal from suggested sleep results in gradual restoration of the reflexes, with speech reactions inhibited first and restored last. Pen & Jigarov (1936) also showed that there is a weakening of conditioned reflexes, with increased latency, in suggested sleep. These authors showed that it is impossible to form new conditioned reflexes in deep states of suggested sleep, and the conditioning is difficult in lighter states.

"Y. Povorinsky's data (1937) indicate that the conditioned reflexes elaborated in the waking state have a longer latent period during suggested sleep and in some subjects they are completely absent. Under these circumstances, the reactions to the verbal influences of the hypnotist are retained even during the deepest suggested sleep. The more complex and ontogenetically later conditioned bonds of the speech-motor analyzer are inhibited first as the subject lapses into a state of suggested sleep and are disinhibited the last as the subject awakens from this state" (p. 75).

"B. Pavlov and Y. Povorinsky observe (1953) that the conditioned bonds reinforced by the words of the hypnotist are formed during suggested sleep faster than in the waking state. In this case, during the somnambulistic phase of suggested sleep verbal reinforcements, as a rule, provoke a stronger and longer reaction with a shorter latent period than a direct first signal stimulus" (p. 76). The conditioning that occurs during suggested sleep does not manifest during waking periods unless suggestions are given during the sleep to react after waking. The author takes this to be evidence that conditioned reflex activity can be modified by verbal suggestions. During the somnambulistic stage of suggested sleep, subjects are less adept at performing addition. This indicates that inhibition has spread to the second signal

system. However, inhibition of different sensory systems seems to vary from person to person. Krasnogorsky (1951) reported one subject did not react to light, but hearing seemed to be more sensitive than in the waking state.

"All of the above testifies to the considerable changes in the character of cortical activity regularly occurring during suggested sleep and determining, on the whole, the specific nature of higher nervous activity, the systematic study of which should be the object of further research" (p. 77).

Schneck, Jerome M. (1954). Hypnotherapy in a case of claustrophobia and its implications for psychotherapy in general. Journal of Clinical and Experimental Hypnosis, 2 (4), 251-260. (Abstracted in Psychological Abstracts, 55: 6064)

#### NOTES

"Summary. This report presents the hypnotherapy of a patient with claustrophobia. The crucial event responsible for symptom formation occurred in military service when the patient was trapped in a trench by a tank which stopped over the patient before proceeding, and at which time the sides of the trench began to cave in. Subsequent traumatic events served as reinforcement. It is likely that a low threshold for the development of anxiety predisposed this patient to the development of the claustrophobia, although the major trauma sustained was undoubtedly of tremendous impact and a distinct threat to life. Emotional experiences were sealed and free expression was permitted through hypnotic revivification. The dynamics, further elaborated in the report, suggest that similar occurrences not necessarily in military settings may be approached therapeutically in this way. Aside from the reliving technique, recall stimulation through a dream induction approach was employed. Other hypnotic methods were described and further implications for psychotherapy in general were elaborated. Hypnotherapeutic and hypnoanalytic approaches to phobic reactions have been described at length elsewhere" (p. 260).

#### Physiology

1995

De Pascalis, Vilfredo (1995, November). Psychophysiological correlates of hypnosis and hypnotic susceptibility. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

#### NOTES

##### STUDY 1 and STUDY 2.

They recorded 40-Hz EEG temporal density (35-45 Hz band) from the left and right temporo-parietal-occipital scalp regions in four emotional conditions (gladness, happiness, fear, and anger). When measures were made in the waking state, for Highs, during positive emotions they found increase in left and right hemisphere activity compared with resting condition. During fear and anger there was reduction in the left hemisphere and an increase in the right, but for some subjects no left hemisphere change.

Low hypnotizables did not show large or reliable differences across emotions. With the hypnotic state, they found the trend was even greater for Highs.

1993

Forbes, E. J.; Pekala, R. J. (1993). Psychophysiological effects of several stress management techniques. Psychological Reports, 72, 19-27.

Progressive muscle relaxation and hypnosis both increased skin temperature and reduced pulse rate, and deep abdominal breathing reduced skin temperature. Hypnotic susceptibility had no effect on the psychophysiological measures.

Abelson, James L.; Curtis, George C. (1989). Cardiac and neuroendocrine responses to exposure therapy in height phobics: Desynchrony within the 'physiological response system'. Behaviour Research and Therapy, 27 (5), 561-567.

Monitored subjective, behavioral, cardiovascular and neuroendocrine responses in 2 men (aged 19 and 34 yrs) with height phobias over a full course of exposure therapy and at 6 and 8 month follow-up. Both Ss showed rising cortisol responses and stable, nonextinguishing norepinephrine responses to height exposure over the course of treatment, while improvement occurred in subjective and behavioral response systems. They had differing heart rate responses. Despite desynchrony among anxiety response systems and within the physiological system at treatment conclusion, Ss had successful outcomes with general measures of change (phobia rating scales, the Fear Survey Schedule, and the SCL-90) showing substantial improvement for both Ss. These outcomes were preserved at follow-up.

Alvarado, C. S. (1989). Dissociation and state-specific psychophysiology during the nineteenth century. Dissociation, 2, 160-168.

Reviews examples of state-specific psychophysiology in nineteenth century reports of dissociative disorders. These cases occurred in the context of rapid developments both in neurology and in the understanding of phenomena suggesting the possible influence of the mind, emotions, or psychological states on general health and

specific bodily functions (e.g., the study of hypnosis and hysteria). It is argued that interest in such cases was part of a general concern with mind/body interactions. The explanations offered to account for these cases reflected different orientations to the mind/body problem prevalent during this era.

Friswell, Rena; McConkey, Kevin M. (1989). Hypnotically induced mood. Cognition and Emotion, 3 (1), 1-26.

This article addresses theoretical and methodological issues that are central to an understanding of hypnotically induced mood. Initially, the hypnotic procedures that are typically used to induce moods are examined. Then the empirical research that has employed hypnotic moods is reviewed; specifically, the impact of hypnotic moods on physiological responses, behavioural performance, perceptual and cognitive responses, and personality, and clinical processes is examined. Finally, major theoretical and methodological issues are highlighted, and the research directions that will lead to a greater understanding of hypnotic mood are specified.

1988

Anderson, Edgar L.; Frischholz, Edward J.; Trentalange, Mark J. (1988). Hypnotic and nonhypnotic control of ventilation. American Journal of Clinical Hypnosis, 31, 118-128.

The present study examined the effects of: 1) breathing air versus breathing 5% CO<sub>2</sub>; 2) waking versus self-hypnotic conditions; and 3) neutral versus reduced respiratory rate instructions on four measures of ventilatory functioning (respiratory rate, tidal volume, expired minute ventilation, and end-tidal Pco<sub>2</sub>). Twelve high-hypnotizable normal volunteer subjects were studied in a repeated-measures, multivariate analysis of variance design; Significant main effects were observed

observed for each experimental condition, whereas none of the two or three way interactions proved noteworthy. Breathing 5% CO<sub>2</sub> produced increased ventilatory functions (e.g., increased respiratory rate, tidal volume, expired minute ventilation, and end-tidal Pco<sub>2</sub>). Being in a state of self-hypnosis is associated with reduced respiratory rate, with a significant increase in expired minute ventilation and end-tidal Pco<sub>2</sub>, but with no significant increase in tidal volume. Finally, reduced respiratory rate instructions were effective in significantly reducing respiratory rate and expired minute ventilation when breathing 5% CO<sub>2</sub> as evidenced by increases in end-tidal Pco<sub>2</sub> levels that were used to monitor ventilation outcomes.

Colgan, S. M.; Faragher, E. B.; Whorwell, P. J. (1988, June 11). Controlled trial of hypnotherapy in relapse prevention of duodenal ulceration. Lancet, 1299-1300.

30 patients with rapidly relapsing duodenal ulceration were studied to assess the possible benefit of hypnotherapy in relapse prevention. After the ulcer had healed on treatment with ranitidine, the drug was continued for a further 10 weeks during which time patients received either hypnotherapy or no hypnotherapy. The two

randomly selected groups were comparable in terms of age, sex, smoking habits, and alcohol consumption. Follow-up of both groups of patients was continued for 12 months after the cessation of ranitidine. After 1 year, 8 (53%) of the hypnotherapy patients and 15 (100%) of the control subjects had relapsed. The results of this study suggest that hypnotherapy may be a useful therapeutic adjunct for some patients with chronic recurrent duodenal ulceration.

#### NOTES

"The aetiology of duodenal ulceration is poorly understood but it is probably multifactorial. ... Stress, both psychological and physical, has since been shown to affect gastric emptying and the secretion of acid and pepsin, but attempts to causally link stress and peptic ulcer disease have produced conflicting results.

"Hypnotherapy can modify the response to betazole-stimulated gastric acid secretion, although the mechanism by which this is mediated remains unclear" (p. 1299).

"The active [treatment] group received 7 sessions of hypnotherapy and were given an audio tape for daily autohypnosis; the other group were seen as often, but did not receive any hypnotherapy. The ranitidine was then stopped and both groups were reviewed every 3 months for a further year, with the active group receiving hypnotherapy at their follow-up visits. All subjects had an endoscopy at the end of the study, or sooner if a symptomatic relapse occurred.

"Hypnosis was induced as previously described, with attention focused on the abdomen by the use of the patient's hand. They were asked to imagine warmth beneath the hand and to relate this to the control of gastric secretion. Reinforcement by visualization was used if the patient had this ability" (p. 1299).

At the end of a year, on follow up, the patient relapse rate was 53% and controls relapse was 100%, a difference significant at  $p = 0.01$ .

In their Discussion, the authors state, "This study shows that hypnotherapy is helpful in maintaining remission in those patients with duodenal ulceration who are particularly prone to relapse. ... In this model, hypnotherapy might operate at a variety of levels in the disease process: it could act in a nonspecific psychotherapeutic sense increasing 'coping' capacities and decreasing perceived stress. Alternatively, hypnotically induced relaxation may affect gastric acid secretion, and there is some experimental evidence for this.

"The early relapse rate in the hypnotherapy subjects was similar to that of controls, but subsequently the curves showed a much greater separation. This finding could indicate that there is a subgroup of subjects who are particularly responsive to therapy. However, a detailed review of psychological and clinical parameters did not reveal any specific feature that could be used to predict a response to this form of treatment" (pp. 1299-1300).

#### NOTES

2:

Current etiology of duodenal ulcers includes the presence of bacteria *Helicobacter pylori* which is important in relapse. In order to compare treatments we must know what is the status of each group regarding the presence of this bacteria. Current treatment of duodenal ulcer includes metronidazole, amoxicillin and tetracycline to

kill it. [Editor's Note: This appears to be a critique of the research methodology rather than notes on the article itself.]

Davies, Peter (1988). Some considerations of the physiological effects of hypnosis. In Heap, Michael (Ed.), Hypnosis: Current clinical, experimental and forensic practices (pp. 61-67). London: Croom Helm Ltd.

#### NOTES

This chapter reviews literature on physiological correlates of hypnosis, but these notes are limited to only one fact reported in the review. The author writes, 'A recently completed, and as yet unpublished study by C. Gillett and H. D. Griffiths at Bradford University investigated the relation between hypnosis and classical conditioning of psychophysiological responses. In a complex design involving both normal conditioning and normal test trials and a repetition of both acquisition and test trials under hypnosis, they found not only suppression of the conditioned response but also suppression of skin conductance responses to the half-second bursts of a 115-dB tone used as the unconditioned stimulus. Not to produce a significant autonomic response to such an intrinsically aversive stimulus is a remarkable feat which is probably outside the repertoire of simulators. However, even such results are not conclusive as the design did not include simulator control groups nor even neutrally instructed non-hypnotized group' (pp. 64-65 ).

1986

Chertok, Leon (1986). Psychotherapeutic transference, suggestibility. Psychotherapy, 23 (4), 563-569.

Discusses suggestion in psychotherapy and defines it as a body-affective process, an indissociable psychosociobiological entity that acts at an archaic unconscious level far beyond that of transference, mediates the influence of one individual on another, and is capable of producing manifest psychological and physiological changes. Present in all types of therapy, indirect (nondeliberate, nonintentional) suggestion is the element that plays an important role in change and can be observed in hypnotic experimentation. It is further argued that transference and suggestion are phenomena that do not altogether overlap. Suggestion is the condition of transference without which transference could not be established.

Gottschalk, Louis A. (1985). Hope and other deterrents to illness. American Journal of Psychotherapy, 39, 515-524.

Reviews animal and human research demonstrating that events during early development influence vulnerability to physical and mental illness. In addition, effectiveness of coping methods used to deal with problems of living can affect susceptibility to illness. The intervening mechanisms between stressful life experiences and illness appear to involve physiological homeostasis and immune competence.

1984

**Bakker, Dirk J. (1984). The brain as a dependent variable. Journal of Clinical Neuropsychology, 6, 1-16.**

The mainstream of neuropsychological research and practice has been devoted to the impact of the brain as an independent variable on behavior as a dependent variable. Evidence is currently available to make clear that the order of causation may be reversed: Behavioral changes can have a durable impact on the brain. The results of extensive research indicate that a large number of neuroanatomical, neurophysiological, neurochemical, and neuropsychological parameters of the animal brain can be modified through environmental manipulation, sensory experience, and systematic training. Some evidence is available to show that psychological stimulation has certain effects on the physiology of the human brain. For instance, hemisphere-specific stimulation through the presentation of words flashed in a visual hemifield appears to modify the electrophysiological activity of the contralateral hemisphere in dyslexic children and to affect their subsequent reading performance. Neuropsychology may profit from paying more attention to the ecology of the human brain.

#### **NOTES**

An 18th Century anatomist in Italy, Malacarne, demonstrated increased cerebellar folds in the brains of trained (vs. untrained) dogs and birds. His approach to neuroanatomy was not continued because psychology has been more concerned with innate traits of the individual, and because of philosophical rationalism (citing Walsh, 1981). Until very recently, scientists have viewed the brain as "structurally insensitive to environmental experience" (p. 3).

Now we have evidence that animal brains are modifiable by experience, in gross morphology, fine (synapse) morphology, and neurochemicals. "Rich environments [for rats] ... produce heavier and thicker cerebral cortices and callosal connections (Walsh, 1981), larger cortex/subcortex weight ratios, larger cell bodies and nuclei (Walsh, 1981), and higher metabolic activity as suggested by increased RNA/DNA ratios (Rosenzweig, Bennett, & Diamond, 1972)" (p. 4). Enrichment leads to more extensive dendritic fields (occipital and temporal cortex, some hippocampal regions); this implies that each neuron has more synapses. Researchers have found large Purkinje-cell bodies and many dendrites in richly educated monkeys.

"Some evidence is available to show that 'preventive' and 'therapeutic' environments positively affect behavioral performances of brain-lesioned animals. However, knowledge about the brain mechanisms which underly these effects is, as yet, lacking" (p. 6). Rats that were handled during the first 21 days of life exhibited different brain lateralization from rats that were not (Denenberg, cited by Marx, 1983). Those stimulated early stored memories mainly in the right hemisphere.

The author also reviews evidence that human brains are psychologically modifiable. Children with astigmatism generate weakened cortical response to visual stimulation (Freeman & Thibos, 1973), because they experience difficulty in processing some visual-spatial patterns. People who have visual-field defects due to brain damage can improve in vision when forced to make eye movements toward lighted targets flashed in the blind areas (Zihl, 1981).

The author also reviews evidence that human brains are psychologically modifiable. Children

with astigmatism generate weakened cortical response to visual stimulation (Freeman & Thibos, 1973), because they experience difficulty in processing some visual-spatial patterns. People who have visual-field defects due to brain damage can improve in vision when forced to make eye movements toward lighted targets flashed in the blind areas (Zihl, 1981).

Bakker theorizes that hemispheric control of reading shifts from right to left during the learning-to-read process of normal readers; at least some aspects of reading are successively mediated by the right hemisphere at age 6 and by the left hemisphere at age 8, according to electrophysiological data in a longitudinal study (Licht, Bakker, Kok, & Bouma, 1983). He thinks P-type dyslexia results from continuing to rely on right-hemispheric strategies, leading to slow reading with fragmentation errors and repetitions. L-type dyslexia results from prematurely adopting a left-hemispheric strategy, i.e. at the very beginning of the learning process, making child insensitive to the perceptual features of script with consequent substantive errors such as omissions and additions. Thus, P-type dyslexics presumably show functional overdevelopment of the right hemisphere and L-types of the left hemisphere. Treatment would involve specific stimulation of the hemisphere that they are ignoring.

He presents data suggesting that "some electrophysiological parameters of the cerebral hemispheres can be modified in dyslexic children through hemisphere-specific stimulation and loading, and that these modifications may induce better reading" (p. 12).

Bishay, Emil; Stevens, Grant; Lee, Chingmuh (1984). Hypnotic control of upper gastrointestinal hemorrhage: A case report. American Journal of Clinical Hypnosis, 27, 22-25.

The use of hypnosis for control of bleeding during and after surgical procedures is common practice. It has also been a useful tool for control of bleeding in hemophiliac children, especially during dental procedures, and in traffic accidents. This paper presents the successful treatment with hypnosis of a patient with upper gastrointestinal tract bleeding. After treatment, the patient was discharged from the hospital without the need for surgical intervention.

#### NOTES

The physician explained to the patient that nothing would hurt her and that nobody would do anything against her will, that if she could "relax," then her unconscious mind would help her control her bleeding. [Gives script used in the hypnosis.] Trance terminated after 20 minutes. "One hour later, endoscopy performed under local anesthesia revealed 'non-bleeding gastritis, no ulcers seen.' She had no bleeding following the hypnotherapy" (p. 23).

Borgeat, Francois; Goulet, Jean (1983). Psychophysiological changes following auditory subliminal suggestions for activation and deactivation. Perceptual and Motor Skills, 56, 759-766.

This study was to measure eventual psychophysiological changes resulting from auditory subliminal activation or deactivation suggestions. 18 subjects were alternately exposed to a control situation and to 25-dB activating and deactivating suggestions masked by a 40-dB white noise. Physiological measures (EMG, heart rate, skin-conductance levels and responses, and skin temperature) were recorded while subjects listened passively to the suggestions, during a stressing task that followed and after that task. Multi-variate analysis of variance showed a significant effect of the activation subliminal suggestions during and following the stressing task. This result is discussed as indicating effects of consciously unrecognized perceptions on psycho-physiological responses -fect of the activation subliminal suggestions during and following the stressing task. This result is discussed as indicating effects of consciously unrecognized perceptions on psycho-physiological responses.

1981

Benson, Herbert; Arns, Patricia A.; Hoffman, John W. (1981). The relaxation response and hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 259-270.

Procedures for self- and hetero-hypnotic induction and for the elicitation of the relaxation response appear to be similar. Further, before experiencing hypnotic phenomena, either during a traditional or an active induction, a physiological state exists which is comparable to the relaxation response. This state is characterized, in part, by decreased heart rate, respiratory rate, and blood pressure. After the physiological changes of the relaxation response occur, the individual proceeds to experience other exclusively hypnotic phenomena, such as perceptual distortions, age regression, posthypnotic suggestion, and amnesia.

Elkind, Leonard (1981). Effects of hypnosis on the aging process. Journal of the American Society of Psychosomatic Dentistry and Medicine, 28 (4), 132-137. (Also presented at the annual meeting of the Am Soc of Psychosomatic Dentistry and Medicine in San Francisco, CA)

This study investigated the possibility of altering physiological measures associated with aging through the use of posthypnotic suggestions of increased youthfulness and vitality. Subjects were 20 women ranging in age from 39 to 56 years old. They were tested individually on Morgan's Adult Growth Examination, the AGE. Test-retest scores of the Control group were not significantly different, the median change being zero. The Experimental group, however, showed a decrease in Body Age for all of the subjects, the range of change from -3 to -18 years with a median change of -11 years.

1980

Barabasz, Arreed F. (1980). EEG alpha, skin conductance and hypnotizability in Antarctica. International Journal of Clinical and Experimental Hypnosis, 63-74.

On the basis of alternative hypotheses in the literature, 9 invited Ss undergoing wintering-over isolation at Scott Base, Antarctica, were tested for EEG alpha and hypnotizability. 8-channels of EEG, bipolar skin conductance (SC) and hypnotizability data were collected at Scott Base prior to and following the wintering-over isolation. Significant increases in alpha density and hypnotizability were found in Ss following isolation. The previously reported relationship between simple eyes closed alpha density and hypnotizability was not found prior to isolation; however, this correlation approached significance following isolation. The possible influence of psychophysiological arousability on baseline EEG alpha records was considered. Correction of EEG records using SC indices of arousal resulted in a significant correlation between EEG alpha and hypnotizability following isolation. A tendency toward significance was evident in the pre-isolation, SC corrected, correlation. The significant influence of environment on EEG alpha and hypnotizability is discussed as is the use of SC arousal indices to enhance EEG alpha/hypnotizability correlations.

1979

Barmark, Susanne M.; Gaunitz, Samuel C. B. (1979). Transcendental meditation and heterohypnosis as altered states of consciousness. International Journal of Clinical and Experimental Hypnosis, 27 (3), 227-239

The effects of transcendental meditation and relaxation-heterohypnosis on subjective phenomena and physiological arousal were examined. One group of Ss, who were experienced meditators, participated in meditation, and a second group of Ss, who were highly susceptible to hypnosis but with little hypnotic experience, were exposed to hypnosis. A period of quiet sitting served as control for Ss in each group. Neither heterohypnosis nor transcendental meditation were identified as low-arousal states. They were assumed to be similar phenomenologically altered states of consciousness, mainly characterized by changes in the distribution of attention and in body image.

Barber, Theodore Xenophon (1978). 'Hypnosis,' suggestions, and psychosomatic phenomena: A new look from the standpoint of recent experimental studies. In Fosshage, J. L.; Olsen, P. (Ed.), Healing: Implications for psychotherapy (pp. 269-297). New York: Human Sciences Press.

#### NOTES

"The first part of this chapter summarizes recent experiments that indicated that suggestions (1) can prevent the skin reaction (contagious dermatitis) that is produced by plants such as poison ivy, (2) can give rise to a localized inflammation of the skin, (3) can stimulate the remission of warts, (4) can ameliorate congenital

ichthyosis (fish skin disease), and (5) can stimulate additional growth of the mammary glands in adult women. The underlying theme throughout the first part of the paper is that "suggestions" (statements that something is occurring or will occur) affect cutaneous and glandular functions when subjects accept the suggestions and incorporate them into their own ongoing cognitions (their ongoing thoughts, images, and feelings). The second part of the paper (1) summarizes recent psychophysiological experiments and biofeedback studies that indicated that our thoughts, images, and feelings affect blood flow to the skin and other organs, and (2) postulates that the aforementioned phenomena produced by suggestions (e.g., the prevention of dermatitis, the production of inflammation, and the remission of warts) may be partly due to the localized alterations in blood flow that occur when the suggestions are accepted and become part of ongoing cognitions" (pp 269-270).

Benson, Herbert; Frankel, Fred H.; Apfel, Roberta; Daniels, Michael D.; Schniewind, Henry E.; Nemiah, John C.; Sifneos, Peter E.; Crassweller, Karen D.; Greenwood, Martha M.; Kotch, Jamie B.; Arns, Patricia A.; Rosner, Bernard (1978). Treatment of anxiety: A comparison of the usefulness of self-hypnosis and a meditational relaxation technique. Psychotherapy and Psychosomatics, 30, 229-242.

We have investigated prospectively the efficacy of two nonpharmacologic relaxation techniques in the therapy of anxiety. A simple, meditational relaxation technique (MT) that elicits the changes of decreased sympathetic nervous system activity was compared to a self-hypnosis technique (HT) in which relaxation, with or without altered perceptions, was suggested. 32 patients with anxiety neurosis were divided into 2 groups on the basis of their responsivity to hypnosis: moderate-high and low responsivity. The NIT or HT was then randomly assigned separately to each member of the two

-nosis: moderate-high and low responsivity. The NIT or HT was then randomly assigned separately to each member of the two responsivity groups. Thus, 4 treatment groups were studied: moderate-high responsivity MT; low responsivity MT; moderate-high responsivity HT; and low responsivity HT. The low responsivity HT group, by definition largely incapable of achieving the altered perceptions essential to hypnosis, was designed as the control group. Patients were instructed to practice the assigned technique daily for 8 weeks. Change in anxiety was determined by three types of evaluation: psychiatric assessment; physiologic testing; and self-assessment. There was essentially no difference between the two techniques in therapeutic efficacy according to these evaluations. Psychiatric assessment revealed overall improvement in 34% of the patients and the self-rating assessment indicated improvement in 63% of the population. Patients who had moderate- high hypnotic responsivity, independent of the technique used, significantly improved on psychiatric assessment ( $p = 0.05$ ) and decreased average systolic blood pressure from 126.1 to 122.5 mm Hg over the 8-week period ( $p = 0.048$ ). The responsivity scores at the higher end of the hypnotic responsivity spectrum were proportionately correlated to greater decreases in systolic blood pressure ( $p = 0.075$ ) and to improvement by psychiatric assessment ( $p = 0.003$ ). There was, however, no consistent relation between hypnotic responsivity and the other assessments made,

such as diastolic blood pressure, oxygen consumption, heart rate and the self-rating questionnaires. The meditational and self-hypnosis techniques employed in this investigation are simple to use and effective in the therapy of anxiety.

**Cauthen, Nelson R.; Prymak, Carole A. (1977). Meditation versus relaxation: An examination of the physiological effects of relaxation training and of different levels of experience with transcendental meditation. Journal of Consulting and Clinical Psychology, 45 (3), 496-497.**

Three groups of meditators with varying amounts of experience, a group trained in relaxation, and a pseudomeditation group were tested for changes in heart rate, respiration, skin temperature, and skin conductance during meditation or relaxation. The two more experienced groups of meditators showed decreases in heart rate during meditation while the relaxation group showed decreases after relaxing. The group trained in relaxation and the least experienced meditators showed increases in skin temperature. There were no significant changes in skin conductance or respiration before, during, or after the meditation or relaxation periods.

**Crosson, B.; Meinz, R.; Laur, E.; Williams, D.; Andreychuk, T. (1977). EEG alpha training, hypnotic susceptibility, and baseline techniques. International Journal of Clinical and Experimental Hypnosis, 25, 348-360.**

3 alpha feedback sessions of 40 minutes were administered after a similar baseline period without feedback to 12 Ss high in hypnotic susceptibility and 12 Ss low in hypnotic susceptibility. Hypnotic susceptibility was not a significant dimension in alpha feedback training and previously reported relationship between alpha density and hypnotic susceptibility were not generally found. Evidence did support the efficacy of the current baseline procedure over others more commonly used. The possibility under certain conditions of there being a relationship between hypnotic susceptibility and alpha density and theoretical considerations in recording baseline are discussed.

**Fisher, R. (1977). On flashback and hypnotic recall. International Journal of Clinical and Experimental Hypnosis, 217-235.**

This essay deals with both the intra-individual and inter-individual varieties of arousal state-bound experiences. The former are labelled as "flashbacks" while the latter embrace the great fantasies and repetitive schemes, the ever re-written plots and images of literature, art, and religion.

Flashbacks are both arousal-state and stage (i.e., set and setting) bound experiences. Flashback and hypnotic recall differ only in the ways by which they are induced. Induction methods should be distinguished from induced states on the hyperaroused perception-hallucination and hypoaroused perception-meditation continuum.

Flashbackers may be characterized by their (a) variability on perceptual-behavioral tasks; (b) tendency to minimize (or reduce) sensory input; (c) high resting heart rates; (d) hypnotizability; and, hence (e) preferential right-cerebral-hemispheric cognition; and (f) a display of EEG-alpha dominance in the resting, waking state.

1976

Dugan, Michelle; Sheridan, Charles (1976). Effects of instructed imagery on temperature of hands. Perceptual and Motor Skills, 42, 14.

#### NOTES

Sixteen college student volunteers were involved in the research. Subjects were randomly assigned to two groups, either to warm or to cool their hands. All 10 subjects attempting to cool their hands were able to cool at least one hand, and six people cooled both hands. For those trying to warm their hands, five warmed at least one hand and one was able to warm both hands. Four people were able to cool their hands without hypnosis, conditioning, or feedback.

Goleman, Daniel J.; Schwartz, Gary E. (1976). Meditation as an intervention in stress reactivity. Journal of Consulting and Clinical Psychology, 44 (3), 456-466.

Meditation and relaxation were compared for ability to reduce stress reactions in a laboratory threat situation. Thirty experienced meditators and 30 controls either meditated or relaxed with eyes closed or with eyes open and then watched a stressor film. Stress response was assessed by phasic skin conductance, heart rate, self-report, and personality scales. Meditators and the meditation condition habituated heart rate and phasic skin conductance responses more quickly to the stressor impact and experienced less subjective anxiety. Meditation can produce a psychophysiological configuration in stress situations opposite to that seen in stress-related syndromes. Research is indicated on clinical applications and on the process whereby meditation state effects may become meditator traits.

Ahlberg, D.; Lansdell, H.; Gravitz, M. A.; Chen, T. C.; Ting, C. Y.; Bak, A. F.; Blessing, D. (1975). Acupuncture and hypnosis: Effects on induced pain. Experimental Neurology, 49, 272-280.

The reactions of 14 volunteers to electrical stimulation near the supra-orbital nerve were studied under acupuncture, placebo-acupuncture, and hypnosis. As the intensity of stimulation increased, a minimum sensation, a minimum pain, and then a maximum or intolerable pain sensation were produced. Under hypnosis the average intensity of the stimulus for producing these sensations was higher than before the trance induction. Under acupuncture and placebo-acupuncture no clear increase in current intensity was observed. Acupuncture, as well as hypnosis, did not consistently change the blood, blood pressure, pulse rate, EKG, respiratory rate, or EEG.

Bender, V. L.; Navarett, F. J.; Nuttman, D. (1975). Effects of neutral hypnosis on a conditioned physiological response. Psychological Reports, 37, 1155-1160.

The objective of the present experiment was to determine whether hypnosis without explicit suggestion of analgesia would diminish physiological responses to an operationally defined painful shock stimulus. Muscle tension (EMG) was significantly lower during hypnosis than pre- or posthypnosis. Pulse rate remained stable throughout all conditions. Also, the question of whether a tone paired with shock might acquire some unique property because of that association was investigated. It was found that EMG response to the tone alone was significantly greater than to the tone-shock combination, in prehypnosis and posthypnosis, but not during hypnosis.

Clawson, T. A.; Swade, R. H. (1975). The hypnotic control of blood flow and pain: The cure of warts and the potential for the use of hypnosis in the treatment of cancer. American Journal of Clinical Hypnosis, 17 (3), 160-169.

Case histories show that hypnosis can control massive bleeding and pain, and it can remove warts, probably by stopping blood flow to them. We propose that blood flow to cancerous tumors can likewise be controlled, which could destroy them outright, or which control could be a useful adjunct to chemo- or radio-therapy.

1970

Evans, Michael B.; Paul, Gordon L. (1970). Effects of hypnotically suggested analgesia on physiological and subjective responses to cold stress. Journal of Consulting and Clinical Psychology, 35 (3), 362-371.

Relative effects of suggested analgesia and hypnotic induction were evaluated with regard to reduction of stress responses (self-report, heart rate, pulse volume) to the physical application of ice-water stress. Four groups (N = 16 each) of undergraduate female Ss, equated on hypnotic susceptibility, were run individually, receiving (a) hypnotic induction plus analgesic suggestion, (b) hypnotic induction alone, (c) waking self-relaxation plus analgesic suggestion, or (d) waking self-relaxation alone. The major findings were that suggestion, not hypnotic induction procedures, produced reductions in the self-report of distress, and that the degree of reduction was related to hypnotic susceptibility in both "hypnotic and "waking" conditions. Neither suggestion nor hypnotic induction procedures resulted in reduction of the physiological stress responses monitored in this study. Several methodological issues are discussed. Although findings add to the bulk of evidence supporting the "skeptical" view of hypnotic phenomena, results are related to other literature, suggesting that an adequate evaluation of hypnotic analgesia as used clinically has not yet been undertaken.

1965

Agosti, E.; Camerota, G. (1965). Some effects of hypnotic suggestion on respiratory function. International Journal of Clinical and Experimental Hypnosis, 13 (3), 149-157.

Several respiratory indices were measured in 10 Ss in 3 states: at rest, with hypnotic suggestion of relaxation, and with hypnotic instructions to imagine muscular work. The same suggestions were given to 10 control Ss in the waking state. The suggestion of relaxation produced a decrease in pulmonary ventilation in both groups, although it was substantial only in the hypnotic group which started from a higher baseline level. The imagined work produced an increase in ventilation, especially in the hypnotic group. However, in both instances because of compensatory changes in respiratory efficiency the actual uptake of oxygen remained almost unaffected. Black, Stephen (1964). Mind and body. London: Kimber.

#### NOTES

Defines psychosomatic disease as one that responds to psychotherapy. Believes only 5% are highly hypnotizable, that hypnosis is learnable in 1/2 hour, that hypnosis is not a useful treatment for psychosomatic disorders because you can't use interpretation [of unconscious]. The 'unconscious' is "... a complex of informational systems derived from such primaeval mechanisms" (p. 133). "Primaeval mind is involved in these mechanisms of genetics and immunology" (p. 133). "There is thus a 'somatic mind' which is unconscious and presumably without any means of

verbalization of experience--and a 'cerebral mind' which is conscious" (p. 133). The dividing line is not clear.

Rapport is discussed on pp. 160, 169 as one of the spontaneous characteristics of hypnosis, in the absence of suggestion. The same for posthypnotic suggestion (rapport and amnesia). Spontaneous physiological changes in hypnosis relate to mind-body relationships (p. 169)

Conditioned reflex is discussed on p. 161

"...the subjective evidence indicates that a perceptual change involving any sensory modality can be produced by DSUH" [direct suggestion under hypnosis] p. 178. Suggestion can selectively affect different parts of the body p. 197.

Research: "Hypnosis is not only the most important and practical way of proving the existence of the unconscious--which is still in doubt in some circles--but is in fact the only way in which unconscious mechanisms can be manipulated under repeatable experimental conditions for purposes of investigation" (p. 152).

Mind-body is "amenability to control" Catatonia, which characterizes both animal and human hypnosis, seen in hypnosis, is induced by constriction (i.e. disorientation). The Cartesian concept of mind and body tends to confuse the issue p. 157.

Rapport is discussed (p. 157).

Suggestion (p. 159) "It was this concept of 'suggestion'--which so obviously parallels 'amenability to control' in animals--that eventually established hypnosis in the French schools of psychiatry as a state of increased suggestibility. ... still the standard definition of hypnosis in most medical psychiatric textbooks and in lay dictionaries" (p. 159).

Black (1969) did some biochemical sleuthing to learn how information transmitted by words becomes information encoded somatically, as when psychosomatic allergies flare and recede or disappear. What accounts for suggestion "curing" an allergic skin reaction in one part of the body while another part not included in the suggestion remains reactive? What accounts for the instantaneous skin allergy cure which sometimes occurs with suggestion (in 24 hours)?

Skin sensitivity tests in highly hypnotizable Ss who were also very allergic were inhibited by direct suggestion under hypnosis under highly controlled experimental conditions--and in one subject the effect (inhibition) was relatively permanent--ruling out (he suggests) a neurological mechanism. He did further experiments to examine whether the result was due to an instant neurological mechanism and a long-term endocrinal mechanism.

p. 212 He ruled out peripheral blood flow as the cause of diminished skin sensitivity (there was no change in blood flow with suggestions of heat or cold). Therefore decrease in blood flow couldn't explain in neurovascular terms the 'instant' inhibition of skin sensitivity (allergy) tests. Was it due to systemic--especially adrenal-- changes? He demonstrated increases in plasma cortisol under hypnosis with suggestions of fear. On p. 230 he summarizes the facts he established by skin sensitivity tests, plasma- cortisol studies, and histology - endocrinological.

Brady, J. P.; Levitt, E. E. (1964). Hypnotically-induced 'anosmia' to ammonia. International Journal of Clinical and Experimental Hypnosis, 12, 18-20.

The procedure to demonstrate anosmia by the inhalation of ammonia is discussed. Deeply hypnotized Ss who are not knowledgeable of the relevant facts of physiology may fail to respond to ammonia fumes when it is suggested that they have no sense of smell (anosmia). However, persons who, in fact, are anosmic do respond to ammonia fumes because they are a powerful stimulus to the pain fibers in the nasal mucosa. This procedure illustrates that the crucial factor in the response of the hypnotized S is not the actual facts of anatomy and physiology, but the S's concept of them. Furieux, W. D. (1964). The heat-illusion test and the structure of suggestibility. International Journal of Clinical and Experimental Hypnosis, 12 (3), 169-180.

2 similar forms of the heat-illusion test are shown to correlate to a smaller degree than would be expected if they measure the same attribute. The 2 versions also differ in the way in which they correlate with other suggestibility tests. It is shown that linear regression techniques are not appropriate for analyzing the data concerned. The interaction of various nonlinear relationships with a difference in "difficulty," as between the 2 forms of the illusion, seems to provide an adequate with a difference in "difficulty," as between the 2 forms of the illusion, seems to provide an adequate explanation for the results. It is suggested that these nonlinear relationships may indicate the existence of an attribute which prevents some Ss from responding to any suggestibility test, irrespective of what the specific mechanisms of response may be. Black, Stephen; Edholm, O. G.; Fox, R. H.; Kidd, D. J. (1963). The effect of suggestion under hypnosis on the peripheral circulation in man. Clinical Science, 26, 223-230.

#### NOTES

"Summary. 1. The effects on the circulation in the forearm and hand of both direct and indirect suggestion under hypnosis of thermal stimuli have been studied. 2. The induction of hypnosis did not significantly alter the forearm blood flow, but a small reduction in hand blood flow was usually observed. Pulse rate in general slowed slightly as did respiration rate. 3. The effect of body heating on forearm and hand blood flow was not modified by hypnosis. 4. Direct suggestion under hypnosis of body heating or body cooling, with and without body heating, produced only small changes. 5. The changes associated with suggestion were not related to the thermal suggestion. Whatever the suggestion, the usual response was a reduction in hand blood flow and an increase in forearm blood flow. 6. The rise of body temperature with heating was not modified by direct suggestion, under hypnosis, of body cooling. 7. No change in body temperature could be elicited by suggestion. 8. In a few experiments marked changes in forearm blood flow occurred. These appeared to resemble the changes in the circulation produced by emotional stimuli. 9. The smaller changes more frequently observed were also similar to those produced by

mild emotional stimuli" (p. 229). [N.B. The Subjects were normal, healthy adults, N = 9, between 21-45 years old; highly hypnotizable, amnesic for trance.]

Damaser, E. C.; Shor, R. E.; Orne, M. T. (1963). Physiological effects during hypnotically requested emotions. Psychosomatic Medicine, 25, 334-343.

4 emotional states were used: fear, calmness, happiness, and depression. The Ss were 17 college undergrads divided into 2 groups (8 hypnotized Ss, 9 simulators). "It was demonstrated that consistent physiological changes occur in response to hypnotically requested emotions, but that similar changes occur just as readily during waking control conditions and can be produced just as clearly by Ss simulating hypnosis." Diamant, J.; Dufek, M.; Hoskovec, J.; Kristof, M.; Pekarek, V.; Roth, B.; Velek, M. (1960). An electroencephalographic study of the waking state and hypnosis with particular reference to subclinical manifestations of sleep activity. International Journal of Clinical and Experimental Hypnosis, 8, 199-212.

(Author's Conclusions) EEG records have been investigated in 10 patients in a waking state and under hypnosis. It was shown that no differences existed between these two states in terms of EEG. EEG signs of decreased wakefulness can be demonstrated in some of the patients, but these were also present without hypnosis. This latter effect appears to be subclinical sleep activity (Roth), frequently seen particularly in neurosis. Reactibility to external stimuli under hypnosis was also, in most cases, equivalent to reactions in the waking state. The authors incline to the view that EEG data does not support the concept that the nature of hypnosis and sleep is qualitatively the same.

### "Summary and Conclusions

"Six 'good' hypnotic Ss were given a ten-minute 'hypnotic induction' and a series of 'hypnotic tests.' Both basic skin conductance and momentary variations in skin conductance (GSR) were recorded during the experiment.

"The results were as follows:

1. There was no significant variation in skin conductance during the 'hypnotic induction procedure.'
  2. Skin conductance generally increased throughout the remainder of the experiment, i.e., when the Ss were given suggestions of 'sensory hallucinations,' 'age-regression,' 'analgesia,' 'negative hallucinations,' and 'post'-hypnotic behavior.
  3. The Ss usually showed a GSR when they were given 'hallucinatory' suggestions, i.e., when they were told that they were becoming 'itchy,' 'thirsty,' and 'very hot.'
  4. The GSR to a pinprick was essentially the same before the experiment and during 'hypnotic analgesia.' Also, the GSR was essentially the same, during 'hypnotic analgesia,' (a) when three Ss were told they would receive a pinprick but did not receive the pinprick, (b) when they were told they would receive a pinprick and did receive the pinprick, and (c) when they received a pinprick without being told they would receive it.
  5. Four Ss showed a GSR each time they were asked to look at a 'negatively hallucinated' object and person. Two Ss did not show a GSR when they were asked to look at the 'negatively hallucinated' object (or person). The four Ss who showed a GSR stated, during or after the experiment, that they were by no means convinced that the person or object was no longer in the room. The two Ss who did not show GSR stated, after the experiment, that they had been 'certain' that the object (or person) was not present in the room.
  6. Although the Ss stated that they did not 'remember' the 'post'-hypnotic suggestion (or anything else about the experiment), they usually showed a GSR when the E made the preliminary movements to give the signal for the 'post'-hypnotic behavior. (They also showed a GSR when E gave the signal for the 'post'-hypnotic behavior.)
- "Since skin conductance is an index of the S's level of 'activation,' 'arousal,' or 'excitation,' these results indicate the following:

### "Summary

"Blood and urine samples were obtained from 18 university students at the beginning and end of two experimental sessions, one with and one without hypnosis. Some of the subjects relaxed during the sessions; others imagined or hallucinated a traumatic experience.

**"Of a variety of measurements made, urinary volumes and 17-ketosteroids, the eosinophil count and psychogalvanometer recordings appear to give useful information about any changes due to the hypnosis. The biochemical changes caused by the experimentally produced emotions seem to depend on the individual and his past experience rather than the hypnosis. The data suggest that if the experience hallucinated is known to the subject, the biochemical changes indicate a relaxed state during the hypnosis. The psycho-galvanometer recordings may indicate an agitated state while the biochemical indices suggest a relaxed state" (pp. 106-107).**

state while the biochemical indices suggest a relaxed state" (pp. 106-107).

Bigelow, Newton; Cameron, G. H.; Koroljow, S. A. (1956). Two cases of deep hypnotic sleep investigated by the strain gauge plethysmograph. Journal of Clinical and Experimental Hypnosis, 4 (4), 160-164.

NOTES

1

"Summary.

"Two subjects, studied by means of a strain gauge plethysmograph, have shown greater changes in the peripheral pulse and the finger volume during deep hypnosis than they did immediately before or after. In the absence of external stimuli, the presence and the degree of such changes reflect the activity of the autonomic nervous system. This result suggests that in hypnosis the inhibiting tendency of the cortex on the autonomic nervous system is reduced or nullified" (p. 164).

2000

Rossi, Ernest L. (2000). In search of a deep psychobiology of hypnosis: Visionary hypotheses for a new millennium. American Journal of Clinical Hypnosis, 42 (3/4), 178-207.

This search for the deep psychobiological foundations of hypnosis begins with a review of some of the paradoxes of historical hypnosis and the impasse of current theory. It is proposed that further progress requires a deeper investigation of how psychosocial cues can modulate the mechanisms of healing at the CNS, autonomic, neuroendocrine and cellular-genetic levels. The dynamics of hypnotic communication and healing from the cognitive-behavior level to the cellular-genetic are outlined in 4 stages: (1) information transduction between the experiences of consciousness and the limbic-hypothalamic-pituitary system; (2) the psychosomatic network of messenger molecules and their receptors; (3) the immediate early gene protein cascade; and (4) state dependent memory, learning and behavior. Neuroscience research is outlined for its contributions to a mathematical model of how a psychobiological approach to the therapeutic applications of hypnosis and the placebo response could facilitate neurogenesis in the human hippocampus and healing at the cellular-genetic-protein level throughout the body. A series of 10 hypotheses is proposed as a guide for theory and research in therapeutic hypnosis. (PscINFO Database Record (c) 2002 APA, all rights reserved)

De Pascalis, V.; Magurano, M. D.; Bellusci, A. (1999). Pain perception, somatosensory event-related potentials and skin conductance responses to painful stimuli in high, mid, and low hypnotizable subjects: Effects of differential pain reduction strategies. Pain, 83 (3), 499-508.

In this study, pain perception, somatosensory event-related potential (SERP) and skin conductance response (SCR) changes during hypnotic suggestions of Deep Relaxation, Dissociated Imagery, Focused Analgesia, and Placebo, compared with a Waking baseline condition, were investigated. SERPs were recorded from frontal, temporal, central, and parietal scalp sites. Ten high, 9 mid, and 10 low hypnotizable right-handed women participated in the experiment. The following measures were obtained: (1) pain and distress tolerance ratings; (2) sensory and pain thresholds to biphasic electrical stimulation delivered to the right wrist; (3) reaction time and number of omitted responses; (4) N2 (280+/-11 ms) and P3 (405+/-19 ms) peak amplitudes of SERPs to target stimuli delivered using an odd-ball paradigm; (5) number of evoked SCRs and SCR amplitudes as a function of stimulus repetition. Results showed, high, mid and low hypnotizables exhibited significant reductions of reported pain and distress ratings during conditions of Deep Relaxation/Suggestion of Analgesia, Dissociated Imagery and Focused Analgesia. High hypnotizable subjects displayed significant reductions in pain and distress levels compared to mid and low hypnotizables during Dissociated Imagery, Focused Analgesia and, to a lesser degree, during Deep Relaxation. Placebo condition did not display significant differences among hypnotizability groups. High hypnotizables, compared to mid and low hypnotizables, also showed significant increases in sensory and pain thresholds during Dissociated Imagery and Focused Analgesia. High, mid, and low groups showed significant reductions in P3 peak amplitudes across all hypnosis conditions and, to a lesser degree, during Placebo. The temporal cortical region was the most sensitive in differentiating SERP responses among hypnotizability groups. On this recording area the subjects highly susceptible to hypnosis displayed significantly smaller P3 and greater N2 peaks during Focused Analgesia than did the other hypnotizable groups. In this condition highly susceptible subjects also reported the highest number of omitted responses and the shortest Reaction Times. These subjects also showed faster habituation of SCRs when compared with mid and low hypnotizables. During Dissociated Imagery and Focused Analgesia, highly hypnotizable subjects also disclosed a smaller total number of evoked SCRs than did mid and low hypnotizable subjects. The results are discussed considering possible common and different mechanisms to account for the effects of different hypnotic suggestions.

1999

Kirsch, Irving; Lynn, Steven Jay (1999). Automaticity in clinical psychology. American Psychologist, 54 (7), 504-515.

The authors provide an overview of the literature on the ability of response expectancies to elicit automatic responses in the form of self-fulfilling prophecies and link it to the broader psychological investigation of automatic processes. The authors review 3 areas of research in which response expectancies have been shown to affect experience, behavior, and physiology: placebo effects, the effects of false biofeedback on sexual arousal, and the alteration of perceptual and cognitive functions by hypnotic and nonhypnotic suggestion. Also reviewed are data suggesting that all behavior, including novel and intentional behavior, is initiated automatically. Following this review, the authors summarize some of the ways in which knowledge of response expectancy effects and other automatic processes that influence experience and behavior can enhance clinical practice.

#### NOTES

1

Although expectancy accounts for some variance in the development of classical hypnosis effects, it is also true that "experimental data suggest that faking accounts for relatively few of these effects" (p. 507). "The best predictors of hypnotic suggestibility are waking suggestibility and response expectancy, and expectancy remains a significant predictor of hypnotic response even with waking suggestibility controlled (Braffman & Kirsch, in press; Kirsch, 1997)" (p. 508). The authors theorize that automatisms (like Chevreul pendulum) are "responses that are primed for automatic activation by two response sets: an intention and an expectancy for their occurrence" (p. 508). They suggest that most behavior is routine, virtually automatic, because cognitive structures like schemas, scripts, or plans that are outside immediate awareness trigger the behavior. They cite research by Libet (1985) and hypotheses developed by Nisbett & Wilson (1977) and Dennett (1991), concluding that "the feeling of will is a judgment, rather than an introspected content" (p. 509). The authors discuss the Chevreul pendulum phenomenon in terms of expectancy theory and explore how their theory would apply to psychotherapy

Price, D. D.; Milling, L. S.; Kirsch, I.; Duff, A.; Montgomery, G. H.; Nicholls, S. S. (1999). An analysis of factors that contribute to the magnitude of placebo analgesia in an experimental paradigm. Pain, 83 (2), 147-156.

Placebo analgesia was produced by conditioning trials wherein heat induced experimental pain was surreptitiously reduced in order to test psychological factors of expectancy and desire for pain reduction as possible mediators of placebo analgesia. The magnitudes of placebo effects were assessed after these conditioning trials and during trials wherein stimulus intensities were reestablished to original baseline levels. In addition, analyses were made of the influence of these psychological factors on concurrently assessed pain and remembered pain

intensities. Statistically reliable placebo effects on sensory and affective measures of pain were graded according to the extent of surreptitious lowering of stimulus strength during the manipulation trials, consistent with conditioning. However, all of these effects were strongly associated with expectancy but not desire for relief. These results show that although conditioning may be sufficient for placebo analgesia, it is likely to be mediated by expectancy. The results further demonstrated that placebo effects based on remembered pain were 3 to 4 times greater than those based on concurrently assessed placebo effects, primarily because baseline pain was remembered as being much more intense than it actually was. However, similar to concurrent placebo effects, remembered placebo effects were strongly associated with expected pain levels that occurred just after conditioning. Taken together, these results suggest that magnitudes of placebo effect are dependent on multiple factors, including conditioning, expectancy, and whether analgesia is assessed concurrently or retrospectively.

Abstract from National Library of Medicine, PubMed

Wickramasekera, Ian (1999). How does biofeedback reduce clinical symptoms and do memories and beliefs have biological consequences? Toward a model of mind-body healing. Applied Psychophysiology and Biofeedback, 24 (2), 91-105.

Changes in the magnitude and direction of physiological measures (EMG, EEG, temperature, etc.) are not strongly related to the reduction of clinical symptoms in biofeedback therapy. Previously, nonspecified perceptual, cognitive, and emotional factors related to threat perception (Wickramasekera, 1979, 1988, 1998) may account for the bulk of the variance in the reduction of clinical symptoms. The mean magnitude of these previously nonspecified or placebo factors is closer to 70% when both the therapist and patient believe in the efficacy of the therapy. This powerful placebo effect is hypothesized to be an elicited conditioned response (Wickramasekera, 1977a, 1977c, 1980, 1985) based on the memory of prior healing. These memories of healing are more resistant to extinction if originally acquired on a partial rather than continuous reinforcement schedule. High and low hypnotic ability in interaction with threat perception (negative affect) is hypothesized to contribute to both the production and reduction of clinical symptoms. High and low hypnotic ability respectively are hypothesized to be related to dysregulation of the sympathetic and parasympathetic arms of the autonomic nervous system. Biofeedback is hypothesized to be the most effective for reducing clinical symptoms in people of low to moderate hypnotic ability. For people high in trait hypnotic ability, training in self-hypnosis or other instructional procedures (e.g., autogenic training, progressive muscle relaxation, meditation, CBT, etc.) will produce the most rapid reduction in clinical symptoms.

self-hypnosis or other instructional procedures (e.g., autogenic training, progressive muscle relaxation, meditation, CBT, etc.) will produce the most rapid reduction in clinical symptoms.

**Kirsch, Irving (1996). Hypnosis in psychotherapy: Efficacy and mechanisms. Contemporary Hypnosis, 13 (2), 109-114.**

Meta-analyses have established that different psychotherapies have different outcomes. Cognitive-behavioural therapies are significantly more effective than psychodynamic therapies, and their superiority increases when long-term follow-up is assessed. Hypnosis enhances the efficacy of both psychodynamic and cognitive-behavioural psychotherapy, and this effect is especially strong in long-term outcome of treatment for obesity. The paucity of procedural differences between hypnotic and non-hypnotic treatments in many of the studies demonstrating a substantial advantage for hypnosis suggests that the effect depends on the use of the word 'hypnosis'. Hypnosis can be regarded as an empirically-validated, non-deceptive placebo, the effects of which are mediated by response expectancies.

**Montgomery, Guy H.; Kirsch, Irving (1996, August). Conditioned placebo effects: Stimulus substitution or expectancy change. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.**

Stimulus substitution models posit that placebo responses are due to pairings of conditional and unconditional stimuli. Expectancy theory maintains that conditioning trials produce placebo response expectancies, rather than placebo responses, and that the expectancies elicit the responses. I tested these opposing models by providing some participants with information intended to impede the formation of placebo expectancies during conditioning trials and by assessing placebo expectancies. Although conditioning trials significantly enhanced placebo responding, this effect was eliminated by adding expectancies to the regression equation, indicating that the effect of pairing trials on placebo response was mediated completely by expectancy. Verbal information reversed the effect of conditioning trials on both placebo expectancies and placebo responses, and the magnitude of the placebo effect increased significantly over 10 extinction trials. These data disconfirm stimulus substitution models and provide strong support for an expectancy interpretation of conditioned placebo effects. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1996, Vol. 5, No. 3.)

Amigo, S. (1994). Self-regulation therapy and the voluntary reproduction of stimulant effects of ephedrine: Possible therapeutic applications. Contemporary Hypnosis, 11 (3), 108-120.

NOTES

1

"Emotional self-regulation therapy is comprised of three phases. In the first phase, several sensory recall exercises are used to teach subjects how to voluntarily reproduce various physical sensations (hand numbness and heaviness, smell and taste) that are initially provoked by real stimuli (cold water, a heavy book, cigarette ashes, and lemon juice). Subjects are asked to associate these sensations with images, words, or other cues that will help them to later reproduce the sensations without the physical stimuli.

"In the second phase, subjects reproduce these sensations without the physical stimuli and are asked to generate them in response to various cues suggested by the therapist (e.g., touching a pencil, pen, book, etc.) ....

"In the last phase ... a demand of any kind generates the suggested effects. In the beginning of this phase, subjects are told that because of previously performed exercises, their minds are highly activated and receptive, so that they can respond to the therapist's verbal suggestions, without needing training for each new sensation. At this point, therapeutic suggestions are given to the patient" (p. 109).

Kirsch, Irving (1994). Clinical hypnosis as a nondeceptive placebo: Empirically derived techniques. American Journal of Clinical Hypnosis, 37 (2), 95-106.

Many psychological problems are maintained, in part, by dysfunctional response expectancies, and changing those expectations is an essential part of treatment. Hypnotic inductions alter response expectancies and have been shown empirically to substantially enhance the effects of psychotherapy. Therefore, hypnosis can be used therapeutically as a nondeceptive placebo. Expectancy plays a major role in hypnotic inductions and their effects. Clinical procedures suggested by these data are explored.

Zachariae, Robert; Bjerring, Peter (1994). Laser-induced pain-related brain potentials and sensory pain ratings in high and low hypnotizable subjects during hypnotic suggestions of relaxation, dissociated imagery, focused analgesia, and placebo. International Journal of Clinical and Experimental Hypnosis, 42 (1), 56-80

Pain reports and amplitudes of painful argon laser-induced brain potentials were obtained for 10 high and 10 low hypnotizable volunteers following placebo and a randomized sequence of four hypnotically induced conditions of (a) neutral hypnosis, (b) deep relaxation, (c) pleasant dissociated "out of body" imagery, and (d) focused analgesia of the hand. Both high and low hypnotizable subjects exhibited significant reductions of reported pain during conditions of neutral hypnosis, relaxation, dissociated imagery, and focused analgesia. High hypnotizable subjects displayed significantly greater reductions than low hypnotizables in all conditions except placebo. Both high and low hypnotizables exhibited significant reductions of reported pain in all five conditions as well as in the posthypnotic condition, when amplitudes of evoked potentials were compared to the prehypnotic baseline. Only the high hypnotizable group showed significant reductions in amplitudes when the data were recalculated to reflect relative changes compared to the average amplitude of the pre- and postconditions to compensate for a possible habituation effect indicated by the significantly lowered amplitudes in the posthypnotic condition. The results are discussed in light of a number of hypotheses concerning mechanisms of hypnotic analgesia.

1993

Baker, Sharon L.; Kirsch, Irving (1993). Hypnotic and placebo analgesia: Order effects and the placebo label. Contemporary Hypnosis, 10 (3), 117-126.

Hypnotic and placebo pain reduction were compared in a sample of subjects whose hypnotic susceptibility was broadly representative of the general population. Replicating the order effect reported by Stam and Spanos in 1987 for highly hypnotizable subjects, hypnosis produced more pain relief than a 'pain-reducing analgesic' placebo only when the hypnosis trial followed the placebo trial. When the placebo was described to subjects as a 'hypnotic drug' that 'increases suggestibility', no differences were found regardless of order of presentation. Both hypnotizability and pain reduction were correlated with subjects' expectancies, and the partial correlation between hypnotizability and pain reduction, with expectancy controlled, was non-significant. These data suggest that, for most subjects, hypnotic analgesia is analogous to a placebo effect, although it may be more useful than a placebo because its administration does not require deception.

Garssen, Bert; de Ruiter, Corine; Van Dyck, Richard (1992). Breathing retraining: A rational placebo?. Clinical Psychology Review, 12, 141-153.

Breathing retraining of patients with Hyperventilation Syndrome (HVS) and/or panic disorder is discussed to evaluate its clinical effectiveness and to examine the mechanism that mediates its effect. In relation to this theoretical question, the validity of HVS as a scientific model is discussed and is deemed insufficient. It is concluded that breathing retraining and related procedures are therapeutically effective, but probably due to principles other than originally proposed, namely

decreasing the tendency to hyperventilate. An alternative principle is the induction of a relaxation response, presenting a credible explanation for the threatening symptoms, giving a distracting task to practice when panic may occur, and promoting a feeling of control.

-posed, namely decreasing the tendency to hyperventilate. An alternative principle is the induction of a relaxation response, presenting a credible explanation for the threatening symptoms, giving a distracting task to practice when panic may occur, and promoting a feeling of control.

#### NOTES

Goal of treatment is to (1) reduce respiratory rate, and (2) cognitive reattribution of physical symptoms to hyperventilation instead of other more catastrophic causes. Reviews a number of studies, mostly small sample, including panic disorder studies, and concludes that the majority point to a therapeutic effect of breathing retraining and cognitive reattribution of physical symptoms to hyperventilation for patients suffering HVS and the closely related panic disorder with or without agoraphobia. However, the specificity of these techniques for HVS is questionable. Vlaender-van der Giessen (1986) found relaxation training just as effective as breathing retraining; and Hibbert & Chan (1989) found breathing retraining equally effective as a placebo treatment, and not more effective with patients who had recognized symptoms at a hyperventilation provocation test than with those who had not.

Tosi, D. J.; Rudy, D. R.; Lewis, J.; Murphy, M. A. (1992). The psychobiological effects of cognitive experiential therapy, hypnosis, cognitive restructuring, and attention placebo control in the treatment of essential hypertension. Psychotherapy, 29, 274-284.

Evaluated the effects of cognitive experiential hypnotherapy (CEH), which includes hypnosis, cognitive restructuring, and developmental staging, on essential hypertension. CEH, Hypnosis alone, cognitive restructuring, and attention-placebo control conditions were randomly assigned to 39 subjects. There was a significant interaction effect with the nine psychobiological outcome measures. Discriminant analysis found a stronger overall effect over time for CEH when compared with its components

Wall, Patrick D. (1992). The placebo effect: An unpopular topic [Editorial]. Pain, 51, 1-3.

#### NOTES

The author presents a useful, brief review of the placebo effect. He suggests three hypotheses about the placebo response mechanism: 1. The effect is attributable to a decrease in anxiety (Evans, 1974). This view has not been validated (White, Tursky, & Schwartz, 1985). 2. Expectation, cognitively mediated, leads to behavioral effects. Certain personalities, described as placebo responders, report a stronger analgesia with a fixed dose of morphine than do people who are placebo non-responders (Beecher, 1968). White et al. (1985) proposed that simply asking what is expected of

a medicine will identify who the placebo responders will be. Also, the placebo response to morphine is stronger than the placebo response to aspirin. Physician or nurse expectancy is influential as well as patient expectancy, and that means that 'blind' experimental trials are not truly blind. Kanto et al. (1966) found that the placebo effect is stronger when the placebo is given second than when it is given first in a crossover design. 3. The effect is due to a classical conditioned Pavlovian response (Wickramasekera 1980). Support for this comes from experiments on normal subjects whose pain and tolerance threshold had been established (Voudouris et al. 1989, 1990). For example, in one experiment in which electric current was the stimulus, a purportedly anesthetic ointment was applied to the locus of stimulation; some of the subjects showed a placebo response of diminished pain. A second group, treated in the same manner, had the pain producing electric current secretly reduced by the Experimenter. This second group, who had experienced reduction in pain that suggested the cream was truly analgesic, A second group, treated in the same manner, had the pain producing electric current secretly reduced by the Experimenter. This second group, who had experienced reduction in pain that suggested the cream was truly analgesic, subsequently became strong placebo responders to the originally painful current and cream.

The author views the expectancy hypothesis and the conditioning hypothesis as not necessarily incompatible. Unlike the cognitively mediated expectation hypothesis, conditioning does not necessarily require cognition. But there is little support for the idea that human conditioning does not involve cognition [See Brewer, W. F. (1974). There is no convincing evidence for operant or classical conditioning in adult humans. In W. B. Weimer and D. S. Palermo (Eds.) *Cognition and the Symbolic Processes*. N.Y.: Wiley, pp 1-42.]

"If then the expectation and conditioning hypotheses are not clearly separate, it may be relevant to add an apparently unrelated group of phenomena. Humans and animals frequently show no signs of pain in the presence of overt injury (Wall 1979). It seems that pain appears only when reaction to injury is biologically appropriate. Could it be that expectation-conditioning is one of the factors which determines which item of our behavioural repertoire with its associated sensation is appropriate?" (p. 3).

**1991**

Moret, V.; Forster, A.; Laverriere, M. C.; Lambert, H.; Gaillard, R. C.; Bourgeois, P.; Haynal, A.; Gemperle, M.; Buchser, E. (1991). Mechanism of analgesia induced by hypnosis and acupuncture: Is there a difference?. *Pain*, 45, 135-140.

Hypnosis and acupuncture can alleviate experimentally induced pain but the mechanism of analgesia remains unclear for both techniques. Experimental pain was induced by cold pressor test (CPT) in 8 male volunteers. Analgesic effect of hypnosis (HA) and acupuncture (AA) was assessed before and after double-blind administration of placebo or naloxone, in a prospective, cross-over study. We found that pain intensity was significantly lower with HA as compared with AA, both with naloxone ( $P < 0.001$ ) and placebo ( $P < 0.001$ ). Within HA or AA groups, pain scores

did not differ significantly when naloxone or placebo was administered. During AA, however, pain scores were similar to control values when naloxone was given ( $P = 0.05$ ) but decreased significantly with placebo ( $P < 0.002$ ). Analog scales for pain intensity and pain relief showed a good correlation ( $r = 0.94$ ). Plasma levels of B-endorphins did not change significantly in any combination. Heart rate, peripheral arterial blood pressure and skin conductance were very insensitive indices to assess pain intensity or relief, as well as intensity of acupuncture stimulation or depth of hypnotic trance. We conclude: (1) HA and AA can significantly reduce pain from CPT, and HA is more effective than AA; (2) HA and AA are not primarily mediated by the opiate endorphin system; and (3) plasmatic levels of B-endorphins are not significantly affected by HA or AA nor by naloxone or placebo administration.

## NOTES

The authors measured blood pressure, heart rate, skin conductance, mood (Clyde Mood Scale), beta endorphin levels, and hypnotizability.

Before the experimental sessions they obtained Ss' opinions about the analgesia effectiveness of hypnosis and acupuncture. For each Subject they established a value for 'intolerable' pain (the longest duration of arm immersion in cold water). Efficacy of treatment was defined as none (0% on the efficacy scale) for this Control session..

During the experimental sessions they gave hypnosis or acupuncture analgesia for 20 minutes, then an injection of either naloxone or placebo. Double-blind controls were used. Five minutes after the injection they began CPT and the Subject was told to maintain their hand in the water for the same amount of time as in the control session. Pain intensity and treatment efficacy were scored, then the S completed a mood scale. Five blood samples were collected over the course of the procedure: (a) first rest period, (b) treatment period, (c) after injection, (d) after CPT, (e) second rest period.

Results (see Abstract). "When naloxone was administered, HA was no more effective than AA in alleviating pain ( $P = 0.109$ ). However HA was significantly more effective than AA when placebo was administered ( $P < 0.05$ ). Whichever technique was used there was no significant alteration in pain relief by either naloxone or placebo ( $P = 0.426$  within the HA group and  $P = 0.519$  within the AA group)" (p. 137).

"Compared to the control session, the pain relief was significantly better with HA, both when placebo (62.53%,  $P < 0.001$ ) and when naloxone (49.3%,  $P < 0.001$ ) was administered. This was not true with AA and placebo (15.21%,  $P = 0.1$ ) nor with AA and naloxone (13.38%,  $P = 0.5$ )" (p. 137).

"When naloxone or placebo was administered, the mean pain relief scores did not differ significantly with HA ( $P = 0.56$ ) or with AA ( $P = 0.852$ ). There was a good correlation ( $r = .94$ ) between ratings of pain and treatment efficacy" (pp. 137-138). Outcome was not related to Subjects pre-experimental beliefs about efficacy of hypnosis or of acupuncture. During the experimental sessions, all Ss reported that hypnosis was more effective than acupuncture.

Neither hypnosis nor acupuncture affected beta endorphin plasma levels; neither naloxone nor placebo affected beta endorphin plasma levels.

Mood was somewhat affected by treatments. "When compared with the baseline value (i.e., before each session), mean scores for happiness were significantly lower after AA with placebo than after AA with naloxone ( $P = 0.05$ ). The other evaluated categories of mood (friendliness, aggressiveness, clear thought, sleepiness and dizziness) were not affected by either session" (p. 139).

In the Discussion, authors indicated that "variables such as heart rate, arterial blood pressure and skin conductance were very insensitive indices for assessing pain or pain relief as well as intensity of acupuncture stimulation or depth of hypnotic trance" (p. 139).

Why was hypnoanalgesia better than acupuncture analgesia? "Firstly, a preconceived opinion could favor hypnosis; this was not the case amongst these subjects. Secondly, the influence of what was felt to be a more pleasant experience (HA) might help to lower pain ratings. Subjective preference for hypnosis was frequently expressed informally; however, scores from the Clyde Mood Scale did not suggest mood enhancement after HA. Thirdly, the intensity of analgesia might have been more uniform with HA than with AA. ... Interestingly, we found no difference in pain ratings between good and poor hypnotic subjects, even if theoretically poor hypnotic subjects could be expected to experience less pain relief with HA" (p. 139).

Effect of naloxone. "Although the failure to achieve statistical significance may be due to the small number of subjects, our results suggest that, if opiate receptors play a role in HA or AA, it is not of primary importance" (p. 139). The authors go on to state that the data on plasma beta-endorphin and CSF beta-endorphin are confusing, and elaborate the discussion of that variable on p. 139.

1990

Clark, Duncan B.; Agras, W. Stewart (1990). The assessment and treatment of performance anxiety in musicians. American Journal of Psychiatry, 148 (5), 598-605.

94 adults with a performance anxiety problem were recruited by mass media announcements and were seen in a university-based outpatient psychiatric clinic. Assessments were questionnaires for all 94 ss, diagnostic interview of 50 ss, and laboratory performance of 34 ss. Treatment conditions were 6 weeks of buspirone, 6 weeks of placebo, a five-session group cognitive-behavior therapy program (CBTP) with buspirone, or the CBTP with placebo. All Ss fulfilled criteria for Diagnostic and Statistical Manual of Mental Disorders-III-Revised (DSM-III-R) social phobia. Of the 15 full-time professional musicians, 10 had tried propranolol and 3 had stopped performing. Most Ss had substantial anxiety and heart rate increases during lab speech and musical performances. CBTP resulted in significant reductions in subjective anxiety, improved quality of musical performance, and improved performance confidence.

**Kirsch, Irving (1990). Changing expectations: A key to effective psychotherapy. Pacific Grove, CA: Brooks/Cole. (Reviewed in *American Journal of Clinical Hypnosis*, 34, 138)**

#### **NOTES**

**This is a clinical hypnosis textbook written from the perspective of a cognitive therapist, and based on response-expectancy theory. The author discusses how expectancy theory can account for results obtained with hypnosis, cognitive behavioral, and psychodynamic psychotherapy, as well as with psychopharmacology. The book draws heavily upon psychological research in psychotherapy as well as hypnosis, and discusses how therapists can mobilize patient positive expectations for change. Hypnotic responses are viewed as 'genuine' responses that subjectively are not perceived to be under voluntary control (similar to other classes of response behavior).**

**Rokke, Paul D.; Carter, Alice S.; Rehm, Lynn P. (1990). Comparative credibility of current treatments for depression. Psychotherapy, 27, 235-242.**

**Current treatments of depression were evaluated for credibility. Interpersonal, communication, self-control, cognitive, social skills, and relaxation placebo therapies were rated significantly more credible and efficacious than psychodynamic and activity-change therapies, which were rated significantly more credible than biological (drug) therapy. Implications were addressed.**

#### **NOTES**

**The authors presented the basic theoretical rationale and procedures associated with the nine therapies. They used the Beck Depression Inventory and the Eysenck Personality Inventory to investigate individual differences.**

**Subjects were 252 psychology students, 128 male and 124 female; 22% had previously sought counseling and 34% had previously been clinically depressed.**

**Spanos, Nicholas P.; Williams, Victoria; Gwynn, Maxwell I. (1990). Effects of hypnotic, placebo, and salicylic acid treatments on wart regression. Psychosomatic Medicine, 52, 109-114.**

**Subjects with warts on their hands and/or feet were randomly assigned to a hypnotic suggestion, topical salicylic acid, placebo, or no treatment control condition. Subjects in the three treated groups developed equivalent expectations of treatment success. Nevertheless, at the six-week follow-up interval only the hypnotic subjects had lost significantly more warts than the no treatment controls. Theoretical implications are discussed.**

#### **NOTES**

**Study involved 15 females, 25 males (18-35 yrs old) with warts on at least one hand or foot, recruited through posters and newspaper ads; N = 10 in each condition. Hypnotic treatment consisted of 10 minute induction (modified from T. X. Barber's**

1969 book) and a suggestion for wart regression that was 2 minutes in duration (the skin around warts was 'beginning to tingle and grow warm'; 'vividly imagine the warts shrinking and dissolving away'; 30 second break; repeated the suggestions). For Ss with warts on more than one limb the complete suggestion procedure was repeated for each wart-infected limb.

Results indicate psychological factors can influence course of some virally produced disorders; that self-medicating with over-the-counter products doesn't explain suggestion-induced wart regression; that expectation of treatment success is the most important variable in psychologically induced wart regression. "Hypnotic subjects attained significantly higher CURSS:S scores than did control subjects. Nevertheless, it is unlikely that between group differences in hypnotizability accounted for the group differences in wart regression. Two previous experiments (3) that used the CURSS found that hypnotizability failed to predict wart loss in either hypnotic suggestion, nonhypnotic suggestion, or placebo treatments, and even in the present study the hypnotic treatment failed to differ from either the real or placebo treatment on CURSS:S scores, and none of the treatments differed significantly on the CURSS:O scores. Our finding and earlier findings that hypnotic subjects reported more intense suggested sensations than placebo subjects is consistent with the hypothesis that vivid suggested imagery facilitates wart loss (7, 8)

"An alternative hypothesis emphasizes that only our hypnotic suggestion treatment encouraged subjects to see themselves as developing cognitive control over their own wart regression. This hypothesis suggests that subjects' subjective sense of cognitive involvement in and control over treatment outcome (as opposed to the vividness of their suggested imagery) may have been the important psychological factor in wart regression. It would be of interest in a future study to manipulate subjects' sense of cognitive involvement in their treatment independently of suggested imagery in order to assess the relative contributions of these variables to wart regression" (pp. 113-114).

of these variables to wart regression" (pp. 113-114).

Van Dyck, R.; Hoogduin, K. (1990). Hypnosis: Placebo or nonplacebo?. American Journal of Psychotherapy, 44, 396-404.

Examines experimental evidence for the view that hypnosis is a placebo in light of A. Grunbaum's (see PA, Vol 74:10891) reconceptualization. According to Grunbaum's definition of placebo, a therapeutic procedure is a non-placebo if it can be demonstrated that its effects are produced according to the theory on which the therapy is based. Evidence suggests that placebo effects are not related to hypnotizability. Clinical outcome studies show that results of hypnotherapy are related to hypnotizability in some disorders (e.g., anxiety, pain), but not in the treating addiction or habit disorders. An example is given in which hypnosis is usefully applied for its placebo value as a method to generate positive expectancies.

1989

Joubert, P. H.; Van Os, B. E. (1989). The effect of hypnosis, placebo, paracetamol, and naloxone on the response to dental pulp stimulation. Current Therapeutic Research - Clinical and Experimental, 46, 774-781

Healthy volunteers with varying degrees of hypnotic susceptibility, as measured by the Stanford Clinical Hypnotic Scale [sic] (SCHS), participated in a trial to evaluate analgesia induced by an indirect hypnotic technique, rapid induction analgesia (RIA). RIA produced increases in the pain threshold, as measured by dental pulp stimulation, in nine of ten subjects. The magnitude of the response was unrelated to SCHS scores. Neither placebo nor paracetamol capsules affected pain threshold measured by this technique. The effect of RIA on pain threshold was not reversed by naloxone, mitigating the possible involvement of endorphins in this phenomenon.

#### NOTES

Rapid Induction Analgesia, developed by Joseph Barber, was employed in this study of pain that was generated with dental pulp stimulation. RIA involves an induction followed by several kinds of suggestion, e.g. "Nothing is going to be done to you and you are free to respond and to experience what is acceptable to you. ... You have the ability to notice things. ... The way things are noticed might change. ... Memory is changeable and you may choose to remember or forget things. ... The comfortable feelings you are experiencing can be experienced easily and quickly again and again. ....To the latter was coupled the idea that this could happen again if the hypnotist put his hand on the subject's arm" (p. 776).

The lowest electrical current that produces slight discomfort was used as the measure of pain threshold.. RIA produced increases in pain threshold for 9 of 10 Ss. The 10th Subject was not used in the rest of the experiment, and one other Subject withdrew due to scheduling problems. The remaining 8 Ss experienced the following sequence of events in the experiment: --Rest 15 minutes --Pain threshold measure --Two 500-mg capsules of paracetamol or two of placebo --Wait 2 hours; then pain threshold measure --RIA (10 minutes); aroused from hypnosis; pain threshold measure with E's hand on arm --Insert IV; give 8 mg naloxone or 0.9% saline --Pain threshold measure with E's hand on arm

The four possible combinations (placebo-saline, placebo-naloxone, paracetamol-saline, and paracetamol-naloxone) were administered to each S on four occasions, in randomized order, with at least one week in between visits.

Whereas pain threshold was elevated by RIA above both the first ( $p < .025$ ) and the second ( $p < .05$ ) baselines, neither placebo nor paracetamol (like Tylenol) raised the threshold. Naloxone did not reverse the RIA effect of elevated threshold; in fact, there was a tendency for RIA pain threshold to increase even more after injections of either Naloxone or saline.

The Experimenters noted that the baselines apparently changed over time. They were significantly lower than the RIA threshold during visits 1 and 2, but during visits 3 and 4 the baselines seemed to approach RIA values.

In their Discussion, the authors wrote, "This study appears to have raised more questions than it answered. There is no doubt that RIA, as used in this study,

produced a significant shift in pain threshold as assessed by means of dental pulp stimulation. The fact that we were unable to detect an effect with paracetamol or placebo [N.B. which were given before the hypnosis procedures] means either that we were not really measuring something that was relevant to clinical pain or that the measurements were not sensitive enough for the detection of placebo effects or the analgesic effects of paracetamol.

"It furthermore appears that the success of RIA does not depend on the hypnotic susceptibility of the subjects. This is contrary to the findings of Van Gorb [sic] et al but agrees with the studies of Barber and Fricton and Roth.

"The temporal effects are also quite interesting. Firstly, it appears that the RIA was potentiated by the injection of either saline or naloxone. This could have been a placebo manifestation of the intravenous injection, but this appears unlikely in terms of the prior explanation given to the subjects. Subjects were told that the injections were to see whether the analgesic effects of RIA, if present, could be reversed. At no time was it suggested that the injections could have an analgesic effect. Another explanation might be that RIA is potentiated by repetition and that the second employment of the technique is more effective than the first. The other temporal effect seen was the tendency for baseline values to increase at later visits (Figure 4). This might mean progressive relaxation of the subject as he/she became more accustomed to the experimental situation with each subsequent visit or that the RIA state induced at the initial visits became associated with the experimental situation and that the posthypnotic suggestion became operative without the cue of the hypnotist's hand on the subject's arm. It does, however, appear that the maximum RIA effect was reached at the first visit and remained constant throughout.

"From our findings several conclusions may be made. Firstly, that RIA appears to be an effective method for producing analgesia in the majority of subjects and does not appear to depend on hypnotic susceptibility. Secondly, endorphins do not appear to be involved in the analgesia produced by this method. Thirdly, dental pulp stimulation using a standard apparatus commonly used in dental practice does not appear to be appropriate for demonstrating placebo effects or for assessing analgesic efficacy of simple analgesics. Pain thresholds determined in this way would therefore not be of use in clinical pharmacology in comparing different simple analgesics. Finally, trial designs should take the temporal shift in baseline values into consideration" pp 779-780.

Kirsch, Irving; Silva, C. E.; Carone, J. E.; Johnston, J. D.; Simon, B. (1989). The surreptitious observation design: An experimental paradigm for distinguishing artifact from essence in hypnosis. Journal of Abnormal Psychology, 98, 132-136.

Administered a hypnotic induction and five standard hypnotic suggestions twice via audiotape to a group of high- hypnotizable subjects and a group of low- hypnotizable simulators. During the first administration, Ss were led to believe that they were alone. However, their behavior was surreptitiously recorded on videotape and observed on a video monitor. The second administration occurred in the presence of an experimenter who had not been informed of group assignment.

When unaware that they were being observed, simulators were significantly less responsive to suggestions than they were when openly observed. In contrast, the behavior of nonsimulating subjects was not affected by the presence of an experimenter. These data indicate that the responses of high- hypnotizable Ss to standard hypnotic suggestions cannot be accounted for in terms of simple compliance with experimental demand.

Spanos, Nicholas P.; Perlini, Arthur; Robertson, Lynda (1989). Hypnosis, suggestion, and placebo in the reduction of experimental pain. Journal of Abnormal Psychology, 98 (3), 285-293.

Two experiments compared placebo and hypnotic analgesia in high and low hypnotizable subjects. Experiment 1 demonstrated that hypnotic and placebo analgesia were equally ineffective in low hypnotizables, but that hypnotic analgesia was much more effective than placebo analgesia in high hypnotizables. Experiment 2 replicated these results, but also included low and high hypnotizables who were given a nonhypnotic suggestion for analgesia. Both the low and high hypnotizables in this group reported greater suggested than placebo analgesia and as much suggested analgesia as high hypnotizable hypnotic subjects. Both experiments found substantial discrepancies between the amount of pain reduction subjects expected from the various treatments and the amount of pain reduction they actually reported following exposure to those treatments. In Experiment 2, subjects in all treatments who reduced reported pain engaged in more cognitive coping and less catastrophizing than those who did not reduce pain. Theoretical implications are discussed.

Stanton, Harry E. (1989). Hypnotic relaxation and the reduction of sleep onset insomnia. International Journal of Psychosomatics, 36, 64-68.

A hypnotic relaxation technique was compared to stimulus control and placebo conditions as a means of reducing sleep onset latency (SOL). Forty-five subjects were matched on their baseline SOL as measured through sleep diaries. They were randomly assigned to one of the three groups and experienced four weekly sessions of 30- minutes' duration, with demand effects being controlled through the use of counter- demand instructions. Data generated by the study suggested that the particular hypnotic relaxation treatment used was effective in helping Ss sleep more quickly. Neither stimulus control nor placebo groups recorded similar improvement.

Zane, Nolan W. S. (1989). Change mechanisms in placebo procedures: Effects of suggestion, social demand, and contingent success on improvement in treatment. Journal of Counseling Psychology, 36, 234-243.

Investigated the treatment effects of three social influence variables frequently implicated in psychotherapy placebos. Socially anxious male Subjects participated in an experimental treatment for reducing dating anxiety. Subjects were either

given or not given specific suggestions for decreasing social anxiety, placed in conditions of high or low social demand, and received feedback indicating either high or moderate success on the therapy task. Results support the importance of social influence variables in therapeutic change. Contingent success had its greatest impact on personal attributes; suggestion affected skill behaviors; and social demand effects were found in the self- evaluation of heterosocial performance. Various social influences appear to mediate change differently and do not exert the generic effects commonly assumed to be characteristic of therapy placebos. Implications for outcome research are discussed.

1988

Council, James R.; Loge, D. (1988). Suggestibility and confidence in false perceptions: A pilot study. British Journal of Experimental and Clinical Hypnosis, 5, 95-98.

Subjects received audiotaped instructions implying that they would perceive increases in odor or heaviness while comparing stimuli in a sensory-judgment task. Stimuli were actually indiscriminable. Subjects pretested as higher or lower in hypnotizability performed the task in either hypnotic or non-hypnotic conditions. In both treatments, greater hypnotizability was associated with more perceived changes in the stimuli and greater confidence in the reality of those perceptions. Results support a general factor underlying suggestibility in hypnotic and nonhypnotic situations. The findings are discussed in relationship to false confidence effects reported in hypermnesia research.

Malone, M.; Strube, M. (1988). Meta-analysis of non-medical treatment for chronic pain. Pain, 34, 231-234.

Conducted a meta-analysis of 109 published studies which assessed the outcome of various nonmedical treatments for chronic pain, 48 of which had sufficient information to calculate effect sizes. The remainder were examined according to proportion of patients rated as improved. Mood and number of subjective symptoms consistently showed greater responses to treatment than than did pain intensity, pain duration, or frequency of pain, indicating the importance of using a multidimensional framework for pain assessment. Effect sizes for treatments were 2.74 for autogenic training, 2.67 for hypnosis, 2.23 for pill placebo, 1.33 for package treatments that allowed patients to choose from diverse pain management strategies, .95 for biofeedback, .76 for cognitive therapy, .67 for relaxation, .55 for operant conditioning, and .46 for TENS units. However, the largest numbers of studies were in the area of biofeedback, a treatment package, and relaxation, and we must be cautious in interpreting the effect sizes due to the small number of studies in the sample.

Spanos, Nicholas P.; Stenstrom, Robert J.; Johnston, Joseph C. (1988). Hypnosis, placebo, and suggestion in the treatment of warts. Psychosomatic Medicine, 50, 245-260.

Two experiments assessed the effects of psychological variables on wart regression. In Experiment 1, subjects given hypnotic suggestion exhibited more wart regression than those given either a placebo treatment or no treatment. In Experiment 2, hypnotic and nonhypnotic subjects given the same suggestions were equally likely to exhibit wart regression and more likely to show this effect than no treatment controls. In both experiments, treated subjects who lost warts reported more vivid suggested imagery than treated subjects who did not lose warts. However, hypnotizability and attribute measures of imagery propensity were unrelated to wart loss. Subjects given the suggestion that they would lose warts on only one side of the body did not show evidence of a side-specific treatment effect.

Evans, Frederick J.; McGlashan, Thomas H. (1987). Specific and non-specific factors in hypnotic analgesia: A reply to Wagstaff. British Journal of Experimental and Clinical Hypnosis, 4, 141-147. (Comment in response to Wagstaff, G. (1987). Is hypnotherapy a placebo? Hypnosis, 4, 135-140.)

#### NOTES

This article is a reply to Wagstaff's (1984) critique of the McGlashan, Evans & Orne (1969) article which was entitled "The nature of hypnotic analgesia and the placebo response to experimental pain," published in Psychosomatic Medicine, 31, 227-246. The paper to which the authors are replying is Wagstaff, G. F. (1984). Is hypnotherapy a placebo? Paper given at the First Annual Conference of the British Society of Experimental and Clinical Hypnosis, University College, London. An abridged version appeared in the British Journal of Experimental and Clinical Hypnosis, 1987, 4, 135-140.

The closing comments of this Evans & McGlashan 1987 paper read as follows: "The strategy in this study [i.e. McGlashan, Evans & Orne, 1969] was quite different from the usual experimental design. Our goal was to maximize all of those non-specific factors that we could build into the experimental procedure. Only by attempting to maximize non-specific effects is it possible to see whether hypnosis in appropriately responsive subjects can exceed that degree of pain control which occurs due to the maximal operation of these non-specific effects. These non-specific components of the hypnotic situation may account for a great deal of clinical change. ... The critical finding was that hypnosis did add a level of pain control that occurred after maximizing clinically related non-specific factors contributing to change in pain tolerance, and that this increased tolerance occurred only in subjects markedly responsive to hypnosis, in contrast to the significant non-specific effects which were uncorrelated with measured hypnotizability" (pp. 143-144).

The principal findings of the McGlashan, Evans & Orne (1969) study were: "(a) The improved ability to tolerate pain following the ingestion of placebo was roughly the same for high hypnotizable and low hypnotizable subjects. (b) The response to the non-specific aspects of taking a 'drug' among low hypnotizable subjects was

identical to, and highly correlated (.76) with, their response to the legitimized expectation that change would occur under hypnosis for low hypnotizable subjects. The placebo component of a believe-in 'drug' ingestion was the same as the placebo component of a believed-in hypnotic experience for these low hypnotizable subjects. (c) The performance of the highly hypnotizable subjects was significantly greater under hypnotic analgesia conditions than it was under placebo conditions.

"This last finding is important conceptually, though of less clinical relevance. It should be noted that not all high hypnotizable subjects showed this result. Even among highly hypnotizable subjects, not all of them had the experience that profound analgesia had occurred! Thus, based on their subjective experience of the relatively small degree of analgesia, 6 of the 12 highly hypnotizable subjects behaved exactly as the low hypnotizable subjects had -- their placebo and hypnotic responses were small, significant, but equal. Only 6 out of 12 carefully screened hypnotizable subjects who subjectively experienced marked analgesia showed dramatic objective changes in pain endurance. Dr. Wagstaff might consider the physiological implications of the observation that we became somewhat frightened about the possibility of tissue damage with two of these six subjects. We had to stop their performance at a point where physiologists had assured us that tissue damage could be expected. They had also assured us, wrongly for these subjects, that we did not have to worry about such a critical point because nobody could endure such a degree of occlusion with this procedure. In fact, for these two subjects, anoxia and muscle cramping were not even apparent!" ( p. 144).

Stam, Henderikus J.; Spanos, Nicholas P. (1987). Hypnotic analgesia, placebo analgesia, and ischemic pain: The effects of contextual variables. Journal of Abnormal Psychology, 96, 313-320.

Two experiments examined the relation between hypnotic and placebo analgesia using ischemic pain. The first experiment examined an artifact in a previously used ischemic-pain stimulus. Experiment 2 investigated the relation between hypnotic and placebo analgesia using a submaximum-effort tourniquet technique to produce ischemic pain. High- and low-susceptible subjects who received placebo analgesia followed on a subsequent trial by hypnotic analgesia showed significant increases in tolerance from placebo to hypnotic analgesia. When presented in the reverse order, however, placebo analgesia and hypnotic analgesia led to equivalent levels of tolerance in both high- and low-susceptible subjects. A similar pattern of findings emerged for Ss' magnitude estimates of pain, but it was not related to hypnotic susceptibility. These findings indicate that both hypnotic and placebo analgesia may be contextually dependent phenomena.

Critelli, Joseph W. (1985). Placebo effects, common factors, and incremental effectiveness. [Comment/Discussion] .

## NOTES

1

This is a comment on Kirsch, Irving (1985). The logical consequences of the common-factor definition of the term placebo. American Psychologist, 40, 239-240.

"It seems apparent that psychologists have underestimated the difficulty of proving incremental effectiveness. Unlike the situation in medicine, placebo controls in psychology rarely if ever attain true double-blind status. They are almost invariably administered by therapists who do not believe in the efficacy of their own procedures. It is hard to believe that this would not affect therapeutic effectiveness. In addition, present measures of credibility-expectancy are rather crude, and they do not control for other placebo variables such as attention, demand for improvement, and emotional investment in being cured. Under these circumstances, it is difficult to maintain the conviction that any current psychological treatment has demonstrated effects beyond those of adequate placebo controls" (p. 851).

Kirsch, Irving (1985, November). Response expectancy as a determinant of experience and behavior. American Psychologist, 40 (11), 1189-1202.

Response expectancies, defined as expectancies of the occurrence of nonvolitional responses, have generally been ignored in theories of learning. Research on placebos, hypnosis, and fear reduction indicates that response expectancies generate corresponding subjective experiences. In many cases, the genuineness of these self-reported effects has been substantiated by corresponding changes in behavior and physiological function. The means by which response expectancies affect experience, physiology, and behavior are hypothesized to vary as a function of response mode. The generation of changes in subjective experience by corresponding response expectancies is hypothesized to be a basic psychological mechanism. Physiological effects are accounted for by the mindbody identity assumption that is common to all nondualist philosophies of psychology. The effects of response expectancies on volitional behavior are due to the reinforcing properties of many nonvolitional responses. Classical conditioning appears to be one method by which response expectancies are acquired, but response expectancy effects that are inconsistent with a conditioning hypothesis are also documented.

Kirsch, Irving (1985). The logical consequences of the common-factor definition of the term placebo. American Psychologist, 40, 237-238.

## NOTES

According to the comments of Critelli (1985 American Psychologist, p. 850), Kirsch "maintained that the common factors definition of placebo is unacceptable because it (a) fails to encompass placebos such as false biofeedback, and it (b) overinclusively identifies as placebos traditional procedures such as contingent reinforcement. He argued that it would be unwise to adopt a definition that 'requires us to conclude that effective ... procedures are placebos' (p. 238). Kirsch suggested that the placebo label be restricted to pharmacologically inert substances and that placebo control groups in psychotherapy be called 'expectancy modification controls' (p. 238). In effect, he suggested formally defining the placebo only within medicine, while

retaining for psychotherapy both the concept of placebo and the use of (relabelled) placebo control groups" (p. 850). Editor's Note: Critelli (1985) is a secondary source.

adopt a definition that 'requires us to conclude that effective ... procedures are placebos' (p. 238). In effect, he suggested formally defining the placebo only within medicine, while retaining for psychotherapy both the concept of placebo and the use of (relabelled) placebo control groups" (p. 850). Editor's Note: Critelli (1985) is a secondary source.

Patterson, C. H. (1985). What is the placebo in psychotherapy?. Psychotherapy, 22 (2), 163-169

Although there is an extensive literature on the placebo effect in psychotherapy, the distinction between the placebo and other elements of the therapeutic process has not been clear. This paper analyzes the therapeutic relationship in terms of separating the placebo elements and the specific factors. The so-called nonspecific elements, often equated with the placebo, are proposed as the specific factors. It is contended that those variables focused upon by those studying the social psychological factors are actually part of the placebo.

1984

Critelli, Joseph W.; Neumann, Karl F. (1984). The placebo: Conceptual analysis of a construct in transition. American Psychologist, 39, 32-39.

The placebo in psychotherapy has unfortunately retained the negative connotation of an inert "nuisance variable," a label that it originally incurred in the field of medicine. In addition, the transition toward more cognitive models of psychotherapy, particularly Bandura's theory of self-efficacy, has led to problems in defining the placebo within psychology. This transition has resulted in an awkward interface between certain preferred cognitive metaphors and the negative connotations of a presumably cognitive placebo construct. As a result, suggestions have recently been made to dismiss the placebo construct from psychology and to do away with the use of true placebo controls in outcome research. The present analysis maintains that (a) the placebo can be adequately defined within psychology, (b) the negative connotation of the placebo label is largely undeserved, (c) the placebo retains a continuing conceptual and empirical utility for evaluating psychotherapy, and (d) the therapeutic efficacy of current therapies is well established even though they have not generally been shown to be more effective than nonspecific treatment.

Handelsman, Mitchell M. (1984). Self-hypnosis as a facilitator of self-efficacy: A case example. Psychotherapy, 21 (4), 550-553.

This article presents the four-session treatment of Elaine, using self-hypnosis to facilitate the mourning process. It is argued that self-hypnosis-- rather than

enhancing imagery-- increases self-efficacy, a person's feeling that he/she can perform behaviors that lead to desired outcomes. Elaine's sense of self-efficacy was increased by allowing her to choose scenes from her life to be explored in the context of the use of imagery. Elaine imagined events surrounding her father's death, and "rewrote history" in an attempt to permit herself the direct expression of emotions.

Lewith, G. T.; Kenyon, J. N. (1984). Physiological and psychological explanations for the mechanism of acupuncture as a treatment for chronic pain. Social Science & Medicine, 1367-1378.

Many suggestions have been made about the possible mechanism of acupuncture as an analgesic therapy. This review provides a comprehensive account of the neurological, neurohumoral and psychologically-based hypotheses put forward. Although the exact mechanism of this treatment remains unclear, it is apparent that reproducible neurological and chemical changes occur in response to acupuncture, and that these changes almost certainly modify the response to, and perception of, pain. The mechanism of chronic pain is incompletely understood, but within this framework we understand acupuncture as completely as most other types of analgesic treatment.

Morrow, Gary R. (1984). Appropriateness of taped versus live relaxation in the systematic desensitization of anticipatory nausea and vomiting in cancer patients. Journal of Consulting and Clinical Psychology, 52 (6), 1098-1099.

Investigated the suggestion that the relaxation part of systematic desensitization--an effective treatment for the nausea and vomiting experienced by approximately 25% of cancer patients in anticipation of chemotherapeutic treatments-- could be learned from a prerecorded audiotape prior to meeting a psychologist for treatment. 10 cancer patients who had developed anticipatory nausea or vomiting were assigned to either a live-relaxation or a tape-relaxation group. Results show that 4 of 5 Ss assigned to the tape-relaxation group experienced nausea while listening to the prerecorded audiotape, while none of the patients in the live-relaxation group reported nausea when subsequently listening to an audiotape made during the live presentation of relaxation.

1983

Boutin, Gerald E.; Tosi, Donald J. (1983). Modification of irrational ideas and test anxiety through rational stage directed hypnotherapy (RSDH). Journal of Clinical Psychology, 39 (3), 382-391.

Examined the effects of four treatment conditions on the modification of Irrational Ideas and test anxiety in female nursing students. The treatments were Rational Stage Directed Hypnotherapy, a cognitive behavioral approach that utilized hypnosis, and vivid emotive imagery, a hypnosis-only treatment, a placebo condition, and a no-treatment control. The 48 Ss were assigned randomly to one of these treatment groups, which met for 1 hour per week for 6 consecutive weeks with

in-vivo homework assignments also utilized. Statistically, significant treatment effects on cognitive, affective, behavioral, and physiological measures were noted for both the RSDH and hypnosis group at the posttest and at a 2-month follow-up. Post-hoc analyses revealed the RSDH treatment group to be significantly more effective than the hypnosis only group on both the post- and follow-up tests. The placebo and control groups showed no significant effects either at posttreatment or at follow-up. Classen, Wilhelm; Feingold, Ernest; Netter, Petra (1983). Influence of sensory suggestibility on treatment outcome in headache patients. Neuropsychobiology, 10, 44-47.

In 45 headache patients the relationship between sensory suggestibility and three measures of treatment effect-ratings on (1) intensity of headaches; (2) efficacy of drugs, and (3) physician's competence - was investigated in a double-blind long-term crossover study. Subjects scoring high on sensory suggestibility clearly showed more relief of headaches upon the analgesic as well as upon the placebo. The physician's competence was rated higher by high-suggestible patients, whereas ratings on drug efficacy were low in all patients. The seemingly controversial behavior of high-suggestible patients was interpreted as a call for continuation of the physician's efforts in spite of the relief the patients already achieved.

O'Connell, Sean (1983). The placebo effect and psychotherapy. Psychotherapy: Theory, Research and Practice, 20 (3), 337-345.

The power of psychotherapy to cure can be comprehended through an investigation into the efficacy of placebo in medical history. The evolution of "placebo" leads to a conceptualization of psychotherapy as a form of placebo. Explanations for the presence of the placebo effect, as well as guidelines for its elicitation, are outlined. "Faith in the gods or in the saints cures one, faith in little pills another, faith in a plain common doctor a third, hypnotic suggestion a fourth. ... Faith in us, faith in our drugs and methods, is the great stock in trade of the profession (paracelsus, 1570)" (p. 337).

Ross, Sherman; Buckalew, L. W. (1983). The placebo as an agent in behavioral manipulation: A review of problems, issues, and affected measures. Clinical Psychology Review, 3, 457-471.

Need for greater recognition and appreciation of placebo effects was stated, and problems hindering their clear conceptualization are noted. Previous reviews of the history and use of placebos are acknowledged. This review provides a summary of research primarily within the last 20 years, and in particular considers studies reflecting on placebos as agents of psychomotor, physiological, cognitive, affective, and clinical manipulations. General conclusions of manipulative efficacy are provided, and issues and problems related to clarification of placebo phenomena are identified. Psychological and medical evidence reflects increasing attention to the placebo and of effects on a wide range of behavioral functions. While important

ethical and methodological questions remain, recent evidence of a physiologic basis for placebo action suggests exciting new insights into placebo phenomena

1982

Frankel, Fred H. (1982). Hypnosis and hypnotizability scales: A reply. International Journal of Clinical and Experimental Hypnosis, 30, 377-392.

The use of the hypnotizability scales in the experimental setting is briefly reviewed, as is the need to separate the effect of hypnosis from the influence of factors such as relaxation and placebo which accompany the use of hypnosis clinically. The clinical relevance of the scales, most of which were developed primarily for experimental work, is affirmed by several studies conducted in the clinical context, in which the scales were used. Levels of hypnotizability have correlated well with patterns of clinical behavior. Although the scales are useful in many instances in helping to plan treatment strategy, their value in investigative studies is emphasized. Sacerdote's (1982) criticisms of the scales are considered. While it is true that the scales are blind to some of the qualitative aspects of the hypnotic experience, the great majority of clinically hypnotizable patients are able to respond to the items on the scales. Sacerdote's reluctance to learn about the value of the scales is evident in his preference for conjecture when he could readily have gathered irrefutable data through the administration of the scales, without the least risk to the treatment of his patients, once the course of treatment was underway or complete.

1982

Stoyva, J. M.; Anderson, C. (1982). A coping-rest model of relaxation and stress management. In Goldberger, L.; Breznitz, S. (Ed.), Handbook of stress: Theoretical and clinical aspects (pp. 745-763). New York: The Free Press.

#### NOTES

"Patients with psychosomatic or stress linked disorders are likely to show signs of high physiological arousal, and they are likely, under stress, to react strongly in the symptomatic system and to show evidence of being deficient in the ability to shift from the coping to the rest mode (e.g., slowness of habituation to, and recovery from, stressful stimulation). A corollary inference is that such patients ... show activity in the symptomatic system for a higher percentage of the time that [sic] do normal subjects. We suggest that this defect in the capacity to shift to a rest condition is the principal reason that various relaxation procedures have so often proved successful in the alleviation of stress related symptoms" (p. 748).

The authors refer to a number of different stress management procedures. Among those associated with primary focus on the rest phase they include: Relaxation training (progressive relaxation, autogenic training, EMG feedback, meditation [Zen, TM]), Specific biofeedback (hand temperature, electrodermal response [EDR], EMG from particular muscle group), and Systematic desensitization. Among those associated with primary focus on coping phase are: Assertiveness training, Social skills retraining and motor skills retraining, Self-statements,

**Imagery (Guided waking imagery, autogenic abreaction, covert reinforcement and covert sensitization, behavior rehearsal). These various procedures may reflect three dimensions or aspects of the stress response, with some addressing physiology and others addressing cognition or behavior change.**

**"Rachman (1978) ... found it useful to divide the phenomenon of fear into physiological, cognitive, and behavioral components. Similarly, Davidson and Schwartz (1976) conceptualized relaxation as consisting of somatic, cognitive, and attentional components. Phillips (1977) argued that pain, such as headache pain, can be viewed as consisting of cognitive, behavioral, and physiological aspects (and that, consequently, we should not expect high correlations between headache pain and a particular physiological measure such as forehead EMG level). ...**

**"... In discussing contemporary studies of dreaming, they [Stoyva and Kamiya (1968)] proposed that there is no single, totally valid indicator of dreaming as a mental experience. Instead, there are several imperfect indicators of the dream experience--verbal report, rapid eye movements, and certain electroencephalographic (EEG) stages. ... Discrepancies among the indicators can serve to generate hypotheses" (p. 749).**

**The authors discuss different ways of retraining the capacity to rest: relaxation training (including biofeedback, etc.), systematic desensitization; and of reshaping the coping response: assertiveness training, social skills and motor skills retraining, self-statements, imagery techniques; and discuss controllability. These notes cover only a very small part of their extensive review, the material most relevant to hypnosis and suggestion.**

**"Although imagery techniques are often employed by stress management therapists, one approaches this area with ambivalence. In part, this uneasiness springs from the unsettling awareness that imagery techniques have been embraced by a freewheeling assortment of lay psychologists such as Emil Coue, Dale Carnegie, and Norman Vincent Peale, not to mention a diverse throng of contemporary 'mind controllers' and self-styled healers. A more serious source of uneasiness is ignorance of the specific processes at work. What are the mechanisms by which imagery affects the stress response?" (p. 756).**

**"There is intriguing recent evidence that simply the illusion of control may exert beneficial effects. Stern, Miller, Ewy, and Grant (1980) noted that subjects who were led to believe by means of bogus information feedback that they were successfully lowering their heart rates showed a reduction in stress type symptoms, especially those of a cardiovascular nature. It seems possible that the feeling of control may be an important part of what we have called 'placebo responding.' Stoyva (1979b) suggested that this phenomenon is probably not a unitary entity but, rather, a cluster of processes, of which the feeling of developing control over factors affecting one's disorder is an important and potentially manipulable component of therapeutic interventions" (p. 758).**

**1981**

**Franck, Jerome (1981, August). Therapeutic components shared by all psychotherapies. [Paper] Presented at the annual meeting of the American Psychological Association.**

## **NOTES**

**The author summarizes as follows. 1. Patients who receive any form of psychotherapy do better than controls. 2. Followup studies show most patients who show improvement maintain it; the closing of gap between patients who improve and those who don't is due to those who do less well catching up. Perhaps the main effect is to accelerate improvement which would eventually happen anyway. 3. Determinants of successful treatment are personal qualities of Patient and Therapist. 4. There are a few conditions which have more specific treatment indications. --Behavior therapy - for phobias, obsessive compulsive disorders, sexuality problems --Cognitive therapy - for depression Further advantages of specific treatments for specific conditions may be found.**

**All patients seek treatment not just for symptoms but because of demoralization. The common elements are: Subjective incompetence, loss of self esteem, alienation, hopelessness, helplessness, a feeling others could help but won't, feeling of loss of control. Demoralization plus distress leads to seeking treatment.**

**A small percentage without demoralization seek treatment for specific symptoms (e.g., patients with a simple phobia of height). Anxiety and depression (or loss of self esteem) are most frequent symptoms in Outpatient Departments.**

**Success in treatment often is due to restoration of morale (which removing symptoms can do very well). 1. Citing Doehrenwald research. 2. People seek treatment only 1-2 years after symptoms appear, after trying other ways of dealing with them. 3. Many patients improve rapidly in treatment (Garfield found the Mean = 5 or 6 sessions.) Mean symptom relief is same after 4 sessions and drop-out than after 6 months; also those on waiting list in phone contact improve as much.**

**Shared components in the various therapies combat demoralization: 1. Emotionally charged and vital relationship with the helping person (or group). 2. Healing setting (which increases Therapist's prestige and promotes healing). (a) Therapeutic rituals (which lead to an external reason for abandoning the symptom; the more spectacular the reason, the greater the motivation). (b) Therapeutic bond.**

**Expectation of help is the best predictor of outcome. (Cites his own placebo study.) One problem found was that responsiveness to placebo didn't correlate with response to psychotherapy. (Cites Lieberman's study). Patients receiving psychotherapy role-induction interview improved more. 3. Provision of learning experiences - movement of values toward those of the therapist 4. Emotional arousal. Supplies motivation for change. Cites his experiments on emotional arousal and attitude change, manipulating arousal using ether drip or adrenalin (leads to temporary attitude change). Something else besides arousal may be needed to sustain change. 5. Enhances sense of mastery, control of one's self and internal states. (a) provides conceptual scheme (b) gives experience of success 6. Provision of opportunities (and incentives) to practice**

Properties of Patient which assure success: 1. Distress 2. Earlier relationship with parent which leads to capacity to relate. (Molly Harrower's predictors) 3. To profit from specific procedures: capacity for insight for psychoanalysis.

Properties of Therapist which contribute to success:

We haven't gotten farther than Rogers' empathy, warmth, and positive regard; Whitehorn & Betz's Type A and B; and [missed reference name] activity level. He thinks success may be related to Therapist's parapsychological ability, healing power.

Physiology of hope: Placebos for dental pain lead to pain relief for some. Endorphin antagonist made pain re-occur for them

1979

Carr-Kaffashan, Lucille; Woolfolk, Robert L. (1979). Active and placebo effects in treatment of moderate and severe insomnia. Journal of Consulting and Clinical Psychology, 47 (6), 1072-1080.

This study examines the efficacy of relaxation training and a highly credible placebo in the treatment of both severe and moderate sleep onset insomnia. The placebo treatment was designed to elicit an expectation for improvement comparable with that of relaxation training. Expectancy of improvement was further controlled by informing subjects to expect improvement only after the third week of therapy, thus allowing comparisons of the treatments to be made during the counterdemand period (first 3 weeks) and the positive demand period (fourth week and beyond). Responses of severe and moderate insomniacs were similar across treatment conditions, over weeks, and in response to the counterdemand/positive demand manipulation. Only subjects trained in relaxation techniques improved significantly during the counterdemand period. The active treatment was significantly more

effective than the placebo in reducing sleep onset latency during the counterdemand period. After the introduction of positive expectancy of therapy outcome, relaxation was no longer superior to placebo. Findings are discussed in terms of the methodological difficulties inherent in controlling for subject expectancy of therapeutic effects in treatment studies of insomnia.

Snow, Lorraine L. (1979). The relationship between 'rapid induction' and placebo analgesia, hypnotic susceptibility, and chronic pain intensity (Dissertation, University of Rhode Island). Dissertation Abstracts International, 40 (n2-B), 937.

## NOTES

Found that the RIA [Rapid Induction Analgesia] was no more effective than oral placebo analgesia in relieving the pain of 30 paraplegics suffering from chronic pain syndrome. Although Snow found that the RIA was unrelated to hypnotizability when the effect of chronic pain experience was controlled, Crowley (1980) did find that hypnotizability was related to multiple chronic pain indices.

## 1978

Karlin, Robert; Mann, David; Carracher, John (1978, September). Placebo considerations in clinical hypnosis. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada. (Reprinted in part in American Psychological Association Division of Psychological Hypnosis Newsletter, April, 1979)

While the last 20 years have seen great progress in understanding factors underlying hypnotic phenomena in the laboratory, underlying process in clinical settings is much less clear. It is suggested that hypnosis, like most other psychotherapeutic techniques, derives most of its efficacy from its value as a placebo. Its assumed efficacy legitimizes high levels of therapist demand for change and increases the patient's efficacy expectations and perceived control. Conceptual distinctions are made between syndromes that should respond well to hypnotic treatment and those that should not. A rationale for the differing views of clinical and experimental workers in hypnosis is suggested. Finally, the central importance of the patient-therapist relationship is noted.

Parwatikar, Sadashiv D.; Brown, Marjorie S.; Stern, John A.; Ulett, George A.; Sletten, Ivan S. (1978). Acupuncture, hypnosis and experimental pain - I. Study with volunteers. Acupuncture and Electro-Therapeutic Research: International Journal, 3, 161-190.

An experiment was designed to evaluate the protective effects of different agents - acupuncture, hypnosis, Morphine, aspirin, Diazepam and placebo - upon experimentally-induced pain in humans. Twenty normal, healthy volunteers were subjected to cold water and tourniquet-induced pain and the protective effects of 35 minutes of hypnotic suggestion, electro-stimulation of both acupuncture points and non-acupuncture points, 10 mg/kg of Morphine, 5 grains of aspirin, 10 mg of Diazepam and a mild sugar placebo were evaluated. Data was collected on

subjective evaluation of pain, EKG, EEG, respiration, skin temperature, peripheral vascular activity and EMG. A special study was also done to evaluate the effects of all the above agents on the somatosensory evoked potentials and EEG. The data were further analyzed on the basis of hypnotic susceptibility of the volunteers. The results indicated: 1) Hypnosis, acupuncture at specific sites with electrical stimulation and Morphine Sulphate had about the same reduction in experimental pain. 2) Hypnosis produced different effects from those resulting from acupuncture stimulation on EEG. 3) Acupuncture stimulation in specific loci resulted in a latency increase in the early secondary response on somatosensory evoked potential. 4) Cold water pain was remarkably reduced after true acupuncture point stimulation. 5) Tourniquet (ischemic) pain was reduced by both hypnosis and true acupuncture site stimulation. 6) Skin temperature was significantly reduced on the side of acupuncture points (true) stimulation.

Slutsky, Jeffrey; Allen, George J. (1978). Influence of contextual cues on the efficacy of desensitization and a credible placebo in alleviating public speaking anxiety. Journal of Consulting and Clinical Psychology, 46 (1), 119-125.

This investigation was designed to determine the extent to which contextual cues mediated the effectiveness of systematic desensitization and a plausible placebo in alleviating public speaking anxiety. After participating in a public speaking situation that allowed the collection of self-report, physiological, and behavioral manifestations of anxiety, 67 subjects were randomly assigned to receive five sessions of either desensitization, "T scope" therapy, or no treatment. Each of these conditions was conducted in a context that either stressed the clinical relevance of the procedure or presented the procedure as a laboratory investigation of fear without therapeutic implications. Analysis of changes both between groups and within individuals indicated that desensitization reduced public speaking anxiety in both contexts, whereas the placebo was effective only in the therapeutic setting. The superiority of desensitization was most pronounced on the physiological variables. The results are interpreted as indicating support for a counterconditioning, rather than an expectancy, interpretation of desensitization.

1977

Berk, Stephen N.; Moore, Mary E.; Resnick, Jerome H. (1977). Psychosocial factors as mediators of acupuncture therapy. Journal of Consulting and Clinical Psychology, 45 (4), 612-619.

This study investigated a number of psychosocial variables that have been suggested as possible mediating factors in acupuncture therapy. Forty-two volunteers with bursitis and/or tendonitis of the shoulder served as subjects. All were randomly assigned to one of four treatment groups: acupuncture - positive milieu, acupuncture - negative milieu, placebo acupuncture - positive milieu, and placebo acupuncture - negative milieu. Pretreatment and posttreatment subjective pain

reports and shoulder motion studies, as well as pretreatment assessments of hypnotic susceptibility and suggestibility, were determined for each subject. Results indicated that (a) acupuncture and placebo acupuncture were equally effective in producing highly significant ( $p < .001$ ) reductions in subjective pain reports; (b) neither treatment effectively improved objective shoulder motion; (c) subjects treated in the positive milieu reported more improvement than those in the negative milieu ( $p < .053$ ); and (d) hypnotic susceptibility, suggestibility, belief in the treatment, and the satisfaction of expectations showed no relationship to treatment outcome. It is concluded that acupuncture therapy provides a powerful placebo. Treatment milieu variables warrant future study in the attempt to understand the acupuncture phenomena.

Lick, John R.; Heffler, David (1977). Relaxation training and attention placebo in the treatment of severe insomnia. Journal of Consulting and Clinical Psychology, 45 (2), 153-161.

This study compared the effectiveness of progressive relaxation training with and without a supplementary relaxation recording, which the subjects played at home, and an attention placebo manipulation in the modification of severe insomnia in adult volunteers. The results indicated that the relaxation training procedures were significantly more effective than placebo and no-treatment controls in modifying several parameters of sleeping behavior, in reducing consumption of sleep-inducing medication, and in influencing a self-report anxiety measure. The supplementary relaxation tape did not increase the effectiveness of relaxation training conducted in the clinic, and there was no difference in the efficacy of the placebo and no-treatment conditions. Physiological data gathered during the last treatment session indicated few significant correlations between reductions in arousal associated with relaxation training and treatment outcome.

MacMillan, M. B. (1977). The cathartic method and the expectancies of Breuer and Anna O.. International Journal of Clinical and Experimental Hypnosis, 25, 106-118.

Expectancies about the consequences of the suppression of behavior and about the effects of expressing emotions are proposed as sources of the "talking cure" which developed during Breuer's treatment of Anna O. and which later became known as the cathartic method. Although the argument is similar to one proposed by Ellenberger (1970, 1972) it sets out a more rational alternative to his explanation that the method was partly a creation of the mytho-poetic unconscious. The analysis of the interaction between Breuer and Anna O. makes explicit the expectancies underlying each of the steps through which the cathartic method developed and traces these expectancies to the general beliefs and the specific theoretical interests shared by them.

Orne, Martin T. (1977). The construct of hypnosis: Implications of the definition for research and practice. In Edmonston, William E., Jr. (Ed.), Conceptual and

investigative approaches to hypnosis and hypnotic phenomena (296, pp. 14-33). New York: New York Academy of Sciences.

#### NOTES

These notes are concerned with only a small part of the article.

The author discusses various ways of defining hypnosis, and then states, "In its simplest form one would define hypnosis as that state or condition which exists when appropriate suggestions will elicit hypnotic phenomena. Hypnotic phenomena are then defined as positive responses to test suggestions which on analysis all turn out to involve suggested alterations of perception or memory. The construct of hypnosis as a subjective state in which alterations of perception or memory can be elicited by suggestion is operationalized in standardized scales of hypnotic susceptibility..."(pp. 18-19). "Though it is necessary to specify responses in behavioral terms, it should be emphasized that the resulting scores validly reflect the hypnotic process only to the degree that the behavior reflects alterations in the individual's subjective experience" (p. 19).

"We would, however, be loath to conclude that hypnosis would not result in increased performance on some of the many dependent variables that have not yet been rigorously studied. For example, I find it difficult to believe that simulating subjects would calmly tolerate major surgery without benefit of anesthesia, although we have long since learned to be cautious about even such improbable possibilities" (p. 25).

"Perhaps the best clinical evidence for the subjective reality of hypnotic effects derives from the treatment of chronic pain and the use of hypnosis as an anesthetic. Though environmental contingencies certainly affect the expression of pain, the repeated choice of hypnosis as an analgesic when alternatives are readily available is difficult to explain without assuming that the anesthesia suggestions effectively alter the individual's experience" (p. 26).

[[The author also describes the transparent hallucination phenomena, source amnesia, and the disappearing hypnotist phenomena.]

Stern, John A.; Brown, M.; Ulett, George A.; Sletten, Ivan (1977). A comparison of hypnosis, acupuncture, morphine, Valium, aspirin, and placebo in the management of experimentally induced pain. Annals of the New York Academy of Sciences, 296, 175-193.

#### NOTES

1

"What general conclusions can we come to on the basis of these investigations? We conclude that hypnosis and suggestions of analgesia, morphine, and acupuncture stimulation (of LI 4, 14, and 15 on the arm exposed to painful stimulation) are effective in reducing experimentally induced pain. This is true for both a cold pressor pain-induction procedure and an ischemic pain-induction procedure. Hypnotic suggestibility does not account for the effectiveness of acupuncture stimulation, though good hypnotic Ss show better protection against pain with hypnotic suggestion and morphine.

"Good hypnotic Ss experience more pain than is true for Poor hypnotic Ss when exposed to the same pain-induction procedure. The effect is more marked for the cold-pressor than the ischemic pain procedure. Good hypnotic Ss are more responsive -- i.e., show greater reduction in pain perception -- to drugs and intervention procedures that produce significant subjective sensations (morphine and diazepam) than is true of Poor hypnotic Ss. This is not true for aspirin and placebo. Last, but not least, Ss low in hypnotic susceptibility tend to perceive painful stimuli as more painful when under the influence of diazepam as compared to the nondrug condition" (p. 192).

Wickramasekera, Ian (1977). The placebo effect and medical instruments in biofeedback. Journal of Clinical Engineering, 2 (3), 227-230.

This article defines a "placebo effect" and identifies some of its parameters in pain control and in other areas of medicine. It proposes a new model of the placebo effect and advances the hypothesis that biomedical instruments used in biofeedback studies, like drugs, can acquire and generate placebo effects. Such placebo effects can complicate the interpretation of specific experimental treatments in human clinical research in which biomedical instruments are used.

1976

Hemme, Robert; Boor, Myron (1976). Role of expectancy set in the systematic desensitization of speech anxiety: An extension of prior research. Journal of Clinical Psychology, 32 (2), 398-404.

**SUMMARY.** The influence of expectancy set with regard to therapy outcome on the effectiveness of systematic desensitization (SD) for reducing public speaking anxiety was investigated. The 7 Ss given a high expectancy set for favorable therapy outcome were informed about psychological research that indicates that SD is effective to reduce public

The 7 Ss given a high expectancy set for favorable therapy outcome were informed about psychological research that indicates that SD is effective to reduce public speaking fears. SD was administered with the standard instructions to the 11 Ss given a neutral expectancy set. This expectancy manipulation did not require deception and perhaps could be used with actual SD therapy clients. As in previous research by Woy and Efran, the expectancy set manipulation significantly modified Ss' self-report of subjective perceptions of anxiety from pretreatment to posttreatment speeches, but did not affect overt behavioral or physiological indices of anxiety. Since subjective perceptions of anxiety responses are psychologically significant behaviors, these data suggest the importance of conveying a high expectation of improvement to SD and perhaps also to other types of therapy clients. SD sessions administered to small groups of clients on consecutive days, as in this study, appeared to be as effective to reduce speech anxiety as SD sessions

administered to each client individually at 1-week intervals, as in the Woy and Efran study" (pp. 403-404).

Moore, Mary E.; Berk, Stephen N. (1976). Acupuncture for chronic shoulder pain: An experimental study with attention to the role of placebo and hypnotic susceptibility. Annals of Internal Medicine, 84 (4), 381-384.

One half of 42 Ss treated for painful shoulders received classic acupuncture, and one half received a placebo in which the needles did not penetrate the skin. Half of each of these groups was treated in a positive setting to encourage the subject, and half in a negative setting designed to keep encouragement at a minimum. All patients were independently rated for susceptibility to hypnosis. Although range of motion did not improve, the majority of patients reported significant improvement in shoulder discomfort to a blind evaluator after treatment; placebo and acupuncture groups did not differ in this respect, however. The positive and negative settings did not affect treatment outcome. In all groups, those who were not rated as highly susceptible to hypnosis tended to fail to achieve the highest levels of relief, but such differences were not statistically significant.

#### NOTES

There were 42 subjects, and they were tested with the Spiegel Hypnotic Induction Profile. "Both acupuncture and placebo proved to be effective in relieving shoulder discomfort. 69% of the total group made lower assessments of discomfort on the post-treatment rating than on the pretreatment rating" (p. 382).

"Acupuncture was not more effective than placebo in relieving discomfort, however. The average percentage of improvement among those who had acupuncture was not, statistically, significantly different from those who had placebo. Indeed, what little difference there was actually was in the opposite direction, the placebo group improving on the average somewhat more than the acupuncture group" (pp. 382-383).

"In the negative setting, however, where the subject was required to suffer in silence, acupuncture seemed to be less effective than the placebo in relieving discomfort" (p. 383).

"Although the subjects perceived that the treatment relieved their shoulder discomfort, there was no objective evidence of improvement in the shoulder as measured by change in the range of motion scores before and after treatment" (p. 383).

(The placebo was needle pricked against the skin at true site, then rapidly and lightly tapped against the surface of the skin without penetration.)

"Those who were not susceptible to hypnosis failed to experience as much relief from discomfort as those who were" (p. 383).

"The fact that acupuncture was not more successful in relieving shoulder discomfort than a sham procedure suggests that its much publicized success may be merely a powerful placebo effect" (p. 383).

Katz, Kao, Spiegel et al (1974) also found that low hypnotizables did not benefit much in terms of pain relief with acupuncture.

The reactions of 14 volunteers to electrical stimulation near the supra-orbital nerve were studied under acupuncture, placebo-acupuncture, and hypnosis. As the intensity of stimulation increased, a minimum sensation, a minimum pain, and then a maximum or intolerable pain sensation were produced. Under hypnosis the average intensity of the stimulus for producing these sensations was higher than before the trance induction. Under acupuncture and placebo-acupuncture no clear increase in current intensity was observed. Acupuncture, as well as hypnosis, did not consistently change the blood, blood pressure, pulse rate, EKG, respiratory rate, or EEG.

Aletky, Patricia J.; Carlin, Albert S. (1975). Sex differences and placebo effects: Motivation as an intervening variable. Journal of Consulting and Clinical Psychology, 43 (2), 278.

NOTES

"... the present findings would suggest that future studies of placebo effects should take into account the nature of the dependent variable and the pertinent differential sex-role expectations" (p. 278). The performance measure was a dynamometer pull task. The placebo was a jelly applied to the forearm "and alleged to relieve muscular fatigue" (p. 278). The motivational instructions were telling Subjects that "individuals in good health and with normal muscle tonus would be expected to show improved performance on the posttreatment trial" (p. 278).

Andrews, Reagan H., Jr. (1975). Placebo effects in EMG biofeedback (Dissertation). Dissertation Abstracts International, 36, 1424.

"Differential instructions were employed in a negative placebo model to alter expectancies of success in achieving criterion frontalis EMG voltage levels in 30 female subjects. The negative placebo model dictated that all subjects receive true feedback during both of two 10-minute experimental trials. On one of the two trials they were informed that feedback would be accurate, and on the other trial, that feedback would be accurate only 50% of the trial period. Data was collected for 20 subjects in a 2 X 2 Latin Square design, while 10 subjects were designated control

subjects and received high-success expectancy instructions on both experimental trials.

Pre-trial measures included administration of a standard hypnotic susceptibility scale and a pre-test subjective questionnaire. Dependent variable was the time from onset of feedback to 70% reduction of resting EMG levels of the frontalis. Significant differences were found between high and low-expectancy trials for experimental subjects. Effects were strongest on the first experimental trial and tended to diminish on the following trial. Correlation of hypnotic susceptibility scores with response latencies was not significant, but subjects' impression of their degree of relaxation during susceptibility scale administration was significantly correlated with criterion latencies. Importance of subject expectancies, instrumentation standards and implications for future studies in the biofeedback area were discussed" (p. 1424).

Berk, S. N. (1975). The mediating effects of hypnosis, suggestibility and placebo in acupuncture therapy (Dissertation). Dissertation Abstracts International, 36, 3020-3021.

"Results strongly support the contention that variables other than physiological mechanisms are involved in acupuncture therapy. It appears as if patient motivation, models, expectations of relief and the quality of the doctor-patient relationship can influence the outcomes of this ancient therapy. However, additional research is needed to confirm these findings. At present, the data seem to suggest that acupuncture therapy may be largely a placebo phenomenon" (p. 3021).

Borkovec, Thomas D.; Kaloupek, D. G.; Slama, Katherine M. (1975). The facilitative effect of muscle tension-release in the relaxation treatment of sleep disturbance. Behavior Therapy, 6, 301-309.

Sleep disturbed subjects were randomly assigned to one of four group therapy conditions: progressive relaxation with muscle tension-release, relaxation without tension-release, placebo, and no treatment. Subjects were instructed not to expect improvement until after the final (fourth) therapy session. Progressive relaxation produced significantly greater improvement in reported latency to sleep onset than the three control conditions prior to the final session and was the only group to display greater improvement than no treatment after the final session. Five month follow-up revealed further gains for the progressive relaxation group. Issues of active mechanisms, demand, and placebo are briefly discussed

Lick, John R. (1975). Expectancy, false galvanic skin response feedback, and systematic desensitization in the modification of phobic behavior. Journal of Consulting and Clinical Psychology, 43 (4), 557-567.

This study compared systematic desensitization and two pseudotherapy manipulations with and without false galvanic skin response feedback after every session suggesting improvement in the modification of intense snake and spider fear.

The results indicated no consistent differences between the three treatment groups, although all treatments were significantly more effective than no treatment in modifying physiological, behavioral, and self-report measures of fear. A 4-month follow-up showed stability in fear reduction on self-report measures for the three treatment groups. Overall, the results of this experiment were interpreted as contradicting a traditional conditioning explanation of systematic desensitization. An alternate explanation for the operation of systematic desensitization emphasizing the motivational as opposed to conditioning aspects of the procedure is discussed. Melzack, Ronald; Perry, Campbell (1975). Self-regulation of pain: The use of alpha-feedback and hypnotic training for the control of chronic pain. Experimental Neurology, 46, 452-469.

Patients suffering chronic pain of pathological origin received alpha- feedback training methods in association with prior hypnotic training. Changes in the intensity and quality of pain were measured with the McGill Pain Questionnaire. The combined procedures produced a substantial decrease in pain (by 33% or greater) in 58% of the patients during the training sessions. Both the sensory and affective dimensions of the pain were diminished. The EEG records indicated that the majority of patients learned to increase their alpha output during the training sessions. In contrast, patients who received the alpha training alone reported no decreases in pain even though they showed increases in alpha output. Patients who received hypnotic training alone also produced increased EEG alpha during the training sessions and showed substantial (though not statistically significant) decreases in pain. The results demonstrate that chronic, pathological pain can be reduced in a significant number of patients by means of a combination of alpha-feedback training, hypnotic training, and placebo effects. It is concluded, however, that the contribution of the alpha training procedure to pain relief is not due to increased EEG alpha as such but, rather, to the distraction of attention, suggestion, relaxation, and sense of control over pain which are an integral part of the procedure.

#### NOTES

The study employed 24 patients with variety of pains, divided into 3 groups randomly:

hypnosis

alpha/biofeedback

combined procedures - the only group which decreased group mean of pain significantly.

Hypnosis - 50% of patients showed decrease in pain Combined Treatment - 50% " "  
" " " " Alpha/biofeedback - None " " " " "

All patients demonstrated higher alpha levels; the authors inferred it was due to relaxation, distraction, a sense of control over pain, or direct suggestion itself.

Russell, Elbert W. (1974). The power of behavior control: A critique of behavior modification methods. Journal of Clinical Psychology, 30 (2), 111-136.

## NOTES

1:

In summarizing the effectiveness of behavior therapy the author states, "At this point there does not appear to be sufficient evidence to demonstrate that all of the effectiveness of various types of behavior therapy is produced by non-specific,

evidence to demonstrate that all of the effectiveness of various types of behavior therapy is produced by non-specific, especially placebo, effects. In fact, it is more probable that many of these techniques will be found to have elements that are not due to non-specific effects and, as such, they will be the treatment of choice for certain limited problems, such as aversive therapy for autistic children or training of the mentally retarded. Nevertheless, concerning the central issue in this monograph, it is increasingly apparent that a very large proportion of the 'power' of behavior methods is due to non-specific, suggestion or placebo effects.

"As such, this 'power' is neither behavioristic, new, nor particularly threatening. It is not new since it has been known to medicine for many decades. As Shapiro states, 'the history of both physiologic and psychologic treatment is largely the history of the placebo effect; those who forget it are destined to repeat it'. In support of the age of this problem, Shapiro also quotes from the compiler of the remedies of the Paris Pharmacologia, a century ago, 'What pledge can be afforded that the boasted remedies of the present-day will not, like their predecessors, fall into disrepute, and in their turn serve only as a humiliating memorial to the credulity and infatuation of the physicians who recommended and prescribed them'" (p. 120-121).

"The large amount of suggestion or placebo effect in behavior therapy does raise at least two vital problems. The first problem involves the ethics of using suggestion or a placebo. Is it ethical to give the patient a false or questionable explanation for the source of the effectiveness of behavior procedures? Such an explanation would be that they are based on proven scientific behavior principles when major people in the field do not believe this and evidence is mounting that the primary source of effect is suggestion. Secondly, what will be the effect on the attitude of the general public toward professional psychology when they realize that the effectiveness of psychological behavior therapy methods is primarily a matter of suggestion? Will they not consider it a modern patent medicine? The damage that could be done to the prestige of psychology might take decades to repair. JH

McReynolds, William T.; Barnes, Allan R.; Brooks, Samuel; Rehagen, Nicholas (1973). The role of attention-placebo influences in the efficacy of systematic desensitization. Journal of Consulting and Clinical Psychology, 41 (1), 86-92.

Systematic desensitization was compared with two attention- placebo control treatments - one taken from Paul and one currently devised as an elaborate, highly impressive "therapeutic" experience - and no treatment. It was hypothesized that (a) fear reductions following desensitization would be no greater than those associated with an equally compelling placebo treatment and (b) fear and control measure changes following the previously used attention-placebo treatment would

be less than those following desensitization and the present placebo control manipulations. Both hypotheses were supported, although support for the first was more consistent than for the second.

McGlashan, T. H.; Evans, Frederick J.; Orne, Martin T. (1969). The nature of hypnotic analgesia and placebo response to experimental pain. Psychosomatic Medicine, 31, 227-246.

#### NOTES

They conceptualized low hypnotizables as providing a placebo condition (p. 230). This is essentially the London-Fuhrer design in experimental situations. It is necessary that the subject be convinced s/he is capable of responding to the hypnotic condition for it to be a good control condition.

**1966**

Pollack, S. (1966). Pain control by suggestion. Journal of Oral Medicine, 21, 89-95.

#### NOTES

Studied the effects of a topical anesthetic applied prior to injection of anesthesia. Ss were 500 dental patients. Half the group received a topical and the other half received a placebo. Each half was further subdivided so that one group received suggestion that the topical would be effective and the other group was not told anything. More calm ratings were given to the suggestion group. Found that the hypnotist's suggestion was the most important factor in obtaining or failing to obtain anesthesia.

**1961**

Glass, Louis B.; Barber, Theodore X. (1961). A note on hypnotic behavior, the definition of the situation and the placebo effect. Journal of Nervous and Mental Disease, 132, 539-541.

Subjects were tested for responses to hypnotizability tests under three conditions: after 20 minute induction, after being told they would not be hypnotized but would take tests of imagination (with motivating instructions to do well), after taking a placebo pill that "would make them deeply hypnotized." Of 12 Ss who dropped in score between Session 1 and Session 2, 11 attained higher scores following placebo than during the control session; mean scores under placebo and control (5.8 and 3.7) differed significantly,  $p < .01$ . Scores were as high in the third as the first session (5.8 and 6.3 respectively).

**1959**

Conn, Jacob H. (1959). Cultural and clinical aspects of hypnosis, placebos, and suggestibility. International Journal of Clinical and Experimental Hypnosis, 7 (4), 175-185.

#### NOTES

The author traces the history of hypnosis, suggestion, and placebo, noting that popularity of hypnosis with professionals waxes and wanes over the years. When practitioners lose faith in a drug, it becomes less effective with their patients. The same holds true for hypnosis. Frequently illness is ameliorated or cured by suggestion without hypnosis.

"Hypnosis is nothing more than the suggestive, placebo effect presented in a specific inter-personal setting. It is not just a state of mind, but the end result of various psychologic processes. (2) A patient may be more suggestible when fully awake. ... Another patient may be more suggestible when asleep. There are those who respond best to suggestions in the light stage of hypnosis, while about 10% of subjects are capable of developing the deeper, somnambulistic phase" (p. 181).

#### Polygraph

1990

Wain, Harold J.; Amen, Daniel G.; Jabbari, Bahmann (1990). The effects of hypnosis on a Parkinsonian tremor: Case report with polygraph/EEG recordings. American Journal of Clinical Hypnosis, 33, 94-98.

Although Parkinsonian tremors typically disappear during sleep and are reduced during relaxation periods, the effects of hypnosis on this type of movement disorder have been generally ignored. We observed a patient's severe Parkinsonian tremor under hypnosis and monitored it with EEG and EMG studies. The patient was taught self-hypnosis and performed it three to four times daily in conjunction with taking medication. The results suggest that daily sessions of self-hypnosis can be a useful therapeutic adjunct in the treatment of Parkinsonian tremors

#### NOTES

The patient scored low on the Hypnotic Induction Profile scale of hypnotizability and was unable to experience any classical hypnotic phenomena, but was motivated to learn self-hypnosis. For self hypnosis he visualized a relaxing scene

1989

Schuyler, Bradley A.; Coe, William C. (1989). More on volitional experiences and breaching posthypnotic amnesia. International Journal of Clinical and Experimental Hypnosis, 37, 320-331.

Highly responsive hypnotic subjects, who were classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia, were compared with each other on four physiological measures (heart rate, electrodermal response, respiration rate, muscle tension)

during posthypnotic recall. Two contextual conditions were employed: One was meant to create pressure to breach posthypnotic amnesia (lie detector instructions); the other, a relax condition, served as a control. The recall data confirmed earlier findings of Howard and Coe and showed that voluntary subjects under the lie detector condition recalled more than the other three samples that did not differ from each other. However, using another measure of voluntariness showed that both voluntary and involuntary subjects breached under lie detector conditions. Electrodermal response supported the subjects' reports of control in this case. Physiological measures were otherwise insignificant. The results are discussed as they relate to (a) studies attempting to breach posthypnotic amnesia, (b) the voluntary/involuntary classification of subjects, and (c) theories of hypnosis.

#### NOTES

The authors suggest that subjects observe themselves not remembering (i.e. not reporting memories) and conclude that they therefore could not remember. Such subjects, they say, are deceiving themselves in so far as they could remember if they were to direct their attention to salient cues.

1985

Coe, William C.; Yashinski, Edward (1985). Volitional experiences associated with breaching posthypnotic amnesia. Journal of Personality and Social Psychology, 48 (3), 716-722.

Highly responsive hypnotic subjects classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia were compared during posthypnotic recall. Subjects reported their voluntariness after the experiment. Two contextual conditions were employed (2 x 2 design): a lie detector condition meant to create pressure to breach amnesia and a relax control condition. In contrast to earlier findings, the recall data showed that both voluntary and involuntary subjects breached under the lie detector condition compared with their counterparts in the relax condition; however, the degree of breaching was not great in any condition. The results are discussed as they relate to studies attempting to breach posthypnotic amnesia and characteristics of the voluntary-involuntary dimension.

1982

Schuyler, Bradley A. (1982). Further investigation of volitional and nonvolitional experience during posthypnotic amnesia (Dissertation, California School of Professional Psychology, Fresno). Dissertation Abstracts International, 44 (n6-B), 1977. (Order No. DA 8324472)

"Electrodermal responses were compared between highly responsive hypnotic Ss who were classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia. Three contextual conditions were employed: Two were meant to create pressure to breach posthypnotic amnesia (lie detector instructions alone or with feedback that Ss had

been detected as not having told all they could remember); the other provided feedback, in addition to the lie detector instructions, that Ss had told all they could remember. The recall data confirmed earlier findings of Coe and Yashinski and showed that voluntary and involuntary Ss did not differ in response to the contextual conditions. However, lie detector instructions alone did not create pressure to breach as in previous studies. In addition, electrodermal results were insignificant. The results are discussed as they relate to (a) amnesia, (b) the physiological detection of deception and physiological activation, (c) the voluntary/involuntary classification of Ss, and (d) theories of hypnosis" (p. 1977).

**Sixty college men, divided into three equal groups, each attended two induced stress sessions in which their physiological, psychological and performance reactions were measured. Their responses were compared to determine if valid stress reactions could be induced through suggestion in an altered state (in this case, hypnosis), and also to determine the validity of such reactions if the subject had never before experienced that stress situation. It was demonstrated that valid stress reactions can be induced in an individual with the aid of suggestions, especially if the real stress situation has been experienced before. If no previous experience with that real situation exists, the subject still exhibits stressful reactions; however, the closest resemblance to real stress is found in the subjective or psychological measures, less similarity is found in the physiological measures, and the least similarity is found in the performance measures.**

Distribution limited to U.S. Government agencies only; Other requests for this document must be referred to Commanding General, U.S. Army Electronics Command, ATTN: AMSEL-PP-CM-CR4, Fort Monmouth, NJ 07703. NOTES 2:**

**This document reports on a U.S. Army research project using hypnosis to collect high fidelity samples of the voice under "combat stress" conditions in the laboratory. Using hypnotic regression, combat veterans "re-experienced" their own, actual high stress combat situations. Besides subjective reports of stress levels by subjects, physiological stress measures were obtained from polygraph recordings of heart, respiration and GSR activity. The voice samples were later analyzed by spectrographic techniques to determine which factors remain invariant to identify and authenticate the speaker in a military communications situation. Hypnotic techniques were shown to be useful in establishing controlled emotional states for laboratory research purposes. (Richard Bloom)**

**1998**

**Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..**

**NOTES**

**"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy**

techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

Duhamel, Katherine N.; Difede, Joan; Foley, Frederick; Greenleaf, Marcia (1997, November). Hypnotizability and posttraumatic symptomatology after burn injury. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Washington, D. C..

#### NOTES

Investigated the relationship between hypnotizability and post traumatic stress disorder (PTSD) symptoms following burn injury, in 43 hospitalized survivors. Authors found an association between these two variables and suggest that assessment of hypnotizability might help identify post-burn patients at risk for PTSD.

1995

Holroyd, Jean (1995). Handbook of clinical hypnosis, by Judith W. Rhue, Steven Jay Lynn, & Irving Kirsch (Eds.) [Review]. International Journal of Clinical and Experimental Hypnosis, 43 (4), 401-403.

#### NOTES

"This is a book for the thinking clinician" (p. 401). "The editors are to be congratulated for making this volume much more coherent than most edited books" (p. 402). "My impression is that the book is best suited for an intermediate or advanced course on hypnotherapy, or for people who are already using hypnosis in treatment. Although there is some material on the basics of hypnotic inductions and a few introductory sample scripts for inductions, a beginners" course should

probably use a different book, or this book could be accompanied by an inductions manual. ... I recommend it very highly" (p. 403).

1994

Bloom, Peter B. (1994). Clinical guidelines in using hypnosis in uncovering memories of sexual abuse: A master class commentary. International Journal of Clinical and Experimental Hypnosis, 42 (3), 173-178.

"Joan," a clinical psychologist, requested a psychiatric consultation to determine whether hypnosis could recover accurate memories of suspected child abuse by her still living father. Are there clinical guidelines in using hypnosis in uncovering such possible memories of sexual abuse? We asked Dr. Peter B. Bloom to share his views with us.

#### NOTES

Gives case example and clinical guidelines for using hypnosis in uncovering memories of sexual abuse. 1. In medical practice, "Primum non nocere," i.e. "First do no harm." 2. "No therapist should ever, either directly or indirectly, suggest abuse outside of a specific therapeutic context--certainly not to a client who is on the phone making a first appointment!" 3. "A therapist must not jump quickly to the conclusion that abuse occurred simply because it is plausible." 4. "A therapist should never simply assume that a client who cannot remember much from childhood is repressing traumatic memories or is in denial." 5. "Remember 'a client is most vulnerable to suggestion and the untoward influence of leading questions when therapy begins to delve into painful life situations from the past, particularly from childhood.'" 6. "Therapists ... should be cautious about suggesting that clients cut off communication with their families." 7. "Therapists should reconsider the 'no pain, no gain' philosophy of treatment." 8. "The context of therapy is as important as the content." 9. "Tolerate ambiguity." (Sincerity and conviction on the part of the patient reporting abuse are not in and of themselves reason to believe the material.) 10. "Respect the current science of memory." 11. "Maintain responsibility for making the diagnosis and choosing the treatment." 12. "Pursue alternative diagnoses to account for the symptoms." 13. "Historical and narrative truth: Understand the difference."

from childhood is repressing traumatic memories or is in denial." 5. "Therapists ... should be cautious about suggesting that clients cut off communication with their families." 7. "Therapists should reconsider the 'no pain, no gain' philosophy of treatment." 8. "The context of therapy is as important as the content." 9. "Tolerate ambiguity." (Sincerity and conviction on the part of the patient reporting abuse are not in and of themselves reason to believe the material.) 10. "Respect the current science of memory." 11. "Maintain responsibility for making the diagnosis and choosing the treatment." 12. "Pursue alternative diagnoses to account for the symptoms." 13. "Historical and narrative truth: Understand the difference."

**COMMENT:** The tenet that insight is necessary for change and growth is not true. Change can occur without insight, although insight may be helpful in maintaining change once it has occurred.

**SUMMARY:** These guidelines are presented to enhance safe practice, however, clinicians should use their own judgement to determine the best path to follow with each patient.

**NOTE:** Guidelines 1, 8, 9, 10, 11, 12, and 13 are those of Peter B. Bloom. Those labeled as Guidelines 2, 3, 4, 5, 6, and 7 were taken with permission from Yapko, M. (1993 September/October). "The seductions of memory. The false memory debate." *Family Therapy Networker*, 17, pp. 30-37. All discussions, however, are those of Peter B. Bloom.

Cardena, Etzel (1994, August). Domain of dissociation. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

#### **NOTES**

Dissociation (a French term) exists when two or more mental contents are not integrated. Dissociation includes a wide variety of behaviors and experiences.

Three Concepts: 1. nonconscious or nonintegrated mental models or processes 2. alteration in consciousness when disconnection from self or environment is experienced 3. defense mechanism

Explanation of these three concepts:

1. Within nonconscious or nonintegrated mental models/processes there are three types: (a) absence of conscious awareness of impinging stimuli or ongoing behaviors (broad, vague, not useful, because we are unaware of physiological processes most of the time) (b) co-existence of separate mental systems or identities that should be integrated (Meyers, 1903, said the memorability of an act is better proof of consciousness than its complexity). Examples: dissociative amnesia (Walter Reed Hospital patient); or in hypnosis telling a person that their hand is going to begin raising on its own (c) ongoing behavior that is inconsistent with person's verbal report. May be part of #2. Example: commisurotomy patients - woman who wanted to smoke couldn't get her hand to lift cigarette to her mouth. Example of student, being criticized, breaking out into a rash while saying that she felt calm.

Often repression and dissociation are confused. When dissociation is used as in (c) above, they are indistinct; they are the same. Freud used the terms for the same thing. When we talk about a dissociated memory, it is same as repression.

2. Alteration in consciousness (disconnection from the self or environment is experienced). In this case we talk about an experiential event. Caveats: Some use it to refer to *\*any\** kind of alteration of consciousness. Braun, 1993, reported that mystical experiences are dissociative; I maintain that many people feel most in contact with the self during mystical experience. Same with drugs: it may not involve primarily separation, disengagement, from self or environment. As you listen to me, you may disengage at times. I think the only legitimate use of "dissociation" is a radical alteration of consciousness; like Tart's altered states of consciousness, like out-of-body experiences. In clinical situation, distraction or

dreaminess is usual; but if a patient disengages and starts reliving a situation, it is legitimately regarded as dissociation.

3. Defense mechanism - a theoretical construct, referring to intentional disavowing things that would cause anxiety or pain. Clinical observations of people in traumatic events, rape, people may have out of body experiences; explained as the person sending the ego somewhere else because they can't bear the pain. But, you get this separation in non-traumatic circumstances (in meditation, reverie, etc.)

**Alternative Paradigm:**

Janet's theory which explains cognitively how dissociation occurs, without necessarily proposing an intentional process.

For further elaboration of these comments, see Cardena, E. (1994). The domain of dissociation. In S. J. Lynn & J. W. Rhue (Eds.) *Dissociation: Clinical and Theoretical Perspectives*. New York: Guilford Press

Frankel, Fred H. (1994, October). On patients remembering abuse when it in fact may not have occurred. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

The concept of hidden memories has supported the profession of psychotherapy for a century. This process can only occur if there is a mechanism to support it. Bowers says, if memory is not reliably accurate, it is not reliably inaccurate either.

"Ideas passing as descriptions lead us to equate the tentative with [the factual.]" - Gould.

Three studies purporting to establish repression: 1. Briere & Comte sampled 450 adults who reported abuse. They asked, "Was there ever a time when you couldn't remember the forced experience?" How does respondent understand the question? Clients were all in therapy. 2. Herman and Schatzow (1989) "verification of abuse" study. 53 Ss in a survivor's group. Reports percentages who had no or little recall. Authors don't acknowledge that the group discussion and the attitude of therapist may have shaped the response. It is also not clear how many Ss who claimed to have "verified" their accounts were among those who had severe amnesia for the event. They could be Ss who had never lost the memory in the first place. 3. Williams interviewed women who earlier were in Emergency Rooms because of abuse being suspected. 38% did not report childhood abuse when questioned, and author concluded it was due to repression. Significant numbers of adults cannot remember things even past the age of 5.

Problem with wording of questions. Some of the women interviewed might have preferred not to report the event. This was not investigated in the study.

Loftus, Elizabeth; Polonsky, Sara; Fullilove, Mindy Thompson (1994). Memories of childhood sexual abuse: Remembering and repressing. Psychology of Women Quarterly, 18, 67-84.

Women involved in out-patient treatment for substance abuse were interviewed to examine their recollections of childhood sexual abuse. Overall, 54% of the 105

women reported a history of childhood sexual abuse. Of these, the majority (81%) remembered all or part of the abuse their whole lives; 19% reported they forgot the abuse for a period of time, and later the memory returned. Women who remembered the abuse their whole lives reported a clearer memory, with a more detailed picture. They also reported greater intensity of feelings at the time the abuse happened. Women who remembered the abuse their whole lives did not differ from others in terms of the violence of the abuse or whether the violence was incestuous. These data bear on current discussions concerning the extent to which repression is a common way of coping with childhood sexual abuse trauma, and also bear on some widely held beliefs about the correlates of repression.

#### NOTES

In previous research, it was reported that violent or incestuous abuse is particularly susceptible to repression. This study differs from previous investigations in the definition of violence. In the present study, 'violence' is defined as any act involving vaginal, oral, or anal sex. Earlier research defined 'violence' as involving sexual assault with physical injury or fear of death.

Depending on the definition of repression, a sizeable minority (31% or almost 1/5) of this sample forgot their earlier abuse for a period of time. The authors state that this suggests there is little 'robust repression' in this sample. They cannot rule out the possibility that some women who were abused still, to this day, do not recall the experience; or that some who continue to have memory loss based on organic causes, including blackouts.

The authors suggest that future research in this area use more specific questions, including assessing whether Subjects respond to statements like: "There was a time when I would not have been able to remember the abuse, even if I had been directly asked about it," or "There was a time when I would not have been able to report the abuse because I had no idea that it had even happened to me." Also, when Subjects report that a memory had emerged after a period in which they had no recall, the Experimenter should enquire about how and when the recovered memory occurred. The authors conclude that remembering abuse is more common than forgetting it.

Marmar, Charles (1994, October). Peritraumatic dissociation and PTSD. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

Following trauma there is a tendency to more dissociation and vulnerability. We completed 3 recent studies. In 1991 Spiegel and Cardena presented review that found: 1. Early childhood abuse is associated with profound dissociation. 2. Repeated abuse is more important and profound than single abuse for producing dissociation. 3. Dissociation in childhood and perhaps in adulthood has been viewed as an adaptive attempt to cope, to take distance in time, place, and person; does that confirm long term adaptation, or is it a risk factor? 4. Dissociation is not limited to childhood trauma; it occurs in adults exposed to overwhelming trauma. 5. In adults

with PTSD, there is an increase in hypnotizability, which is interesting because most Axis I disorders are associated with reduced hypnotizability.

Peritraumatic dissociation is defined as an immediate dissociative response to trauma. We developed a scale that robustly captures the phenomena. The scale has both self report and rater versions.

Authors used this measure in many studies: combat trauma, accident trauma, victims of terrorism. The scale predicts who will be a PTSD patient 5 months later, even after controlling for initial response in first week (how many symptoms they had) and for the degree of trauma.

**Study 1 (Am. J. Psychiatry, June 1994)**

Studied 251 male Vietnam Theater Veterans, mean age 41 at time of study. Had high combat exposure and high risk for PTSD. Rater version of Peritraumatic Dissociative Experiences Questionnaire was used. There was a lot of variability in response, but one underlying dimension resulted from the factor analysis (and this factor accounts for 40- 50% of the variance).

Author hypothesized that those who have a greater response to trauma will have more problems later, and would predict stress symptoms but not necessarily psychopathology. The score correlates highly with: Mississippi Scale for PTSD .51; Horowitz's scales; Impact of Events Scale (Intrusion .53, Avoidance .60); MMPI derived PTSD .42; Dissociative Experiences Scale (recall of time of event) .41; and War Zone Stress Exposure .48.

MMPI-2 clinical scales had almost no correlation with this scale (using partial r's, and controlling for MMPI-2 PTSD scores).

Prediction of PTSD case classification from this scale, after taking into consideration other predictors: War Zone Stress War Zone Stress, DES War Zone Stress, DES, PDEQ-RV Kappa is .63

You know much more about who will be a case taking into consideration the DES and DEQ than just knowing the amount of stress. Peritraumatic stress is strongly associated with PTSD but not with psychopathology.

**Study 2**

Replicated Study 1 using 77 female veterans. Females Ss were more highly educated, older, more likely to be in a health profession role (trauma was working with death and dying, exposure to sex abuse and harassment, given even less support than the males). Yet women have had a better course of recovery, though rates were the same (30% developed PTSD after return from war).

Correlation with Impact of Event Scale (Intrusion .41 and Avoidance .40), but correlations with MMPI-2 are low (and with other PTSD scales are lower than with the males). Hierarchical multiple regression models show R squared doesn't increase with DES but does with PDEQ to Intrusion (less so to Avoidance).

This study replicates the same pattern, with peritraumatic dissociation strongly related to PTSD symptoms years later, and not to general psychopathology, even after accounting for the nature of the stress and for the degree of dissociation.

**Study 3**

-trusion (less so to Avoidance).

This study replicates the same pattern, with peritraumatic dissociation strongly related to PTSD symptoms years later, and not to general psychopathology, even after accounting for the nature of the stress and for the degree of dissociation.

### Study 3

After the 1989 Loma Prieta earthquake in Northern California we studied emergency services personnel involved in the collapse of a freeway in Oakland. 1000 rescue workers were involved. The workers (police, fire personnel, paramedics, CALTRANS road workers) involved one I-880 cohort and a replication cohort, with two control groups (smaller scale incidents like attending a child drowned in swimming pool, removing someone from a wrecked auto). In all 3 samples, 90% were male.

What characteristics of the person or their exposure account for which workers go on to cope and which will later have PTSD symptoms? Predictors: IES-I IES-A IES-H M-PTSD SCL-GSI.

Variables most associated with problems 1.5 to 3 years afterward were years of experience, exposure, adjustment (measured by the Hogan Personality Inventory measure of adjustment), social support, DES, and PDEQ. Regression analyses used the best predictors first: forced exposure, adjustment, years experience, locus of control, social support. For Intrusion scores there were modest but significant increments by the DES and PDEQ; for avoidance scores, there were very significant contributions (.072 and .078).

There is a robust relationship between the DES and PDEQ and how much hyperarousal there is afterward (.104 and .110 %). DES measures a trait, PDEQ measures a state; yet the latter continues to contribute even after accounting for variance by the DES.

The PDEQ also has been found to predict among rape victims who will have PTSD. This was replicated in different cultures and different language groups.

**FUTURE DIRECTIONS.** Authors plan to examine people with moderate to high exposure after the L.A. earthquake. They gathered personality and coping style data on the rescue workers to answer the question: what characterizes those who are more vulnerable to dissociative tendencies during trauma?

There are treatment implications: given that those who develop the most profound response are the ones who will have more PTSD later, what are the implications?

Uncovering the trauma that caused the PTSD is often associated with re-dissociation There is a question of how this should be managed.

The authors will attempt to see if they can predict in advance if a person would dissociate if exposed. Do those who dissociate have more childhood abusive environments? Hypothesis: there may be an interaction of childhood trauma and combat trauma that produces PTSD.

Nash, Michael R. (1994). Memory distortion and sexual trauma: The problem of false negatives and false positives. International Journal of Clinical and Experimental Hypnosis, 42 (4), 346-362.

Logically, two broad types of mnemonic errors are possible when adult psychotherapy or hypnosis patients reflect on whether they were sexually abused or

not as a child. They may believe that they were not abused when in fact they were (false negative error), or they may believe they were abused when in fact they were not (false positive error). The author briefly reviews the empirical evidence for the occurrence of each of these types of errors, and illustrates each with a clinical case. Further, in considering the incidence, importance, and clinical implications of these errors, the author contends that clinical efficacy in no way assures that a false negative or a false positive has been avoided. A plea is made for theorists and researchers to acknowledge that both categories of errors can occur and to conduct future clinical and laboratory research accordingly.

of these errors, the author contends that clinical efficacy in no way assures that a false negative or a false positive has been avoided. A plea is made for theorists and researchers to acknowledge that both categories of errors can occur and to conduct future clinical and laboratory research accordingly.

Spiegel, David (1994, October). Acute stress disorder and dissociation in DSM-IV. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

Starting with the theme on hysteria introduced by Frankel (1994), and Cardena (1994) on trance disorder [Spiegel notes that] in the West our problem is of individuality, so fragmentation of personality is our disorder. There is cultural content in the delusions of schizophrenia, and cultural content in dissociative disorders. We have further evidence of trauma being involved in dissociation. Trauma is the experience of being made into an object, and the core problem is helplessness (not anxiety or fear), and discontinuity in experience. Dissociation permits people to retain control of their minds when they have lost control of their bodies. The discontinuity of dissociation reflects the discontinuity of experience.

Spiegel, David (1994, October). On patients not remembering abuse when it in fact may have occurred. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

False memories and false non-memories may be two sides of the same coin. What is the evidence for repression?

If people are abducted by extraterrestrials, why don't they just keep them? [Joke!] It seems counter-intuitive that people would forget important, arousing things that happen.

The three main components of hypnosis (suggestibility, absorption, and dissociation) are also aspects of memory: 1. Absorption relates to encoding (narrowing attention); also happens during traumatic events (Loftus' "gun memory" which is so clear, while they don't encode what gunman's face looks like). 2. Dissociation relates to memory storage (compartmentalization of information). Traumatized people have symptoms of dissociation, depersonalization. If you are in an unusual mental state, you may watch the event; the memory is stored without the usual network of

associations. 3. Suggestibility relates to retrieval. The way questions are asked influences one's response. But hypnosis is not an infinite influencer; the main damage to memory contributed by hypnosis is "confident errors" (McConkey).

We did research one week after the Loma Prieta earthquake, and found significant cognitive alterations, memory alterations, etc. In our sample, 1/4 of the people felt detached from their body or from the ground right after the earthquake.

Memory alterations were compared with data from other studies after other traumas. Difficulties with memory occurred in 29% of our sample.

The disorganization of memory can follow even just witnessing trauma (e.g. the recent slaying of 8 people in the law office in San Francisco) And people who witnessed the execution of Harris. They were in no danger themselves, yet the level of dissociative symptoms were as high in the former.

The Briere & Cone and Herman & Shatzow studies are based on self report of earlier trauma, and that is a problem in research. But Williams' study does have the age of people when they were abused as children; see her article in Journal of Consulting and Clinical Psychology.

#### **COMMENTS FROM THE AUDIENCE:**

Dabney Ewin: Sex abuse trauma differs from earthquakes because the abuser says, "If you tell anybody I'll kill you." This is like a post hypnotic suggestion, which is carried out compulsively when given to the victim during fear.

Dale: How do we account for the vigor in the attempts of each side to convince the other. The people who have been real victims of sexual abuse need to be able to talk with the people who are victims of False Memory Syndrome. The impact on a family is just as traumatic as the sexual abuse itself.

1993

Alden, Phyllis A. (1993, October). Hypnosis in the treatment of posttraumatic stress. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

[Author is at Grimsby Hospital in England.] Discussion of practical aspects of treatment of PTSD. Work began with Janoff-Bulman (1985) and Epstein (1990) focuses on cognitive appraisal. Affect and meaning are shunted into unconsciousness. She observes that when patients report intrusions, there are pieces missing from the memory: they recall the horror but not the positive part.

Used the following technique: Ask patient to get comfortable and imagine being in a theater; then go to a projection room where she can control all parameters; then watch herself watching a pleasant film; then the scene; then return to a seat in the theater and watch the upsetting film, freezing it; when uncomfortable, describe associations; then return to projection room where she watched film of what she imagined might have occurred--the image behind the image, that holds the affect; then going back to image and playing it through, with more comfort; then leave the theater and go into the film, into the screen, to go through the scene. Then asked patient to get back the intrusive image and go through it, which she did with comfort.

With another patient she introduced the "current" person into the image to reassure her that everything would be all right--i.e. she would survive. This is called "double dissociation method."

She also has the patient tell people in the scene what they should have done, or express anger verbally toward them, etc. Or she might have them make the intrusive imagery less threatening or amusing by introducing other imagery.

Cardena, Etzel (1993, October). Trance and possession as dissociative disorders: How exotic are they?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

Joke: "What happened to the possessed patient who didn't pay his exorcist?"

Answer: "He got repossessed."

Began with a quotation of Lagerkvist's book describing possession of a Sybil in Greek temple. Possession is part of religious experience worldwide, that he is not discussing here.

The revised diagnostic manual, ICD-10, has included "dissociative trance disorders." To diagnose this one must have either trance (narrowing awareness or focusing and stereotyped movements, behaviors) or possession trance (replacement of sense of personal identity by a new identity, with stereotyped culturally-determined behaviors or movements that are experienced as being controlled by the possessing agent), \*and\* full or partial amnesia for the event. Cardena emphasizes it doesn't need to be full amnesia.

To be diagnosed as dissociative trance disorder, the trance or possession state observed cannot be a normal part of a broadly accepted cultural or religious practice, and it must produce distress or maladjustment.

These are the most common type of dissociative disorders in non-Western cultures, e.g. 90% in India. So this diagnosis in India is not "atypical." "Non-Western" applies to 80% of the World and 1/3 of the USA population. DSM is trying to expand cultural relevance.

Also, even in the Western culture Allison and others have published cases of dissociative trance disorder, and others have described trance disorders:

Spiegel & Spiegel's Grade 5 personality is vulnerable to dissociative disorder. Hartman's chronic nightmare patients have "boundary thinness" (i.e. they are not clear if they are awake or asleep, lack separation from themselves and others). Lynn & Rhue's fantasy prone individuals, 22% of people, are vulnerable to maladjustment.

Cardena's recommended change in diagnosis of dissociation is critiqued in Transcultural Psychiatric Research Review (1992). Criticisms of the new diagnosis, published in that journal, are: 1. Culture-bound syndromes cut across Western diagnostic boundaries. 2. The diagnosis may be insensitive to the cultural context in which phenomena occur (e.g. distress may lead a person to participate in a cult of affliction) and it may require anthropological sophistication of diagnosticians or consultation with someone who has that knowledge. 2a. It may disregard considerations such as who has the power to "authorize" the phenomenon, under what circumstances, etc. [That would be true with any diagnosis however.] 3. Dissociative Trance Disorder may assume greater within and across-culture uniformity for the conditions than is warranted. 4. It may give validity to metaphysical explanations for spirit possession. [But in psychiatry we often use terms that don't take into consideration validating metaphysical explanations, e.g. "phantom limb" pain. 5. The medical model that underlies DSM is inappropriate for ontological considerations on the nature of the self. [But those with this diagnosis give us some understanding, not what the ultimate nature of the self and consciousness are. Diagnoses are pragmatic ways of dealing with problems.]

At the present time, the diagnosis of Dissociative Trance Disorder is included in the Appendix of DSM-IV.

For further elaboration of this material, see Cardena, E. (1992). Trance and possession as dissociative disorders. Transcultural Psychiatric Research Review, 29, 283- 297.

London, Ray William (1993, October). Refreshed adult memories: Abuse survivor or therapeutic victim?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

The author addresses four areas: 1. public policy 2. psychological issues 3. legal issues (evidence) 4. how to properly deal with it

A definition of sexual abuse is being applied to behaviors that for years were not considered out of bounds (e.g. entering a bathroom where someone else is). Furthermore, using the word "survivor" for abused people equates patients with

survivors of concentration camps, who do not present with repressed memories typically. National incidence of child abuse remains unclear estimates are 6 to 60% of females. In Florida, only 13% of cases reported are confirmed.

Some therapists who specialize in this area in surveys indicate that they have false beliefs regarding memory and effects of trauma.

[These represent only partial notes on a lengthy and substantial paper.]

Rhue, Judith W.; Lynn, Steven Jay (1993, October). Dissociation, childhood sexual abuse, and fantasy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL. We are reporting on part of an ongoing study, with results still being analyzed. We are looking at imagination, fantasy, and dissociation in abused and non-abused children. This focuses on the relationship between dissociation and fantasy and imagination.

For Janet, dissociation was the primary defense against trauma. [Quotes D. Spiegel also.] There is a body of research on trauma associated with the development of dissociation. 1. NIH found 97% of multiple personality patients reported trauma in childhood; 83% were sexually abused; 75% were repeatedly physically abused; 68% had both types of abuse. 2. Bliss - studied 70 MPDs and found same results. 3. Ross, Norton, and Noosney [?name] - found same results 4. Coombs & Milstein - same

The incidence of retrospective reports of abuse is much lower in other types of patients.

So, what is going on during child abuse? We wanted to look at children experiencing or who recently experienced abuse. Also looked at a children's scale of dissociation symptoms and validated other studies.

We studied 39 children referred to Ohio University College of Osteopathic Medicine; 12 had primary problem as sexual abuse (8 of whom were female). Non-abused Ss were either behavioral or adjustment disorders. 8 reported severe physical abuse. Parents concurred in presence of abuse. Physical abuse consisted of broken bones, burns, etc. Average age 9-10.

Ss were given the Beck Depression Scale, Children's Fantasy Inventory, Meyers' Children's Creative Imagination Scale, Children's Perception Alteration Scale, Figure Drawings, WISC-R, and 2-3 other measures. Research assistants administering the scales didn't know the children's diagnoses.

We found no support for the hypothesis that sexual abuse in childhood is associated with imagination, fantasy, or dissociative tendencies--not surprising considering that only 4 Ss were abused by their father or stepfather, 2/3 of Ss had fondling as the most severe abuse they had experienced; only 2 had intercourse; 2/3 were abused only 1-3 times. Sexual abuse that is not violent, severe, prolonged, or perpetrated by a parent may not lead to the same problems.

In a sample of women whose assaults were rape, only 25% reported it as rape.

On other hand, physical punishment was more reliably associated with dissociation (.47), imagination and fantasy in absorption scale (.41-.51 with question about using imagination to block awareness of punishment). Physical punishment was associated with increased dissociation.

Sample size is small and the trend is in the predicted direction, so later results may be significant.

**Conclusion:** measures of fantasy, dissociation, and imagination were correlated. Children's Perception Alteration Scale and the measures of fantasy and imagination were validated. Diverse measures of fantasy were highly correlated with one another.

We need a non-abused sample to add to this research.

The clinical sample had a higher dissociation score than Evers, Sanders, and Shostick's cutting score. We use 60 as a cutting score (for an abused sample) while they used 55.

**COMMENTS FROM THE AUDIENCE:**

**Jack Watkins:** the sexual abuse for the most part was not painful. Answer by Rhue: The group of sexual abuse cases includes very wide varieties of experiences; we need to examine that in our research. Also, trauma and the perception of trauma is an individual matter.

**Etzel Cardena:** We presented a paper at APA in which sexual abuse was a predictor of psychogenic seizures, and most important, the duration of the abuse.

**Phyllis Alden:** In a recent study in Germany, it was length of time for the abuse that predicted [dissociative symptoms?].

Spiegel, David; Koopman, Cheryl; Classen, Catherine; Freinkel, Andrew (1993, October). Dissociation, trauma, and DSM-IV Acute Stress Disorder. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

This represents a progress report on the research in our laboratory, which is different from traditional approaches that link childhood trauma to current problems. We say if there is a link between dissociation and trauma, one should find the symptoms in people who have trauma.

**Earthquake Research:**

They examined data from Loma Prieta earthquake; Stanford had \$164 million damage. Oct 1989. [Presents data that he has presented before.] There was a drop in dissociative symptoms over 4 months. McFarlane found that numbing was the best predictor of later PTSD symptoms, and we find that too.

Most trauma researchers have focused on anxiety because that is what they are interested in; they have ignored dissociative experiences, because such symptoms are designed not to be noticed.

Andrew Frankel and Cheryl Koopman studied 15 journalists who saw Robert Alton Harris' execution--volunteers who reported on the execution, to whom the event did not personally threaten. 40% reported depersonalization experiences, 2/3 felt detached or estranged from others, 27% had problems remembering everyday activities, etc. Dissociative symptoms were especially high in TV journalists, lowest in radio journalists, and in the middle range in newspaper reporters.

**Oakland Fire Research:**

Koopman & Classen looked at immediate psychopathology and later problems. They studied people of low, medium, and high exposure as defined by distance from the fire, which related strongly to both dissociative and anxiety symptoms.

There were strong relationships between the Mississippi PTSD scale scores and anxiety and dissociative symptoms (.50 and .59 respectively). People who reported recent life stress in the intervening period had higher PTSD and dissociative symptoms. The combination of initial dissociation and subsequent stress was additive in their relationships to PTSD.

People who had higher dissociation scores tended to do higher risk things (e.g., cross police barriers). This may explain how clinicians see patients who appear to get themselves re-victimized.

#### **Law Office Shooting Research:**

We followed up on the 1993 shooting of 14 people (8 fatally) in a law office in San Francisco. Survivors filled out dissociation questionnaires in the office (N = 36). They had high scores on the Impact of Event Intrusion Scale. The more they thought they or colleagues were in danger, the higher their scores on anxiety and dissociation measures and on Impact of Event scale.

#### **Dissociation Definition:**

These studies led to a project, with Etzel Cardena, in trying to revise DSM-III-R, which doesn't capture the symptoms [of post traumatic dissociation]. In DSM-IV there will be the diagnosis of 308.3 Acute Stress Disorder, characterized as: A. Same as DSMIII-R, except it doesn't require that the trauma be "unusual" B. Requires 3 of 5 dissociative symptoms. C, D, and E are classic dissociative symptoms F, G, and H are delimiting factors (e.g., causes significant impairment, length of time, not due to other factor).

Also, the multiple personality disorder (MPD) diagnosis has been changed to Dissociative Identity Disorder. The problem for these patients is not in having more than one personality, but not having one functioning personality.

Watkins, Helen H. (1993). Ego-State therapy: An overview. American Journal of Clinical Hypnosis, 35, 232-240.

Ego-state therapy is a psychodynamic approach in which techniques of group and family therapy are employed to resolve conflicts between the various "ego states" that constitute a "family of self" within a single individual. Although covert ego states do not normally become overt except in true multiple personality, they are hypnotically activated and made accessible for contact and communication with the therapist. Any of the behavioral, cognitive, analytic, or humanistic techniques may then be employed in a kind of internal diplomacy. Some 20 years experience with this approach has demonstrated that complex psychodynamic problems can often be resolved in a relatively short time compared to more traditional analytic therapies.

1992

Claridge, Karen (1992). Reconstructing memories of abuse: A theory-based approach. Psychotherapy, 29, 243-252.

The recovery of traumatic memories is an important part of therapy with survivors of abuse. This article describes a conceptual framework for memory reconstruction based on Horowitz' (1986) theory of stress response syndromes. The client's history of intrusive symptoms provides a way to anticipate the nature of the trauma, even when no memory of it exists. Ongoing intrusive symptoms are used to retrieve memory fragments, and their emotional impact is used to build the client's emotional tolerance. Emphasis is placed on preparing for memories by identifying what the client will need when the memories return, building coping skills, and beginning to restructure cognitions at the "what if" stage of remembering. Case material is used to illustrate.

Darken, Rachel (1992). Hypnosis in the treatment of survivors of sexual abuse. Australian Journal of Clinical and Experimental Hypnosis, 20, 105-110.

This paper outlines the problems of child sexual abuse and its long-term sequelae, often reaching down generations. In psychotherapy with survivors of childhood sexual abuse, hypnosis offers a flexible treatment modality and the paper focuses particularly on the use of hypnosis and self-hypnosis for the "reparenting" element of psychotherapy.

Faller, Kathleen Couborn (1992, Summer). Can therapy induce false allegations of sexual abuse?. The Advisor (Published by American Professional Society on the Abuse of Children), 5 (3), 3-6.

NOTES: "Concern about the impact of therapy on children's accounts of sexual abuse should be understood in the context of two phenomena: (1) the adult need to deny that children are sexually abused, and (2) adult identification with the alleged abuser. These phenomena operate at both individual and societal levels" (p. 3).

"Research related to impact of stressful situations on children's ability to recall provides mixed results, some studies finding children are less accurate if the event is traumatic (Peters, 1991) and others finding they are not (Goodman, Reed, & Hepps, 1985).

"Research reveals that it is rare for children to falsely allege that they have been touched in their private parts. In one study, a substantial proportion of children who experienced genital and anal touch during a physical examination by a doctor did not volunteer this information when asked general questions about the examination. The majority of children in the study revealed genital and anal touch only when they were asked specific questions like, "Did the doctor touch you there?" (Saywitz, Goodman, Nicholas, & Moan, 1991)" (pp. 3-4).

"Clarke-Stewart and her colleagues (1989) have demonstrated that children's interpretation of ambiguous events can be manipulated and altered by an authority figure who insists upon a particular interpretation (see also Lindberg, 1991)" (p.4).

"In sum, the research suggests that older children are likely to provide more complete unassisted disclosure than younger children. Younger children may need more memory cues in the form of specific questions than older children. Therapists

are much more likely to find false negatives than false positives. Finally, therapists should be aware of the possibility the child may identify the wrong person. ... Generally, however, the research indicates that concern about the contaminating effects of therapy on children's recollections of sexual abuse is exaggerated" (pp. 4-5).

"Research indicates that the proportion of fabricated reports may be higher in the divorce scenario than in other contexts (Faller, 1990; Jones & Seig, 1988). Studies suggest most false reports are made by adults, not children (Jones & McGraw, 1987; Jones & Seig, 1988)" (p. 5).

"Clinical research (Sorenson & Snow, 1991) and experience (Faller, 1988) indicate that for most children, revealing sexual abuse is a process which occurs over time. A typical pattern is one in which children begin with the least overwhelming experience and gradually disclose more and more as their accounts are accepted and believed" (p. 5).

"[In conclusion]... therapists should be aware of the findings from research on children's memory and suggestibility. This research indicates that there are vulnerabilities which should be taken into account during therapy" (p. 6).

Murrey, Gregory J.; Cross, Herb J.; Whipple, Jim (1992). Hypnotically created pseudomemories: Further investigation into the 'memory distortion or response bias' question. Journal of Abnormal Psychology, 101 (1), 75-77.

In order to study whether pseudomemories represent actual memory distortions or are a result of response bias, 60 highly hypnotizable subjects and subjects from the general population were divided into 4 experimental groups and were tested for pseudomemory manifestation after receiving a false suggestion. Of the 4 groups of subjects, 3 were offered a monetary reward as a motivation to distinguish false suggestion from the actual occurrence. Pseudomemory manifestation was found to be significantly higher among subjects not offered a reward than among subjects who were offered such a reward. The implications of these findings are discussed.

## NOTES

The article contains a review of the literature through 1989. The study tested the hypothesis that when it is important to distinguish fantasy from reality in a hypnosis experiment, subjects can do so--a position presented by Spanos and McLean (1986). They used a verifiable event to test for pseudomemory production, as in research published by McCann and Sheehan (1988). Subjects were 30 high hypnotizable and 30 unselected students.

Subjects were shown a videotape of a mock robbery scene. The next week, Groups A, B, and C heard audiotapes "to enhance memory," but in addition to motivating statements about "trying to remember" certain details, the tapes included misleading information (e.g. "Remember the color of the hat the robber was wearing" when in fact there was no hat on the robber). Subjects in these groups were 'influenced.'

"Both highly hypnotizable subject groups (Groups A and B) listened to the audiotape after being administered a 10-min hypnotic induction procedure

(modified from that of Barber, 1969). Subject Group C listened to the audiotape without hypnosis. The control group, Group D, did not listen to the audiotape and was, therefore, classified as 'uninfluenced.'

A week later subjects responded to multiple-choice and yes-no or true-false questions about the robbery scene. The yes-no question about whether the robber was wearing a hat served as the dependent variable, a measure of pseudomemory. "To motivate subjects to report the truth rather than to follow any perceived expectations of the experimental or social context, we offered subjects in Groups B, C, and D a monetary reward if they achieved the most correct answers on the quiz (according to the videotape). The reward was offered just before administration of the quiz to ensure that no collusion between the subjects could occur. Group A was not offered any such reward" (p. 76).

"The number of subjects in Group A (hypnotized, influenced, no reward) who reported the false information at posttest (12) was significantly greater than that of Group B (hypnotized, influenced, offered reward.... However, the difference in incidence of pseudomemory between Group B and the control group, Group D (not hypnotized, uninfluenced, offered reward), was nonsignificant" (p. 76).

Table 1 Incidence of Pseudomemory Per Group -----

	Group A	Group B	Group C
Accepted	12	6	7
Rejected	3	9	8

----- Note. Group A = hypnotized, influenced, not offered reward.

Group B = hypnotized, influenced, offered reward.

Group C = not hypnotized, influenced, offered reward.

Group D = not hypnotized, not influenced, offered reward.

In the Discussion, the authors wrote, "Because the only variable among these groups was the reward, a reasonable conclusion from the findings is that pseudomemories manifested by the subjects were (for the most part) not actual memory distortions. Presumably, the reward provided the subjects in Group B an incentive to 'report the truth' and a disincentive to give biased reports on the basis of the perceived expectations of the social or experimental context. Thus these data suggest that pseudomemory effects or the occurrence of the pseudomemory phenomenon among highly hypnotizable subjects can be minimized by providing a motivation to subjects to give unbiased reports.

"A major implication of these findings is that researchers should control for response bias resulting from perceived social demands or from leading test designs when they conduct pseudomemory research. Of further concern is the fact that a number of researchers contend that hypnotic interrogation of eye-witnesses can greatly facilitate the creation of pseudomemories (Levitt, 1990; Loftus, 1979; Orne, 1979; Putnam, 1979), and therefore hypnosis either should not be allowed in the courtroom or should be strictly controlled. Yet in light of our findings, response bias may be a confound in pseudomemory research, and thus researchers need to be

cautious when making inferences to specific situations from data obtained in an experimental setting.

"Despite the existence of a confound of (unmeasured) differences in hypnotizability between the two groups, there was no significant difference between Group B and the control group (Group D). This suggests that if response bias is controlled for, there may not be significant differences in manifestation of pseudomemories between highly hypnotizable subjects and subjects representative of the general population. However, further research is needed in order to address this question" (pp. 76-77).

Ofshe, Richard J. (1992). Inadvertent hypnosis during interrogation: False confession due to dissociative state; mis-identified multiple personality and the satanic cult hypothesis. International Journal of Clinical and Experimental Hypnosis, 40, 125-156.

Induction of a dissociative state followed by suggestion during interrogation caused a suspect to develop pseudo-memories of raping his daughters and of participation in a baby-murdering Satanic cult. The pseudo-memories coupled with influence from authority figures convinced him of his guilt for 6 months. During this time, the suspect, the witnesses, and all the evidence in the case were studied. No evidence supported an inference of guilt and substantial evidence supported the conclusion that no crime had been committed. An experiment demonstrated the suspect's extreme suggestibility. The conclusion reached was that the cult did not exist and the suspect's confessions were coerced- internalized confessions. During the investigation, 2 psychologists diagnosed the suspect as suffering from a dissociative disorder similar to multiple personality. Both psychologists were predisposed to find Satanic cult activity. Each concluded that the disorder was due to "programming" by the non-existent Satanic cult.

Perry, Nancy W. (1992, Summer). How children remember and why they forget. The Advisor (Published by American Professional Society on the Abuse of Children), 5 (3), 1-2; 13-16.

'My memory is the thing I forget with.' (a child's definition, cited in Grossberg, 1985, p. 60)" (p. 1).

"Unlike the simpler forms of memory retrieval, free recall is strongly age-related... the recall skills of preschool children develop gradually" (p. 2). "...in some cases, younger children can provide more accurate information than adults (Lindberg, 1991). For example, if an event is particularly salient (as sometimes happens in cases of trauma), recall may be exceptionally good (Brainerd & Ornstein, 1991; Lindberg, 1991)" (p. 13).

"Children have limited ability to use memory strategies. For this reason, children often know more than they can freely recall" (p. 13).

"The use of rehearsal as a memory strategy is almost automatic for adults. ... Ten-year-olds also commonly use rehearsal to aid memory. Young children, however, have not mastered rehearsal (Harris & Liebert, 1991).

"Another memory strategy is imagery, which involves (1) mentally picturing a person, place, or object, or (2) visually associating two or more things that are to be remembered. Children develop imagery much later than other memory strategies. Indeed, some people never learn this memory strategy (Flavell, 1977)" (p. 13).

"... stress alone may not impair memory processes. Indeed, stress can lead to arousal, heightened attention, and improved encoding (Deffenbacher, 1983). However, stress that results from intimidation may lead to either impairment in encoding or problems in recalling or reporting memories" (p. 14).

"Because the effect of suggestion on material that has been well encoded tends not to be significantly different across age groups (Cohen & Harnick, 1980), it may be that younger children's inferior performance on suggestive tasks results from inferior encoding" (p. 15).

Putnam, Frank W. (1992). Using hypnosis for therapeutic abreactions. Psychiatric Medicine, 10, 51-65.

Abreaction, the dramatic reliving of traumatic events under hypnosis, is a powerful therapeutic intervention useful in the treatment of victims of trauma. First systematically applied in World War I, abreaction coupled with psychotherapeutic processing of the recovered material is increasingly being used with victims of child abuse and chronic PTSD. Abreactions are helpful in recovering dissociated or repressed traumatic material, reconnecting missing affect with recalled material and for transforming traumatic memories. Although abreactions can be induced with medications, hypnosis is the method of choice except in acute situations where it is not possible to establish rapport. A variety of hypnotic techniques for the induction and management of abreaction are discussed, together with the indications and contraindications for their use.

Summit, Roland C. (1992, Summer). Opinion: Misplaced attention to delayed memory. The Advisor (Published by American Professional Society on the Abuse of Children), 5 (3), 21-25.

"I believe this is the time to cap a century of progress with a monumental achievement in awareness. We must cherish and develop the concept that what we don't know can hurt us. We can establish, for the first time, that our lives and even the nature of our society can be shaped by experiences so terrible that they are, in the words of Josef Breuer a century ago, 'forbidden to consciousness' (1895, p. 225). We may learn that huge chunks of oppositional thought, cruelty, perversity, helplessness, self-destruction and mental illness are derived from this hidden reservoir of suffering, and we could inspire unprecedented achievements in healing, prevention and enlightened peacemaking" (p. 21).

"We have been slow to consider the implications of dissociation for protective awareness of child sexual abuse" (p. 22).

"And we should respect the painful threat that enlightenment poses for our comforting faith in a just and fair society. We would have to consider that we may be capable as a people of hiding our most grotesque activities under the cover of

dissociation, so that we don't know we're doing it, our victims can't say it's happening, and as an outer society we will insist that no such thing could possibly exist" (p. 22).

"While it is urgently important to know that dissociation is real, it is doubly important not to endorse as accurate, in fact, details or encounters that may be part of a still unknown process of distortion" (p. 22).

"The most distinguished clinicians, the people who occupy the platform of authority as scientists and educators, are joining with those who, until now, have been recognized mainly for their adversarial positions. Now those two poles are coming together in aroused opposition to the phenomenon of delayed memory, especially when acquired in therapy with young women in their 30's, especially when those therapists lack an M.D. or a Ph.D. diploma. We face, once again, an ageist, sexist, elitist professional standoff around an issue that deserves to be explored in harmony" (p. 24).

"In California and several other states the statute of limitations has been suspended for individuals who can demonstrate delayed discovery of childhood trauma" (p. 24).

"The rush to judgment is not confined to civil litigation. There is no statute of limitations on murder" (p. 24).

"How many kids have hidden the memory of unspeakable assaults which can be unearthed years later to plunge them into courtroom testimony? How many free citizens could be sued or imprisoned by such remote discoveries? What should we do as scientists in support of or in opposition to those delayed memories?" (P. 24).

"We know that skepticism can quash the emergence of dissociated memories. Can we prove that therapeutic zeal cannot enhance such memories? Survivors who gain a clear picture of sexual assault in the climactic period of discovery tend to fade out the sharp edges as they achieve resolution and healing. The most seasoned survivors may discount the intermediate memories which once provided the impetus for their recovery" (p. 25).

**Vijselaar Joost; Van der Hart, Onno (1992). The first report of hypnotic treatment of traumatic grief: A brief communication. International Journal of Clinical and Experimental Hypnosis, 40 (1), 1-6.**

In 1813 the Dutch physicians Wolthers, Hendriksz, De Waal, and Bakker reported the hypnotic treatment of a woman suffering from traumatic grief, in which the therapist had to deal directly with the patient's spontaneous reenactments of the circumstances surrounding the death. This report, summarized in the present article, has historical value, as it is probably the first known precursor of the uncovering hypnotic approach. The original authors' views on the case are discussed, and a modern view for understanding the patient's traumatic grief and its treatment is presented.

**1991**

**Friedrich, William N. (1991). Hypnotherapy with traumatized children. International Journal of Clinical and Experimental Hypnosis, 39 (2), 67-81.**

The psychological impact of trauma can include cognitive, affective, and behavioral components. The degree to which a child is either overwhelmed by or unable to access the traumatic event can make the working through of the event in therapy difficult. Hypnotherapy is a useful modality not only for alleviating symptoms but also for uncovering the traumatic event(s) with associated affects, integrating and making sense of the experience. 4 case studies are reported to illustrate the utility of hypnotherapy with young, traumatized children.

Smith, William H. (1991). Antecedents of posttraumatic stress disorder: Wasn't being raped enough? A brief communication. International Journal of Clinical and Experimental Hypnosis, 39, 129-133.

Many rape victims, like those traumatized by war, accidents, and natural disasters, are able to recover from their ordeal with supportive, crisis-oriented treatment. For others, however, symptoms may persist and require more intensive treatment. Hypnosis allows a modulated re-experiencing and abreaction of the traumatic event that can help to provide the victim with a relieving sense of mastery, and it fosters a receptive context for reassurance and interpretation regarding the irrational or exaggerated thoughts and feelings involved. 2 case examples are presented in which earlier conflicts appeared to play a role in perpetuating the patients' symptoms. Detecting and addressing these antecedents resulted in complete alleviation of long-standing problems through relatively brief treatment using hypnosis.

Spiegel, David (1991, August). New directions in traumatic stress research. [Paper] Presented at the annual meeting of the American Psychological Association, San Francisco.

Trauma is the experience of being made into an object of someone else's rage. It is a sudden discontinuity in experience: our physical and mental state can be changed radically. The experience of loss of control is what is most horrifying, more than fear of death. Guilt, (blaming oneself) helps deny the loss of control. People who experience trauma distance from the information but the cortex maintains the traumatic memories.

Author reviewed literature on effective interventions with trauma victims. 1. Harbor & Pennebaker: Contrast how earthquake victims can talk about it but rape victims often are isolated. The importance of having someone listen raises the question of usefulness of only writing about the trauma. 2. Greenberg: Studied 103 trauma cases; employed a clever methodology, using 2 control groups (but it is difficult for the imaginary control group to be free of associating to their own traumas). I believe the health findings, but it troubles me that there were intrusions (thoughts); the control group utilization [of health services?] went up. 3. Kilpatrick: It is important not to blame the victim for being traumatized. But there may be some people who for sociological or other reasons do not get out of dangerous situations. 4. Terri Orbach: There is a process of "going public" about the trauma,

like in Alcoholics Anonymous disclosures. Trauma victims create an account and they go to someone else to tell about it.

Summary of what seems important about treatment: There are three means of working with trauma, with thinking, writing, and talking. If you just think but don't talk, assault rate goes up (Pennebaker); and if you don't talk with someone else you feel worse physically. In simply writing about the trauma, there may be an increase of mental intrusions, or avoidance. What seems to be beneficial is not just making sense to oneself about the experience cognitively, but the traumatized person must get feedback from another individual that they are not transformed as a person.

Van Der Kolk, Bessel; Van Der Hart, O. (1991). The intrusive past: The flexibility of memory and the engraving of trauma. American Imago, 48, 425-454.

Describes the work of Janet concerning narrative versus traumatic memory, dissociation, and subconscious fixed ideas. Janet (1904) believed PTSD patients suffer from a phobia for the traumatic memory. Repression and dissociation are distinguished. Contemporary concepts of memory processing and the concept of schemas are then reviewed. Finally, a model is presented about how the mind freezes some memories. Evidence for the involvement of autonomic hyperarousal, triggering, and state dependent learning in PTSD is reviewed. They conclude that helplessness and the inability of the PTSD victim to take action (psychological and physical immobilization) facilitates dissociation. Includes practical ideas for the working through of trauma.

## NOTES

Traumatic memories are triggered by autonomic arousal ... and are thought to be mediated via hyper-potentiated noradrenergic pathways originating in the locus coeruleus of the brain... The locus coeruleus is the 'alarm bell' of the central nervous system, which properly goes off only under situations of threat, but which, in traumatized people, is liable to respond to any number of triggering conditions akin to the saliva in Pavlov's dogs. When the locus coeruleus alarm gets activated, it secretes noradrenaline, and, if rung repeatedly, endogenous opioids. These, in turn, dampen perception of pain, physical as well as psychological (van der Kolk et al. 1989). These neurotransmitters which are activated by alarm affect the hippocampus, the amygdala and the frontal lobes, where stress-induced neurochemical alterations affect the interpretation of incoming stimuli further in the direction of 'emergency' and fight/flight responses" (p. 443).

Wolpe, Joseph; Abrams, Janet (1991). Post-traumatic stress disorder overcome by eye-movement desensitization: A case report. Journal of Behavior Therapy and Experimental Psychiatry, 39-43.

Post-traumatic stress disorder is an exceptionally stressful syndrome that has been extremely difficult to treat. The prognosis was recently dramatically improved by the introduction of eye-movement desensitization. This paper reports, in substantial detail, a case that was precipitated by a rape 10 years earlier, describing its

manifestations and various unsuccessful attempts to treat it: followed by a detailed exposition of the eventual, completely successful treatment by eye-movement desensitization.

**1990**

Somer, E. (1990). Brief simultaneous couple hypnotherapy with a rape victim and her spouse: A brief communication. International Journal of Clinical and Experimental Hypnosis, 38 (1), 1-5.

This paper presents a case involving a rape victim and her emotionally affected spouse. Although the assault occurred before the couple met, the husband was too upset to concentrate when the victim wanted to share her rape-related feelings, nor could he provide the much needed empathy and support. This, apparently, was due to his difficulties in handling his own rage. Simultaneous couple hypnotherapy was used to allow the victim to share her experience under conditions safe for both her and her spouse. As he imagined in trance the rape account described by his age-regressed wife, he learned to identify his emotions and experience them in a controlled manner. During subsequent sessions, the husband was encouraged to include himself in his wife's abreaction and reshape the traumatic scene for both of them. The husband's rescuing behavior and the expressions of violent anger towards the perpetrator had several positive consequences. Not only did they change the abandonment component of the victim's traumatic memory, but they also helped the husband deal in better ways with his own feelings of anger. It also provided the couple with a helpful coping mechanism they later effectively applied under different circumstances.

Spiegel, David; Cardena, Etzel (1990, October). New uses of hypnosis in the treatment of posttraumatic stress disorder. Journal of Clinical Psychiatry (Supplement), 51, 39-43.

Vietnam veterans with PTSD and those abused as children have above average hypnotizability. Hypnosis provides controlled access to memories that may otherwise be kept out of consciousness. New uses of hypnosis with PTSD victims involve coupling access to the dissociated traumatic memories with positive restructuring of those memories. Hypnosis can be used to help patients face and bear a traumatic experience by embedding it in a new context, acknowledging helplessness during the event, and yet linking that experience with remoralizing memories, such as efforts at self-protection, shared affection with friends who were killed, or the ability to control the environment at other times. In this way, hypnosis can be used to provide controlled access to memories that are then placed into a broader perspective. Patients can be taught self-hypnosis techniques that allow them to work through and thereby reduce spontaneous, unbidden, intrusive recollections.

**1989**

Cooper, Nancy A.; Clum, George A. (1989). Imaginal flooding as a supplementary treatment for PTSD in combat veterans: A controlled study. Behavior Therapy, 20 (3), 381-391.

14 Vietnam veterans suffering from posttraumatic stress disorder (PTSD) were assigned either to standard treatment (control group), or standard treatment plus imaginal flooding (experimental group). The 2 groups were closely matched on medications and combat roles and tours of duty were comparable. Experimental Ss received up to 14 sessions of flooding for a maximum of one and one-half hours per session. Self-report measures were administered at pre-treatment, post-treatment, and at 3-mo follow-up. These measures included the Behavioral Avoidance Test, the Beck Depression Inventory, and a Modified Vietnam Experiences Questionnaire. Results indicate that flooding increased the effectiveness of usual treatment, particularly in such areas as re-experiencing symptoms and sleep disturbances. However, flooding had no effect on level of depression, trait anxiety, and violence-proneness.

Eisen, Marlene R. (1989). Return of the repressed: Hypnoanalysis of a case of total amnesia. International Journal of Clinical and Experimental Hypnosis, 37 (2), 107-119.

A case study is presented of a woman suffering from global amnesia so profound that she had lost all sense of personal identity. Hypnotherapy was used to establish, through imagery, a solid inner core on which to rebuild a sense of self. From the image of a strong column on which rested a book with a golden lock (her history), to reading about other lives, books and stories were utilized to establish a safe external environment in which the reawakening of repressed memories was not longer perceived as dangerous. A discussion of relevant literature on the subjects of global amnesia, loss of personal identity, and post-traumatic stress is offered as a basis for discussing the present case.

Litz, Brett T.; Keane, Terence M. (1989). Information processing in anxiety disorders: Application to the understanding of post-traumatic stress disorder. Clinical Psychology Review, 9, 243-257.

Several of the key defining features of PTSD are symptoms that reflect problems related to perception, attention, and memory processes (hypervigilance, flashbacks, nightmares, psychogenic amnesia, and concentration difficulties). Although there have been several recent attempts to explain such phenomena through facets of cognitive psychology, little empirical work has been completed to confirm or explicate such processes in PTSD. This paper critically reviews the theoretical and empirical work done to date in the area of information processing in anxiety disorders, so as to provide a context for future empirical work to identify the specific psychological mechanisms and controlling variables responsible for symptoms of PTSD. A working theoretical model of information processing variables in PTSD is also proposed to stimulate future research in this area.

**Peebles, M. J. (1989). Through a glass darkly: The psychoanalytic use of hypnosis with post-traumatic stress disorder. International Journal of Clinical and Experimental Hypnosis, 37, 192-206.**

**A severe case of post-traumatic stress disorder stemming from consciousness (with auditory and pain perception) during surgery was treated with 8 sessions of hypnosis. Abreaction and revivification used alone initially retraumatized the patient, and her symptoms worsened. Ego-mastery techniques were then added; emphasis was placed on the role of the therapist as a new object presence to be internalized in restructuring the traumatic memory; memory consolidation and working-through techniques were instituted. The patient's symptoms abated and her condition remitted. The similarities between hypnotic and analytic work are highlighted. In addition, the case material provides a clinical example of the existence and potential traumatic effects of conscious awareness during surgery.**

**Pillemer, D. B.; White, S. H. (1989). Childhood events recalled by children and adults. In Reese, H. W. (Ed.), Advances in child development and behavior. New York: Academic Press.**

#### **NOTES**

**Authors discuss a dual memory theory. The first memory system is prominent in early childhood, and is a system in which are organized and evoked by persons, locations, and emotions. Such memories are not easily "transportable" outside the original experience. These memories are accessed through images of face and place, actions, or feelings. The second memory system begins to develop in early childhood, is verbally mediated, and stores experiences in narrative form. Such memories are accessible through verbal interaction, and can be reviewed and shared with others verbally. For a small child, to access all of a memory one would need to tap into both memory systems. The authors suggest that the first memory system continues to be available throughout one's life, especially when strong emotion was associated so that verbal cues are not attached. [This has implications for retrieval of "lost" memories using imagery-based approaches like hypnosis.]**

**Chu, James A. (1988). Ten traps for therapists in the treatment of trauma survivors. Dissociation, 1, 24-32.**

**Patients who have survived trauma, particularly those who have experienced early childhood abuse, stand out in the clinical experience of many therapists as being among the most difficult patients to treat. These patients have particular patterns of relatedness, along with intense neediness and dependency which make them superb testers of the abilities of their therapists. They often push therapists to examine the rationales and limits of their therapeutic abilities, and frequently force therapists to examine their own personal issues and ethical beliefs. A conceptual framework for understanding treatment traps is presented, along with 10 traps which these patients present, consciously and unconsciously, in the course of treatment. Included**

are traps around trust, distance, boundaries, limits, responsibility, control, denial, projection, idealization, and motivation.

**Kingsbury, Steven J. (1988). Hypnosis in the treatment of posttraumatic stress disorder: An isomorphic intervention. American Journal of Clinical Hypnosis, 31, 81-90.**

Reviews literature on hypnosis treatment for PTSD and presents a rationale, based on the type of symptoms presented (blunting vs intrusions). Case presentations are provided.

"Several types of physiological processes may underlie dissociation. State-dependent learning, in which that learned during drug-induced alterations in consciousness may only be recalled during later similar alterations, is believed to be dependent upon hippocampal mechanisms (Gerrien & Chechile, 1977). The relationship of state-dependent learning to hypnosis has remained at the level of theory (Hilgard, 1977; Rossi, 1986). A second possible explanatory construct suggests everyday experience is primarily (but not exclusively) mediated by verbal, dominant hemisphere functioning. The images and sets mediating hypnosis, PTSD, and other forms of dissociation may be mediated by analogic processing and the nondominant hemisphere (Carter, Elkins, & Kraft, 1982; Galin, 1974; Hilgard, 1977; Watzlawick, 1978)" (p.83).

**Loewenstein, R. J.; Putnam, F. W. (1988). A comparison study of dissociative symptoms in patients with complex partial seizures, MPD, and posttraumatic stress disorder. Dissociation, 1, 17-23.**

Depersonalization and dissociative symptoms have been widely reported in chronic seizure disorder patients, especially those with temporal lobe involvement and complex partial seizures (CPS). It has been theorized that development of multiple personality disorder may be related to temporal lobe pathology. We administered the Dissociative Experiences Scale (DES) to 12 male patients with severe chronic epilepsy, primarily of the complex partial type. Patients had epilepsy from 1 to 30 years. Most were being evaluated for intractable seizures occurring several times per week. DES data on the epileptic patients were compared with DES data on 9 male MPD patients and 39 PTSD patients. MPD and PTSD patients were significantly different from CPS patients in median DES scores and all DES subscale scores. MPD and PTSD patients were far more similar on the DES, although MPD patients had a significantly higher score on the dissociation/psychogenic amnesia subscale of the DES. The authors conclude that there is little data to support a relationship between MPD, dissociation, and epilepsy.

**Spiegel, David; Hunt, Thurman; Dondershine, Harvey E. (1988). Dissociation and hypnotizability in posttraumatic stress disorder. American Journal of Psychiatry, 145 (3), 301-305.**

**: The authors compared the hypnotizability of 65 Vietnam veteran patients with posttraumatic stress disorder (PTSD) to that of a normal control group and four patient samples using the Hypnotic Induction Profile. The patients with PTSD had significantly higher hypnotizability scores than patients with diagnoses of schizophrenia (N=23); major depression, bipolar disorder-depressed, and dysthymic disorder (N=56); and generalized anxiety disorder (N=18) and the control sample (N=83). This finding supports the hypothesis that dissociative phenomena are mobilized as defenses both during and after traumatic experiences. The literature suggests that spontaneous dissociation, imagery, and hypnotizability are important components of PTSD symptoms.(Am J Psychiatry 1988; 145:301-305)**

**Terr, Lenore C. (1988). What happens to early memories of trauma? A study of twenty children under age five at the time of documented traumatic events. Journal of the American Academy of Child and Adolescent Psychiatry, 27, 96-104.**

The verbal and behavioral remembrances of 20 children who suffered psychic trauma before age 5 were compared with documentations of the same events. Ages 28 to 36 months, at the time of the trauma, serves as an approximate cutoff point separating those children who can fully verbalize their past experiences from those who can do so in part or not at all. Girls appear better able than boys to verbalize parts of traumas from before ages 28 to 36 months. Short, single traumas are more likely to be remembered in words. At any age, however, behavioral memories of trauma remain quite accurate and true to the events that stimulated them.

**Venn, Jonathan (1988). Hypnotic intervention with accident victims during the acute phase of posttraumatic adjustment. American Journal of Clinical Hypnosis, 31, 114-117.**

Victims of accidents or other trauma often experience acute symptoms of confusion, disorganization, and intrusive memories. Victims can be extremely suggestible during their initial adjustment, and they readily comply with suggestions to enter hypnosis. Reframing and other hypnotic interventions can be useful in managing acute symptoms and may facilitate long-term adjustment. A case is presented in which hypnosis was successfully used with a man who was acutely distressed after accidentally killing a pedestrian. Whether the heightened suggestibility experienced during acute posttraumatic adjustment entails an increase in hypnotizability is an interesting topic for future research, and one which has theoretical import.

**1987**

**Fromm, Erika (1987). Significant developments in clinical hypnosis during the past 25 years. International Journal of Clinical and Experimental Hypnosis, 35 (4), 215-230.**

In the past 25 years, important changes have taken place in clinical hypnosis. It has become scientifically respectable as the field has moved from publishing anecdotal case reports to testing hypotheses on significant samples of patient populations. In

addition, new treatment approaches have been introduced, foremost among them hypnoanalysis of psychotic, borderline, narcissistic, and post-traumatic stress disorders, as well as hypno-behavioral methods for the treatment of habit disorders and somatic and psychosomatic diseases. The former treatment approaches combine hypnotic techniques with the newer psychoanalytic methods derived from object relations and self-theories; the latter combine hypnosis with the methods of behavioral medicine and attempt to teach the patient voluntary control over ordinarily involuntary somatic processes. In general, while formerly the therapeutic use of hypnosis involved mainly direct and indirect suggestion, in the last 25 years hypnotherapists of all persuasions have become more and more convinced of the important role imagery plays in the application of hypnosis for therapeutic purposes. Several areas of clinical application are described.

**1986**

Herman, Judith; Russell, Diana; Trocki, Karen (1986). Long-term effects of incestuous abuse in childhood. American Journal of Psychiatry, 143, 1293-1296.

Studied 2 groups of adult women with histories of incest, a nonclinical sample (n - 152) and an outpatient sample (n - 53) to investigate long-term outcomes of sexual abuse. Results indicate that Ss in the community sample reported a range of long-term effects from the incest. Most said they had recovered well from their trauma. Most Ss who had suffered forceful, prolonged, or highly intrusive sexual abuse, or who had been abused by their father or stepfather, reported long-lasting negative effects. The patient sample reported histories comparable to the most severe traumatic histories in the community sample.

MacHovec, Frank J. (1985). Treatment variables and the use of hypnosis in the brief therapy of post-traumatic stress disorders. International Journal of Clinical and Experimental Hypnosis, 33 (1), 6-14.

This paper describes treatment variables in the use of hypnosis in the brief treatment of 4 post-traumatic stress disorder cases. The number of sessions varied with the length of time between trauma and treatment, severity of stressor, and the personality of the patient. Individual differences in response to treatment are reported, as well as considerations for differential diagnosis to prevent misdiagnosis.

Stumpfe, Von Klaus-Dietrich (1985). Psychosomatic reactions of near-death experiences. A state of affective dissociation. Zeitschrift fur Psychosomatische Medizin, 31, 215-225.

The feelings of persons who had encountered life-threatening danger were analyzed and compared with the feelings of persons, who are in hypnoses or trained in autogenic training. The symptoms are widely alike. The result of the comparison is, that there exists a state of affective dissociation, which can be caused by conscious or unconscious actions

**Stutman, Randall K.; Bliss, Eugene L. (1985). Posttraumatic stress disorder, hypnotizability and imagery. American Journal of Psychiatry, 142 (6), 741-743.**

Administered a posttraumatic stress disorder (PTSD) scale, the Stanford Hypnotic Susceptibility Scale--Form C, a vividness of imagery scale, and a self-report of 313 symptoms found in 11 major psychiatric disorders to 26 Vietnam veterans to determine the relationship between posttraumatic stress disorder and hypnotizability. Ss with low or no PTSD scores had normal hypnotizability scores and normal imagery scores, whereas those with high PTSD scores had high hypnotizability scores and high imagery scores. It is concluded that either combat traumas enhanced hypnotic potential in some Ss or that Ss with excellent hypnotic potential to begin with were more susceptible to posttraumatic stress. It is suggested that some humans may revert to spontaneous self-hypnosis as a primitive coping tactic.

**1984**

**Nash, Michael R.; Lynn, Steven Jay; Givens, Deborah L. (1984). Adult hypnotic susceptibility, childhood punishment, and child abuse: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32, 6-11.**

Earlier empirical and theoretical work has suggested that there is a relationship between higher hypnotic susceptibility and severity of childhood punishment. Experiment 1 surveyed the parents of 14 extremely high and 11 extremely low susceptible Ss concerning punishment. Low susceptible Ss were found to be more frequently punished than highs; no significant differences were found on the severity measure. Experiment 2 assessed the hypnotizability of 16 adult Ss who reported being physically abused before the age of 10 and compared these scores to those of 300 adult Ss who had not reported being abused. The mean hypnotizability of abused Ss was greater than that of controls, and the distribution of their scores appeared bimodal. Limitations of both experiments are discussed and suggestions are made for future investigations.

**Brende, Joel O. (1982). Electrodermal responses in post-traumatic syndromes: A pilot study of cerebral hemisphere functioning in Vietnam veterans. Journal of Nervous and Mental Disease, 170, 352-361.**

This paper summarizes the findings of a pilot study which found a relationship between the post-traumatic symptoms of a) psychic numbing, b) intrusive recollections of traumatic events, and c) hypervigilance and lateralization of electrodermal response (EDR) measurements in six victims of psychological trauma. Hypnotically induced imagery of past traumatic events was often associated with left-sided EDR increases, psychic numbing with left-sided EDR decreases or bilateral EDR unresponsiveness, and revivifications of hypervigilant states with right-sided EDR lateralization. In several cases control of the experience of fear was associated with left- sided or bilaterally decreased EDR. These pilot study findings

support previously stated hypotheses: a) EDR obtained from an extremity reflects contralateral cerebral hemisphere functioning; b) left hemisphere functioning is associated with hypervigilance; and c) right hemisphere functioning is associated with emotions and imagery. In addition, the pilot study findings suggest additional hypotheses: a) Post- traumatic symptoms are associated with poorly controlled or integrated cerebral hemisphere functioning; b) psychic numbing and intrusive images, flashbacks, and nightmares are associated with abnormal activation, suppression, or integration of right hemisphere functioning in relationship to the left; c) aggressive behavior, hypervigilance, and character pathology are associated with abnormal activation, suppression, or integration of functioning of the left hemisphere function in relationship to the right; and d) "splitting" as a psychological defense in Vietnam veterans with Borderline Personality Disorders is associated with physiologically impaired interhemispheric integration.

#### NOTES

The authors report that previous research suggests that electrodermal asymmetry may be related to emotional factors. They further suggest that electrodermal responsiveness reflects contralateral cerebral hemispheric functioning, with lower GSR associated with higher activation of the opposite cerebral hemisphere (see Lacroix and Comper, 1979). They indicate that the right hemisphere, which is involved in experience of emotion, also is associated with depression (when there is abnormal inhibitory function of right hemisphere) and affective disorders. The left hemisphere is involved in vigilance (Dimond & Beaumont, 1974). "Based on these findings, the post-traumatic symptoms hypervigilance, anxiety, and behavior disorders appear to be associated with atypical left hemisphere activation, intrusive recollections of traumatic memories and disturbing emotional states with atypical right hemisphere activation, and psychic numbing or emotional unresponsiveness with diminished right hemisphere activation, or overactivation of the left hemisphere" (p. 354).

In this pilot study, the therapist, who used hypnosis in all but one case, interviewed the patient for 30-50 minutes, focusing on helping the S to recall experiences of a traumatic nature. The therapist was supportive when disturbing emotions were evoked, responding flexibly by monitoring S's anxiety and moving back and forth between uncovering and supportive techniques.

**SUMMARY:** "There were observably variable changes and bilateral differences in EDR within each of the six subjects in relationship to varying verbal, emotional, and imagery content, postulated to reflect contralateral hemispheric functioning. These observed changes were considered conclusive evidence of such functioning in post-traumatic states" (p. 358). "1. Lateralization of EDR to the left is associated with unpleasant emotions and traumatic imagery. ... "2. Lateralization of EDR to the right is associated with hypervigilance and aggressive outbursts. ... "3. Psychic numbing is associated with inhibition of bilateral EDRs (for example, lack of bilateral EDR activation occurred in every case at times) or with suppression of the left EDR. ... "4. General physiological arousal, a normal response to fear, is associated with increased EDRs bilaterally. ... "5. Relaxation and the subjective experience of safety and well-being, which have been reported to foster

interhemispheric integration in normal subjects ... were observed to be associated with bilaterally decreased EDR in case I, an example of a less severe post-traumatic condition, but not observed during attempts at relaxation in Vietnam veterans with more severe post-traumatic symptoms. "6. Voluntary efforts to cognitively control fear were related to left hemispheric functioning, as observed in case IV when the subject attempted to control intrusive thoughts with cognitive activity and in Case III following the revivification of a frightening event when he made a shift from the hypnotic trance state to waking cognitive activity. In both cases, such cognitive activity was associated with a decreased right-sided EDR" (p. 359).

**DISCUSSION:** "The results of this pilot study, which demonstrated frequent EDR differences between hands during subjects' recollections of or attempts to suppress recollections of prior traumatic experiences, alters the traditional belief that increased skin conductance is always a predictable physiological measurement when the electrode is placed on only one hand, as Lacroix and Comper (46) have pointed out.

"The finding of EDR lateralization is consistent with the findings of deBonis and Baque (10) who reported that the degree of anxiety determines the presence of lateralization of EDR responses, of Gruzelier and Venables (30, 32) and Myslobodsky and Horesh (53) who reported that the presence or absence of psychopathology determines the direction of the lateralized response, and of Lacroix and Comper (46) that activation of one hemisphere may suppress contralateral EDR" (p. 359).

1978

Nichols, Michael P.; Bierenbaum, Howard (1978). Success of cathartic therapy as a function of patient variables. Journal of Clinical Psychology, 34 (3), 726-8.

Treated sample of 42 patients with cathartic psychotherapy and evaluated differential effectiveness on types of patients. Patients without mental disorders experienced more emotional catharsis than all others, and those with obsessive compulsive personality disorders improved more than all others as a result of emotive treatment. Contrary to popular notions, neither women nor hysterics experienced more catharsis or improved more in cathartic therapy. Although women and hysterics may cry more easily in daily life, obsessives are apparently more able to maintain focus on unhappy experiences and are therefore able to express more emotion in cathartic therapy. Furthermore, it seems that cathartic treatment is beneficial by disrupting long-standing defenses against emotional experience, rather than by releasing stored-up affects.

Fisher, R. (1977). On flashback and hypnotic recall. International Journal of Clinical and Experimental Hypnosis, 217-235.

This essay deals with both the intra-individual and inter-individual varieties of arousal state-bound experiences. The former are labelled as "flashbacks" while the latter embrace the great fantasms and repetitive schemes, the ever re-written plots and images of literature, art, and religion.

Flashbacks are both arousal-state and stage (i.e., set and setting) bound experiences.

Flashback and hypnotic recall differ only in the ways by which they are induced. Induction methods should be distinguished from induced states on the hyperaroused perception-hallucination and hypoaroused eprception-meditation continuum. Flashbackers may be characterized by their (a) variability on perceptual-behavioral tasks; (b) tendency to minimize (or reduce) sensory input; (c) high resting heart rates; (d) hypnotizability; and, hence (e) preferential right-cerebral-hemispheric cognition; and (f) a display of EEG-alpha dominance in the resting, waking state.

## Possession

1996

Desmangles, Leslie G.; Cardena, Etzel (1996). Yearbook of Cross-Cultural Medicine and Psychotherapy, 1994. Berlin: Verlag fur Wissenschaft und Bildung. (Theme Issue: Trance, possession, healing rituals, and psychotherapy)

In this paper, we analyze trance possession in its cross-cultural, psychological and religious contexts, and describe its role specifically within Haitian Vodou and society. In contrast with the earlier analysis of spirit possession as a form of psychopathology, more recent scholarships (sic) has emphasized its import as a common and meaningful religious practice. Vodou is a syncretic religion that, for historical reasons, fused African traditions with Catholicism. In Haiti, the possessed individual plays a liminal function that bridges the sacred and the secular, and temporarily transcends the limitations imposed provided by social or economic status.

## NOTES

1994

Cardena, Etzel (1994, August). Spirit possession in Haiti. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

## NOTES

**THREE DIMENSIONS OF POSSESSION:** 1. Shift from one identity into another (e.g. substituting the everyday identity for that of a spirit) 2. Transitional (you are not having one type of identity substituted for another); involves a transition between states of consciousness (e.g. confusion, dizziness) 3. Transcendent possession - you have a human identity that is not quite there, but another identity has not taken over, like the oracle.

He disagrees with Eliade and Roger Walsh who imply that shamanism is a higher form than possession because possession is "out of control."

Flight of mind - you are able to remember and bring back the information, mostly visual/imaginal.

vs Possession - involves an embodied alteration of consciousness and, frequently, amnesia.

For further information, consult Cardena, E. (1989). The varieties of possession experience. *Association for the Anthropological Study of Consciousness Quarterly*, 5 (2- 3), 1-17.

1993

Cardena, Etzel (1993, October). Trance and possession as dissociative disorders: How exotic are they?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

NOTES

Joke: "What happened to the possessed patient who didn't pay his exorcist?"  
Answer: "He got repossessed."

Began with a quotation of Lagerkvist's book describing possession of a Sybil in Greek temple. Possession is part of religious experience worldwide, that he is not discussing here.

The revised diagnostic manual, ICD-10, has included "dissociative trance disorders." To diagnose this one must have either trance (narrowing awareness or focusing and stereotyped movements, behaviors) or possession trance (replacement of sense of personal identity by a new identity, with stereotyped culturally-determined behaviors or movements that are experienced as being controlled by the possessing agent), \*and\* full or partial amnesia for the event. Cardena emphasizes it doesn't need to be full amnesia.

To be diagnosed as dissociative trance disorder, the trance or possession state observed cannot be a normal part of a broadly accepted cultural or religious practice, and it must produce distress or maladjustment.

These are the most common type of dissociative disorders in non-Western cultures, e.g. 90% in India. So this diagnosis in India is not "atypical." "Non-Western" applies to 80% of the World and 1/3 of the USA population. DSM is trying to expand cultural relevance.

Also, even in the Western culture Allison and others have published cases of dissociative trance disorder, and others have described trance disorders:

Spiegel & Spiegel's Grade 5 personality is vulnerable to dissociative disorder. Hartman's chronic nightmare patients have "boundary thinness" (i.e. they are not clear if they are awake or asleep, lack separation from themselves and others). Lynn & Rhue's fantasy prone individuals, 22% of people, are vulnerable to maladjustment.

Cardena's recommended change in diagnosis of dissociation is critiqued in *Transcultural Psychiatric Research Review* (1992). Criticisms of the new diagnosis, published in that journal, are: 1. Culture-bound syndromes cut across Western diagnostic boundaries. 2. The diagnosis may be insensitive to the cultural context in which phenomena occur (e.g. distress may lead a person to participate in a cult of affliction) and it may require anthropological sophistication of diagnosticians or consultation with someone who has that knowledge. 2a. It may disregard considerations such as who has the power to "authorize" the phenomenon, under

what circumstances, etc. [That would be true with any diagnosis however.]  
3. Dissociative Trance Disorder may assume greater within and across-culture uniformity for the conditions than is warranted. 4. It may give validity to metaphysical explanations for spirit possession. [But in psychiatry we often use terms that don't take into consideration validating metaphysical explanations, e.g. "phantom limb" pain. 5. The medical model that underlies DSM is inappropriate for ontological considerations on the nature of the self. [But those with this diagnosis give us some understanding, not what the ultimate nature of the self and consciousness are. Diagnoses are pragmatic ways of dealing with problems.]

At the present time, the diagnosis of Dissociative Trance Disorder is included in the Appendix of DSM-IV.

For further elaboration of this material, see Cardena, E. (1992). Trance and possession as dissociative disorders. *Transcultural Psychiatric Research Review*, 29, 283- 297.

1993

Don, Norman S. (1993, October). Trance surgery in Brazil. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

Showed a videotape of a Brazilian trance surgeon, who cuts without analgesia or asepsis. Patients later report no pain, infections, etc. The healer/surgeon is believed by everyone to be in a trance state, and the body is believed to be taken over by a spiritual doctor. The people involved deny that the patient is in trance.

Ofshe, Richard J. (1992). Inadvertent hypnosis during interrogation: False confession due to dissociative state; mis-identified multiple personality and the satanic cult hypothesis. International Journal of Clinical and Experimental Hypnosis, 40, 125-156.

Induction of a dissociative state followed by suggestion during interrogation caused a suspect to develop pseudo-memories of raping his daughters and of participation in a baby-murdering Satanic cult. The pseudo-memories coupled with influence from authority figures convinced him of his guilt for 6 months. During this time, the suspect, the witnesses, and all the evidence in the case were studied. No evidence supported an inference of guilt and substantial evidence supported the conclusion that no crime had been committed. An experiment demonstrated the suspect's extreme suggestibility. The conclusion reached was that the cult did not exist and the suspect's confessions were coerced- internalized confessions. During the investigation, 2 psychologists diagnosed the suspect as suffering from a dissociative disorder similar to multiple personality. Both psychologists were predisposed to find Satanic cult activity. Each concluded that the disorder was due to "programming" by the non-existent Satanic cult.

Richeport, Madeleine M. (1992). The interface between multiple personality, spirit mediumship, and hypnosis. American Journal of Clinical Hypnosis, 34, 168-177.

#### NOTES

The author draws parallels between multiple personality disorder (dissociative identity disorder), spirit mediumship, and hypnosis. She uses historical, anthropological, and clinical perspectives. According to the author, Milton Erickson's view of multiple personality disorder was that it was not necessarily pathological, and he employed hypnosis to gain access to personalities and to transform their behavior from involuntary to voluntary actions. "Natural trance therapies in other cultures offer a new perspective for viewing the normalcy or pathology of "other selves"" (p. 168).

Spanos, Nicholas P. (1992, October). Multiple identity enactments: A social psychological perspective. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

Frequency of reports of multiple personality disorder has varied over the centuries. The diagnosis is limited now to North America; and some therapists see more than others. Contemporary cases report severe child abuse, but this was much less so at the turn of the century. The diagnosis is limited now to North America; and some therapists see more than others. Contemporary cases report severe child abuse, but this was much less so at the turn of the century.

There is an older syndrome, called demonic possession, which shares all of these characteristics. Demonic possession was diagnosed for almost 2000 years and the disorder included: secondary (demonic) selves, and the patient being amnesic during the personality take-over by a demon. The diagnosis was more prevalent during some periods (when Christianity was proselytizing but not when it was a state religion; then again in the 16th Century when Christianity was breaking up and both Catholics and Protestants had interest in it--each inspired by the other group). Demonic possession was more often found by some experts than others; and often was diagnosed as something else initially-- e.g. psychosomatic problems. Symptoms that were ambiguous were more definitive when patients were then seen by expert.

Some symptoms--convulsions, increased strength, and insensitivity to pain--were common across Europe. But in Catholic countries the possessed manifested a secondary personality: the demon, with a different voice, spoke through the person. This rarely happened in Protestant countries, where there were convulsions, amnesias, extra strength, etc. but no alter personality.

Why were there such different symptoms in Catholic and Protestant countries? The main difference was that Catholic countries used exorcism--getting information from the demon (name, when the demon entered the body, why, how long demon planned to stay). The exorcist didn't address the possessed person directly; he would

say "I'm not talking to Mary; I'm talking to the demon." If the demon didn't reply, they would use brimstone, etc. to elicit a reply.

In Protestant countries it was believed that exorcism was inappropriate, because that would mean going to the Devil for help. They used prayer and fasting, but no attempt to communicate with the Demon. Hence, in France 20 nuns had secondary personalities, whereas in Protestant Salem, none of them had secondary personalities.

Often demon possession would occur to several people, with one person saying an image is attacking someone else, and then that second person would be possessed--so people would respond to social context, experience being possessed in terms of what that meant to them. Demonic possession was maintained by the community, so it was a social phenomenon.

Reports of ritual abuse then occurred, with witches talking about mockery of the Catholic mass, etc. Modern historians say these were fantasies, and that there were no witches' Sabbaths or ritual abuse of children.

One could infer that a therapist may be carrying out a secularized exorcism when he diagnoses multiple personality disorder.

To examine the contribution of social context to the reports of alternate personalities, we conducted a series of experiments.

We experimentally studied people instructed to simulate "an accused murderer remanded for psychiatric evaluation," and to behave as a criminal would. [They were hypnotized?] We used the interview employed with hypnotized Ss calling for a different part of themselves to speak. Of these simulators, 80% reported a secondary personality, and almost 100% claimed amnesia.

We took the people who displayed a secondary personality and amnesia and gave them psychological tests. They gave different pictures on the semantic differential [for the different personalities?].

A second experiment looked at how students would develop an alter personality. They were hypnotized and age regressed "to a past life," and were told about reincarnation. We then studied those who reported a past life. For half we told them

studied those who reported a past life. For half we told them people with a past life were likely to be born of a different race, etc. (because that is rarely reported spontaneously). Those who were told this were more likely to incorporate that information in their report of a past life experience.

In a third study, we told them that people in past eras, being less enlightened, tended to punish their children more. Those given this information were more likely to report abuse than those who were uninstructed.

A fourth study looked at how a hypnotist could influence the belief that it is a real past life rather than fantasy. They varied what Ss were told: Group 1 was told reincarnation is real. Group 2 was told reincarnation is fantasy. Group 3 was not told anything.

The first group reported a stronger belief that it was real than fantasy. (Oddly, the neutral group was nearly as high.) The Fantasy group had lower mean rating for credibility.

Hughes, Dureen J.; Melville, Norbert T. (1990). Changes in brainwave activity during trance channeling: A pilot study. Journal of Transpersonal Psychology, 22, 175-189.

## NOTES

Authors studied 10 people known trance channels--all had been channeling for more than one year. Used an anthropological field method. Electrode was placed only on left occipital (O1) area, referenced to left ear. Calculated difference between each S's pre- trance and trance EEG beta percentages, for alpha and theta percentages also.

Basically, the pre-trance versus trance sums of differences scores were greater than the post-trance versus trance sums of different scores for each of the three frequency bands--indicating a residual of the trance state. There were large, statistically significant increases in amount and percentage of beta, alpha and theta brainwave activity, and some suggestion of a pattern. The large amount of beta differentiates these Ss from what has been observed with meditators (increases in alpha and theta). Among the Subjects, large amounts of beta activity were recorded continuously throughout the trance period and were coupled with large amounts of high amplitude alpha and theta (relative to the pre- and post-trance states).

The authors compare these results to older hypnosis literature. They conclude that the trance channeling state may be a distinctive state characterized by a particular EEG profile that differs from that found in certain meditative states, hypnotic states, various pathological states, or the waking states of the trance channel Subjects who participated in the study. Authors also liken the differences seen between trance and non-trance states of these Subjects to the differences seen for different alter personalities among people diagnosed with Multiple Personality Disorder.

**DISCUSSION.** The foregoing research suggests that the trance channeling state, as measured in the current study, is characterized by large, statistically significant increases in amount and percentage of beta, alpha and theta brainwave activity. There appear to be definite neurophysiological correlates to the trance channeling state, and furthermore there is some evidence that these correlates may be patterned. This pattern might be provisionally compared to those associated with other altered states of consciousness.

Barnier, Amanda J.; McConkey, Kevin M. (1999). Hypnotic and posthypnotic suggestion: Finding meaning in the message of the hypnotist. International Journal of Clinical and Experimental Hypnosis, 47 (3), 192-208.

High hypnotizable subjects were asked a question before, during, and after hypnosis and were given a suggestion before, during, or after hypnosis to rub their earlobe when they were asked this question. In this way, the experiment placed a question that required a verbal response in contrast with a suggestion that only sometimes required a behavioral response. Subjects were more likely to respond behaviorally when the question was associated with the suggestion but more likely to respond verbally when the question was a social interaction; furthermore, the likelihood of subjects responding behaviorally and/or verbally shifted across the tests with the changing message of the hypnotist. The findings highlight hypnotized subjects' attempts to interpret the hypnotist's communications and their ability to resolve ambiguity in the nexus of those messages in a way that promotes their hypnotic behavior and experience.

1997

Barsby, Michael (1997). Hypnosis in the management of denture intolerance. In Mehrstedt, Mats ; Wikstrom, Per-Olof, (Eds.) (Ed.), Hypnosis international monographs : Number 3 : Hypnosis in dentistry (pp. 71-78). Munich Germany: M.E.G.-Stiftung.

Intolerance of dentures may have dental or psychological causes. It is within the latter group of patients, provided that they are genuinely motivated to wear a denture, that the use of hypnosis may be helpful. The importance of careful patient assessment and exploration of appropriate treatment strategies with the patient is emphasised. Principles of treatment including relaxation, controlled breathing, visual imagery and reframing are described. All of these techniques may be used in conjunction with conditioning / desensitisation and a gradual progression to denture wearing.

1995

Matthews, William J.; Isenberg, Gail L. (1995). A comparison of the hypnotic experience between signing deaf and hearing participants. International Journal of Clinical and Experimental Hypnosis, 43 (4), 375-385.

This study compared the hypnotic responsiveness of 17 hearing and 34 deaf individuals, all of whom received visual induction and hypnotic suggestions via some form of signing. The comparison between deaf and hearing participants was analyzed on five dependent measures: (a) the Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C); (b) participants' individual item performance; (c) overall trance depth; (d) a rapport scale; and (e) a resistance scale measuring attitudes of participants toward the hypnotist. Although all participants showed at least a moderate level of hypnotic responsiveness, the data did not indicate a significant main effect between deaf and hearing participants on any of the dependent measures. However, there was a tendency ( $p < .08$ ) for hearing participants to show a greater hypnotic responsiveness than deaf participants. Additionally, there was a significant difference between all the signing participants combined when compared to the norming population on three

items of the SHSS:C. Clinical and theoretical implications of these data are discussed.

Lynn, Steven Jay; Weekes, J. R.; Neufeld, U.; Ziuney, O.; Brentar, J.; Weiss, F. (1991). Interpersonal climate and hypnotizability level: Effects of hypnotic performance, rapport, and archaic involvement. Journal of Personality and Social Psychology, 60, 737-743.

Designed to extend research by McConkey and Sheehan, they tested 24 hypnotizable and 21 un hypnotizable Ss in high interpersonal/high rapport (including education about misconceptions about hypnosis, eye contact, and friendly self-disclosure) and low interpersonal/low rapport testing contexts. Overall, hypnotizable Ss were more responsive to hypnosis, rated the hypnotist more positively, and experienced greater involuntariness and archaic involvement than un hypnotizable subjects. However, results provide support for the hypothesis that low hypnotizable Ss are particularly sensitive to variations of the hypnotist's interpersonal behavior. Only low hypnotizable Ss' objective and subjective hypnotic performance on the SHSS, Form C, was enhanced by hypnotist behavior designed to optimize rapport. Hypnotizable Ss' behavior was stable across testing contexts.

NOTES

1:

"There are several different ways to classify the model that is expounded in this chapter. One may view it ... as an individual-differences model of hypnosis, because it emphasizes the significance of intragroup differences in the pattern of hypnotic performance. Alternatively, one may view it as a phenomenologically based model.... Invariably, however, single categories fail to do justice to the nature of theories, and hence it is perhaps wisest to view this theory as a means of exploring particular hypotheses about hypnotic phenomena that focus primarily on the meaning of suggestion as perceived by susceptible subjects. This model focuses, in a way that most other theories do not, on the motivational implications of the cognitive involvement of the susceptible subject in the events of the hypnotic setting. It offers a variant of contextual theories of psychological functioning, but is experiential in its emphasis rather than simply behavioral" (p. 537).

Coe, William C. (1990). Are the Conclusions Valid? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 237-239.

NOTES

1:

NOTES: The authors confounded variables, e.g. hypnotic susceptibility and monetary incentive (in Study IV), and Study IV was different from the other 3 studies, so that any differences/similarities between these studies can't be attributed to susceptibility level, degree of incentive, or interaction between them.

A simulator design would clarify why 50% of Ss in Study IV did not resist and lost \$100; also, postexperimental interviews focusing on Ss' reasons for resisting or not resisting would be helpful. Did nonresisters actually believe that they would receive \$100 for resisting?

The Subject population was not homogeneous in occupation, and students are financially poorer than others--which would affect incentive strength. Were those who resisted the ones who could use the money the most?

Small sample sizes obviating statistical tests is a problem. Coe nevertheless evaluates 4 variables in terms of the 'power' of their effects on hypnosis: 1. Susceptibility level. Studies I, II, and III all show correlations between hypnotizability and compliance with resistance, suggesting that high

hypnotizables are not as susceptible to resistance manipulation; however across studies, highs in one study seem to comply at the same rate as lows in another study, and as many as 50% of high hypnotizables in the strong incentive (\$100) study were able to resist suggestions. 2. View of the Hypnotist. Coe states that one can't evaluate the question with the data given. One would need an experimental condition that would also create a negative view of the hypnotist, as all samples tended to view the hypnotist positively. 3. View of Resistance Instructor. Again, one would need a research design that separates the effects of hypnotic susceptibility from effects of Ss' views of the resistance instructor. "Nevertheless, Study IV suggests that for high susceptibles the view of the resistance instructor has little effect. Three resisters viewed him as positive, whereas the other three viewed him as negative; further, nearly all of the nonresisters viewed him as neutral" (p. 238). 4. Degree of Incentive. This too was confounded with susceptibility level, as "the higher value was only offered to the very high susceptibles in study IV. Half of them took it, half did not" (pp. 238-239).

Coe also remarks that "the expectational effects on subjects of being in an experiment have not been addressed adequately. It is possible that the experimental paradigm as currently presented is incapable of providing an unambiguous answer to the question of coercion. In naturalistic settings subjects may react quite differently than they do when they know they are participating in an experiment" (p. 239).

## NOTES

1:

This chapter is a reprint of an article published in the American Journal of Clinical Hypnosis in 1987. It provides a conceptual framework for understanding psychotherapy processes in the context of a hypnotic state. Based on empirical and theoretical considerations, the author identified nine changes occurring with hypnosis: changes in attention and awareness, imagery, dissociation, reality orientation, suggestibility, mind-body interactions, initiative or volition, availability of affect, and relationship. "This chapter proposes that hypnotherapy exploits hypnotic phenomena-- takes advantage of them--in the service of standard therapy endeavors" (p. 125).

Smith, Alexander (1990). The hypnotic relationship and the holographic paradigm. American Journal of Clinical Hypnosis, 32 (3), 183-193.

The holographic paradigm is a recently constructed model of consciousness derived from neuropsychology and quantum physics. It views the processing of mental forms as occurring within the context of a part/whole relationship, where the identified part exists within the code of the whole. In this paper I have applied this paradigm to the hypnotic relationships, viewing the hypnotic process as an undulation of form and transitional states and proposing the holographic paradigm as a cutting edge to understand the curative processes in hypnosis.

## NOTES

1:

The proposed model represents a synthesis of neuropsychology and quantum physics.

"Based on precise neuroanatomical and neurophysiological processes, Pribram was able to account for a distribution of memory across the brain in its entirety. This occurs not within each neuron, but between them. Graded waves of neural potentials, rather than neural impulses, accounted for the structure of interference patterns (Pribram, 1982, p. 32)" (p. 185).

"Pribram then set out to answer these implied questions: What if there is no world of objects 'out there?' What if the world as we know it is a hologram itself? This search led him to David Bohm's work on the quantum theory.

"Bohm's (1980) world view, based upon study of light waves, consists of a primary reality that remains enfolded (within the frequency domain) and unfolded reality (the world of 'objects' and images).

Appearances or objects and images are abstractions reconstructed from the frequency domain" (p. 185).

"A holographic interpretation resets the therapy relationship as a shared partnership: 'The sharing emphasizes the whole of which a partner holds a part, but the holographic paradigm makes it clear that each partner holds not just a part, but the whole because each part contains the whole' (Zinkin, 1987, p. 18)" (p. 186).

"Pribram (1983) seems to suggest, in a similar vein, that the unconscious and consciousness are 'opponent processes' of implicate and explicit orderings. Citing Matte Blanco's (1975) concept of unconscious processes as infinite sets (of opponent emotional states, for example), he considers the process relationship between conscious and unconscious: 'Conscious intelligence is manifest when circumscribed sets can be appropriately partitioned into reasonably unambiguous categories. When behavior is guided by sets of variables which cannot be readily partitioned--variables which show opponent characteristics--we are apt to conclude that behavior is based on intention or that unconscious processes are at work' (Pribram, 1983, p. 10)" (p. 187).

"Tart's (1967) procedure of mutual hypnosis resulted in such an overlapping of experiential detail between participants that the startling, consensually derived reality became too much to tolerate" (p. 187).

"It is possible that during hypnosis, at some point the therapist and patient's organizations of consciousness in some way literally and not metaphorically cross into a wave length or plane in which there is neither reality nor fantasy but the enfolded- implicate-primary reality that is mutually shared? If so, how would these wave length resonances be determined? What would this mean for various psychopathological states?

"To answer these questions we may be catapulted into a whole rethinking of just what hypnosis is in connection to repression, to developmental capacities to form self and object images, and to the shifts to more advanced levels of adaptation. In particular, the hologram will become perhaps a means of exploring this challenging advance, if it can bring the hypnotic relationship more squarely into focus.

"The expansion and contraction of conscious awareness, as a holistic process between therapist and patient within the context of the trance, may provide us with more precise clues to understand altered states of consciousness, rather than the other way around" (p. 191).

Matheson, George; Shu, Karen L.; Bart, Catherine (1989). A validation study of a short-form hypnotic-experience questionnaire and its relationship to hypnotizability. American Journal of Clinical Hypnosis, 32, 17-26.

NOTES

1:

Investigated the validity of a 16-item scale inquiring about hypnotic experience, drawn from the Hypnotic Experience Questionnaire developed by Kelly (1985) to measure components of hypnotic experience. We administered the HEQ-S and the Harvard Group Scale of Hypnotic Susceptibility: Form A (HGS: A) to 198 students. Factor analysis of the scale produced three stable principal components accounting for 70% of the data variance: Dissociation/Altered State (DAS), Rapport (RAP), and Relaxation (REL). Subscales representing these three factors and a composite measure, "General Depth," were constructed. Subscale correlations with HGS: A scores were highest for the DAS subscale (.69) and lowest for REL (.41). Applications of the HEQ-S in clinical and research use are considered.

Using the phenomenological studies and theories of J. R. Hilgard (1979) and Shor (1962), Kelly (1985) constructed the Hypnotic Experience Questionnaire (HEQ), a 47- item scale designed to demonstrate the existence of five factors of the hypnotic experience. These factors included dissociation/altered state, relaxation, rapport, visual imagery, and a negatively correlated factor of cognitive rumination measuring the amount of anxious self-reflective, and interfering thought. A composite scale, General

Depth, was also derived to provide a summary measure of the subjective quality of the hypnotic experience. The HEQ was developed as a research instrument.

The HEQ-S was administered immediately after Ss completed the Harvard response record. Items were responded to on a 5-point Likert scale ranging from one (No, none or not at all) to 5 (Yes, a great deal, or almost completely).

Rønnestad, Michael Helge (1989). Hypnosis and autonomy: A moderator analysis. International Journal of Clinical and Experimental Hypnosis, 37, 154-168.

The study focused on autonomy as a moderator variable in the prediction of subjectively reported hypnotic depth. Ss in the experimental part of the study were 56 undergraduate psychology and education majors classified as either high or low in autonomy. Ss who were equated on capacity for absorption were individually administered 1 of 3 hypnotic inductions: an authoritarian induction, a permissive hetero- induction, or a self-hypnosis induction. The study had a double-blind design. The data suggest that situational manipulation has greater impact on low than on high autonomy Ss. Individual-difference variables such as absorption, have greater impact on hypnotic depth for high than for low autonomy Ss. The data indicate that the hypnotic behavior of high autonomy Ss is more likely to be self-congruent and less likely to be demand-congruent. A factor-analytic inquiry of absorption confirmed the importance of affective/regressive capacity for hypnotic functioning for high autonomy Ss. The study supported the alternate-path perspective of hypnosis.

## NOTES

1:

There is very little research on autonomy and hypnosis. The authors cite studies showing only a modest relationship between hypnotizability and locus of control.

In this study, 176 students were assigned to the high autonomy group if they were in the upper 1/3 of two of 3 autonomy scales (Rotter's Locus of Control Scale, the Inner-Directedness Subscale of the Shostrom Personal Orientation Inventory, and the Autonomy subscale of Jackson's Personality Research Form) and not in the lower 1/3 of the third scale. Ss were designated as low autonomy if the obverse obtained. This procedure yielded 27 high and 29 low autonomy Ss.

Ss were hypnotized with one of three inductions: authoritarian with many motor items (Barber Suggestibility Scale), permissive with mostly imagery (Barber & Wilson's Creative Imagination Scale), or guided self-hypnosis with mostly imagery (taken from Fromm et al, 1981). After hypnosis, Ss rated their own hypnotic depth on a 1-10 scale, and their perception of E or the procedure as authoritarian and directive. Ss' attitude, expectations, motivation, and experienced effortlessness were measured. E rated Ss for pre-hypnosis rapport and post-hypnosis rapport.

The results indicated that there was no difference in hypnotizability level between high and low autonomy Ss. The correlation between effortlessness of experience and hypnotic depth was high for low autonomy Ss (.51) but not significant for high autonomy Ss (.12). In general the two groups were very similar in terms of mean scores on most variables. The differences appeared in the correlations between self-reported hypnotic depth and the other variables. For low autonomy Ss correlations were not significant between depth and pre-hypnotic variables (rapport-pre, absorption, expectation) but for highs the same correlations were significant (rapport-pre .47, absorption .54, expectation .48).

But for post-hypnosis variables, low autonomy Ss had significant correlations between depth and the two variables measured from post-hypnosis interviews (perceived authoritarian/directiveness .40, effortlessness .51) and the highs did not have significant correlations. The multiple correlation between these variables and depth was  $R = .28$  for low autonomy Ss (with no contribution from rapport-pre) and  $R = .72$  for high autonomy Ss, with absorption contributing most. The more they perceived the induction as authoritarian or directive, the greater depth reported by low autonomy Ss. Although low and high absorption Ss did not differ on the Absorption Scale, absorption predicted hypnotic depth better for the highs.

The author divided the Absorption Scale into four rational factors: Affective/Regressive, Perceptual/Cognitive, Dissociative, and Mystical. Low and high autonomy Ss scored at approximately the same level on these categories, but correlations between these categories and depth for low and high autonomy Ss were somewhat different. (See Table.)

**Correlations between Categories of Absorption and Hypnotic Depth for Low and High Autonomy Ss**

Absorption Category	Low Autonomy	High Autonomy	All Ss
Affective/Regressive	.14	.56**	.33**
Perceptual/Cognitive	.25	.33*	.29*
Dissociative	.32*	.57**	.47**
"Mystical"	.07	.16	.11

In their discussion, the authors note that one might assume that high autonomy Ss would be less affected by variations in hypnosis procedures than low autonomy Ss. The differences found in depth scores for these two groups were supportive of this expectation. "Fluctuations in subjectively reported depth scores for low autonomy Ss only, clearly suggest autonomy to be a moderator variable" (p. 163). Moreover, the results indicate "that high autonomy Ss in comparison to low autonomy Ss are more likely to express their inner dispositions, such as absorption and expectation, in the hypnotic setting. High autonomy Ss may be more reflective of and attuned to individual predisposing characteristics and less influenced by situational demands. ... the hypnotic behavior of high autonomy Ss is more likely to be self-congruent and less likely to be demand-congruent. Low autonomy Ss, however, are more likely to be demand congruent and less likely to be self-congruent. The latter finding was suggested both by the significant F ratio for low autonomy Ss across treatments, and also by the stronger relationship found for this group between depth and how authoritarian/directive they perceived the procedure to be" (p. 163).

[Paradoxically, among low autonomy Ss an authoritarian approach yields less depth but greater suggestibility (higher hypnotizability scores).] "The tendency for low autonomy Ss to have a higher behavioral score on the authoritarian procedure is consistent with Tellegen's (1979) assumption that there are two pervasive dimensions in current hypnotizability measures--a compliance dimension and a true hypnotic responsiveness dimension. According to Tellegen, motor items may be more saturated with compliance, while cognitive items may be more saturated with true hypnotic responsiveness. The BSS has a motor emphasis, and the higher behavioral scores for the low autonomy group of Ss may be interpreted as an expression of compliance.

"In addition to the inner-directedness and self-congruence hypothesis of why autonomy may be a moderator variable, another possible explanation is related to accuracy of self-perception. The intercorrelational and multiple regression data showed repeatedly that a stronger relationship existed between prehypnotic variables and hypnotic depth for high autonomy than for low autonomy Ss. The relational capacity, as tapped by the rapport-pre variable, absorption, which may be conceptualized as a personality trait; and expectation, a cognitive variable, were all related to depth for high autonomy Ss. For low autonomy Ss, none of these variables were individually related to depth. Differences in Ss' accuracy of self-reporting may explain this. According to ego-psychology theory, highly individuated Ss, with clear self-other differentiation and congruence in self-perception, are better able to make accurate statements about themselves. The self-assessments of Ss with low differentiation capability may be less accurate and possibly more affected by demand characteristics and response set. In other words, their self-assessments have more error. The generally lower correlations for the low autonomy Ss may reflect this" (p. 164).

"A report of subjectively reported hypnotic depth following CIS and the self-hypnosis scales may reflect clarity of imagery, while a report of depth following BSS may reflect experiences of kinesthetic/bodily changes" (p. 165).

1989-1990

Spanos, Nicholas P.; Flynn, Deborah M.; Niles, Judy (1989-90). Rapport and cognitive skill training in the enhancement of hypnotizability. Imagination, Cognition and Personality, 9 (3), 245-262.

The role of interpersonal rapport in facilitating the enhancements in hypnotizability produced by cognitive skill training was examined in two experiments. In Experiment 1 low hypnotizable subjects either received skill training or passively oriented training that was designed to facilitate rapport with the trainer without teaching subjects how to generate the responses called for by test suggestions. Subjects in the two treatments reported equivalently high levels of rapport with their trainer, but only those given skill training attained large gains on two hypnotizability posttests. Subjects given passive training did not differ from untreated controls at posttesting. In Experiment 2 subjects received skill training under conditions designed to either heighten or minimize rapport with the trainer. Those in the high rapport condition showed large hypnotizability gains on both posttests, whereas those in the low rapport condition failed to differ from no treatment controls in the regard. Our findings indicate that high rapport is not sufficient for producing training-induced enhancements in hypnotizability. However, the absence of such rapport may interfere with subjects' learning and applying skills that can enhance hypnotizability.

1988

Lynn, Steven Jay; Weekes, John R.; Matyi, Cindy L.; Neufeld, Victor (1988). Direct versus indirect suggestions, archaic involvement, and hypnotic experience. Journal of Abnormal Psychology, 97 (3), 296-301.

This study examined the effects of direct (Harvard Group Scale of Hypnotic Susceptibility; Shore & Orne, 1962) versus indirect (Alman-Wexler Indirect Hypnotic Susceptibility Scales; Pratt, Wood, & Alman, 1984) suggestions on archaic involvement (Nash & Spinler, in press) with the hypnotists, objective responding, and subjective involvement and involuntariness ratings, when the scales were administered in all possible combinations (direct/indirect, N = 61; indirect/direct, N = 61, direct/direct, N = 57; indirect/direct, N = 95), across two sessions. At the initial testing, subjects who received indirect suggestions reported a greater emotional bond with the hypnotist and increased fear of negative appraisal than subjects who received direct suggestions. Repeated testing resulted in response decrements on measures of objective responding, subjective involvement, and involuntariness that were paralleled by diminished involvement with the hypnotist. The most stable relation between scales was evident when scales were defined as direct hypnosis across both sessions. Although direct and indirect suggestions produced comparable effects in the first session, in the second session, direct suggestions fostered greater subjective involvement and feelings of involuntariness.

Diamond, Michael Jay (1987). The interactional basis of hypnotic experience: On the relational dimensions of hypnosis. International Journal of Clinical and Experimental Hypnosis, 35, 95-115.

The ubiquitous interactional basis of hypnosis remains neglected and poorly understood. Vignettes from clinical practice are research are presented to illustrate the significance of hypnotic relational factors and their internal representations. A descriptive theoretical framework is formulated enumerating 4 relational dimensions: (a) transference phenomena in which previous object relationships are enacted; (b) a goal-oriented working alliance comprised of "rational" and "irrational" expectations about the efficacy of hypnotic procedure and its participants; (c) a symbiotic or fusional alliance in which the hypnotist is experienced as a purely internal figure; and (d) a realistic contemporary relationship. Each dimension is considered as it subjectively operates within hypnosis, and a case example is employed to compare the psychotherapeutic operation of these dimensions in waking and hypnotic contexts. Implications of the interactional framework are discussed and further empirical and clinical directions suggested.

1987

Gfeller, Jeffrey D.; Lynn, Steven Jay; Pribble, W. Eric (1987). Enhancing hypnotic susceptibility: Interpersonal and rapport factors. Journal of Personality and Social Psychology, 52 (3), 586-595.

This research supported the hypothesis that hypnosis can be thought of as a set of potentially modifiable social-cognitive skills and attitudes. A low-interpersonal- training treatment devised by Gorassini and Spanos (1986) was compared with a treatment designed to modify not only cognitive factors but also to augment rapport with the trainer and diminish resistance to responding (high-interpersonal training). Fifty percent of the initially un hypnotizable subjects in the high-interpersonal condition tested as being highly susceptible to hypnosis (high susceptibles) at posttest on the Harvard Group Scale of Hypnotic Susceptibility (Shor & Orne, 1962); 25% of the un hypnotizable subjects in the low-interpersonal condition responded comparably. Eighty-three percent of the medium-susceptibility (medium susceptibles) subjects tested as being highly susceptible at posttest in both conditions. Practice-alone control subjects' performance was stable across testings. The study was the first to demonstrate that treatment gains generalize to a battery of novel, demanding, suggestions (generalization index) that have been found to differentiate highly susceptible subjects from un hypnotizable simulating subjects. The importance of rapport was evidenced by the finding that rapport ratings paralleled group differences in hypnotic responding and that rapport correlated substantially with susceptibility scores at posttest and with the generalization index. Whereas initial hypnotizability scores correlated significantly with retest susceptibility scores, initial hypnotizability failed to correlate significantly with the generalization index.

#### NOTES

1:

On p. 593 one could get the impression that S's feelings of rapport may result from success in the hypnotic experience.

Holroyd, Jean (1987). How hypnosis may potentiate psychotherapy. American Journal of Clinical Hypnosis, 29, 194-200.

Hypnotherapy is defined as doing psychotherapy in the hypnotic state. This article reviews cognitive, affective, and motivational changes associated with hypnotic trance, attempting to demonstrate how the hypnotic state might influence ordinary psychotherapy processes. Nine characteristics of trance probably potentiate psychotherapy: (1) changes in attention and awareness, (2) imagery enhancement, (3) increase in dissociation, (4) decrease of reality orientation, (5) increase in suggestibility, (6) increased accessibility of mind-body interactions, (7) diminution of initiative resulting in a sense of nonvoluntariness, (8) increased availability or manipulability of affect, and (9) development of a fusional relationship (rapport). This article touches upon the psychotherapeutic implications of these hypnosis attributes.

Diamond, Michael Jay (1986). Hypnotically augmented psychotherapy: The unique contributions of the hypnotically trained clinician. American Journal of Clinical Hypnosis, 28 (4), 238-247.

In the last century, psychotherapists trained in clinical hypnosis have made a number of unique contributions to the psychotherapeutic endeavor, particularly in the areas of psychotherapeutic theory, technique, and practice. Nine factors indexing the contribution of hypnotherapists are discussed. They are: 1) communication focus; 2) maximizing expectation and belief; 3) mind-body emphasis; 4) handling of resistance; 5) employing trance phenomena; 6) using archaic levels of relationship; 7) stressing healthy, adaptive ego functions; 8) using therapist trance; and 9) permitting responsible creativity. Each factor is considered as it pertains to hypnotic technique and phenomena as well as how it is manifested in clinical treatment.

Kelly, Paul James (1985, November). The relationship between hypnotic ability and hypnotic experience (Dissertation). Dissertation Abstracts International, 46 (5), 1690-B.

This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experiences were: dissociation, the experience of involuntariness, altered state effects, such as perceptual alterations and diminished reality sense rapport, transference-like involvement with the hypnotist, and relaxation. A 47-item scale, the Hypnotic Experience Questionnaire was developed to measure types of hypnotic experience. It was given to 484 subjects and then to a subsample of 272 students. When the scale was factored, four stable factors emerged: Nonconscious/Trance, Rapport, Relaxation, and Cognitive Rumination. A Group Profile Scale was also developed to measure students and when it was factor analyzed four factors were extracted: Hallucinations and Fantasies, Amnesias and Post-Hypnotic Compulsions, Motor Inhibition, and Direct Motor Suggestion. "Two statistical approaches were used to investigate the connections between hypnotic ability and hypnotic experience . Canonical analysis was used to identify the main relationships between hypnotic ability and hypnotic experience and factor analysis was used to explore the relationship among measures of hypnotizability and hypnotic experience. Two canonical variates from the canonical analysis were significant. The first variate was characterized by a dissociative-imaginative involvement process, and the second variate tapped a rapport-social compliance process. "When 25 variables, representing components of hypnotic ability and hypnotic experience, were factored, five factors were extracted. Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. The results of the factor analysis suggested that dissociative experience and altered state experience are related to hypnotic ability but rapport and relaxation are not. "The results of study, taken as a whole, suggest that relaxation and rapport may happen in the hypnotic situation, but neither experience is related to the condition of being hypnotized in any essential way. The results suggest that the hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. From a theoretical point of view, the results strongly supported Hilgard's theory, partially supported Shor's theory, and failed to support Edmonston's theory" (p. 1690).

1984

Frauman, David C.; Lynn, Steven Jay; Hardaway, Richard; Molteni, Andrew (1984). Effect of subliminal symbiotic activation on hypnotic rapport and susceptibility. Journal of Abnormal Psychology, 93 (4), 481-483.

L. H. Silverman's subliminal symbiotic activation paradigm (Silverman, 1982) was used to manipulate unconscious affective factors in hypnosis to determine whether gratification of symbiotic fantasy would enhance hypnotic susceptibility and rapport with the hypnotist. Seventy-two male undergraduates were divided into two groups matched for susceptibility (high, medium, low). The experimental group received symbiotic, MOMMY AND I ARE ONE, subliminal stimulation via tachistoscope in a double-blind design. The comparison group received a psychodynamically neutral stimulus, PEOPLE ARE WALKING. Following subliminal stimulation, subjects were hypnotized individually. Projective tasks that indexed rapport with the hypnotist and the mother were administered during hypnosis. Rapport was also measured by rated intimacy of self-disclosure topics and by valence of topics selected to disclose to the hypnotist. A significant multivariate group selected more positively valenced topics to disclose on. The effect for symbiotic activation on hypnotic susceptibility was not quite significant ( $p < .056$ , two-tailed).

## NOTES

1:

2350, Frauman, Lynn, Mare, & Kvaal, 1992 NOTES: [Paper presented by Lynn.] A number of observations and conclusions are based on literature reviews done with Brentar (British Journal of Experimental and Clinical Hypnosis; Chapter in Rhue, Lynn, & Kirsch [Eds.] Handbook of Clinical Hypnosis) and 15 years of training students in hypnotherapy. Some of this may seem elementary to some of you.

For half a century there have been reports of negative effects after hypnosis: minor, serious, transient, and chronic. Clinicians need be as wary (but no more wary) of negative effects in hypnosis as in other therapies. There are more negative effects in clinical situations than non clinical situations.

Therapists must be prepared to recognize negative effects and intervene.

Too often hypnosis is seen as a technique divorced from psychotherapy. The hypnotist must be a competent psychotherapist. What makes you a good therapist will make you a good hypnotherapist.

There should be careful assessment of the client for: 1. those with history of unusual experiences following anesthesia or drugs 2. those with a history of dissociation

People may recapitulate a previous bad experience with anesthesia, based on the unusual physiological feelings. The dissociative client must be stabilized before using hypnosis. Depressed clients may also have problems, with the imagery becoming dysphoric. Those vulnerable to psychotic decompensation, with paranoid or borderline character structures, must be evaluated carefully. A lot depends on your comfort zone in therapy.

Life experiences with parents and authority figures may also play into the reaction.

Many clients, and experimental Ss, are ambivalent about hypnosis. This ambivalence must be acknowledged and one must work with the ambivalence before proceeding. One may: - explain hypnosis - reframe in terms of self hypnosis or relaxation - explain as a state of awareness with full consciousness - offer active induction which is just as effective as the passive induction - do induction with eyes open

Research clearly shows that Subjects can monitor events outside the framework of a suggestion--especially if you suggest they can do so with ease.

We do not use ideomotor suggestions because they aren't necessary. We tell them to open their eyes and communicate with us during hypnosis.

We always assess their feelings about hypnosis, have them have a fantasy about what hypnosis would be like, do an informal semantic analysis of the descriptors clients use (and then reframe them), inquire about previous experiences with counseling and psychotherapy, and do a mental status. Don't make assumptions. We want to know about early life experiences to know about transference and form an alliance.

Hypnosis procedures employed must have explicit informed consent (cf MacHovic book), which also provides opportunity to demystify the experience. Our research shows the great majority of Ss find it relaxing, invigorating. Even perceptual distortions can be created without hypnosis. Can create confidence by sharing the research information on hypnosis.

Elicit cooperation with easier suggestions, then use graded suggestions. We want to titrate the demands on clients, move at a pace that keeps anxiety low, promote self efficacy and mastery through ... [missed a few words] and graduated tasks.

Carefully monitor clients for frowns, lack of attention, etc. It is important to ask them what they are experiencing. Rarely, a client appears unable to talk, in which case the therapist can offer hypotheses to the hypnotized client.

Don't terminate hypnosis if there is a problem (Orne also says this); instead, offer reassurance to explore/release the feelings. It is beneficial to work through what is being experienced. There is a somewhat higher risk of emotional reactions with age regression or induced dreams. We simply tell people they can tell us at any time about what they are experiencing, without going through any ritual.

When we give suggestions about amnesia, we ask what they would like to remember and suggest that they forget what they would like to forget. The usual permissive suggestion doesn't work; find out what it is, exactly, that they want to forget and then devise strategies for it. Follow for 2 weeks after any abreactive experience that may have occurred. Let them know they can contact you.

Forceful suggestions to abandon symptoms can promote resistance and the therapist may generate negative transference. (See their chapter in book edited by Rhue, Lynn, and Kirsch, *Handbook of Clinical Hypnosis*, published by the Amer Psychological Association.)

Kelly, Paul James (1984, December). The relationship between hypnotic ability and hypnotic experience. Newsletter of Division 30, Psychological Hypnosis, of the American Psychological Association, 5.

This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experience were: dissociation, the experience of involuntariness; altered state effects, such as perceptual alterations and diminished reality sense; rapport, transference-like involvement with the hypnotist; and relaxation. A sample of 230 students was given the HGSHS:A, a group version of the SHSS:C, and the Hypnotic Experience Questionnaire (Kelly, 1984), a 47-item multidimensional scale of hypnotic experience. Items were taken from these tests to form 11 hypnotic ability variables (Positive Hallucinations, Dreams and Regressions, Post- Hypnotic Compulsions, Amnesia (HGSHS:A), Amnesia (SHSS:C), Arm Rigidity, Arm Immobilization, Other Motor Inhibitions, Head Falling, Moving Hands Together, and Hand Lowering). Fourteen hypnotic experience variables were also formed (Generalized Dissociative Effects, Dissociative Inhibition, Trance, Unawareness, Transference-like Involvement, Trust, Friendliness, Physical Relaxation, Mental Relaxation, Imagery Presence, Imagery Vividness, Imagery Detail, Self Consciousness, and Analytic Thoughts). The 25 variables were intercorrelated and factored with principal axis factoring. Five factors with eigenvalues greater than 1 were extracted and rotated to varimax criteria. These factors, which accounted for 54.4 percent of the variance, were called: Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. Hypnotic ability variables loaded significantly on three of the factors (Imaginative Involvement, Ideomotor Response, and Cognitive Inhibition) and these three factors also tapped some aspect of altered state experience and/or dissociative experience. It was concluded therefore that dissociative experience and altered state experience are related to hypnotic ability. The remaining two factors, Rapport and Relaxation, showed significant loadings only for rapport variables and relaxation variables, respectively. Neither of these two factors were related to any of the traditional measures of hypnotic ability or to the experience of dissociative effects or altered state effects. The results of this study suggest that rapport and relaxation may happen in the hypnotic situation but neither experience is related to the condition of being hypnotized in any essential way. The hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. The results also raise questions about Edmonston's (1981) theory that relaxation is the essence of hypnotic responsiveness. The finding that the experience of relaxation is unrelated to hypnotic ability is more congruent with Hilgard's (1977) view that relaxation is a nonhypnotic process.

## NOTES

1:

This is an abstract of an unpublished Ph.D. dissertation, University of Waterloo, 1984. It won the American Psychological Association Division 30 award for Best Student Paper at the 1984 APA Convention.

Lynn, Steven Jay; Nash, Michael R.; Rhue, Judith W., Frauman, David C.; Sweeney, Carol A. (1984). Nonvolition, expectancies, and hypnotic rapport. Journal of Abnormal Psychology, 93 (3), 295-303.

: Prior to hypnosis, subjects were informed either that hypnotizable subjects can resist motoric suggestions or that such control does not characterize good hypnotic subjects. During hypnosis, susceptible and simulating subjects received countering suggestions involving inhibiting suggestion-related movements. Susceptible subjects' responses were found to be sensitive to prehypnotic normative information. There was a corresponding tendency for reports of involuntariness to be sensitive to the expectancy manipulation. Furthermore, subjects were able to feel deeply hypnotized and to rate themselves as good subjects yet concomitantly experience themselves as in control over their actions when normative information supported this attribution. Reports of suggestion-related sensations but not imaginative involvement were associated with movements in response to countersuggestion. Simulators were unable to fake susceptibles' reports of sensations and involuntariness. However, for all subjects, movements paralleled expectancies about appropriate response, supporting the hypothesis that involuntary experiences are sensitive to the broad expectational context and are mediated by active cognitive processes. Also, rapport with the hypnotist was found to be a factor. Susceptible subjects with highly positive rapport resolved hypnotic conflict, in part, by achieving a compromise between meeting normative expectations and complying with the hypnotist's counterdemand.

1983

Diamond, Michael Jay (1983). Therapeutic indications in applying an innovative hypnotherapeutic technique: The client-as-hypnotist. American Journal of Clinical Hypnosis, 25 (4), 242-247.

A novel hypnotic induction technique is described wherein the client reverses roles and serves as hypnotist for the therapist willing to enter trance. Indications and contraindications in employing innovative hypnotherapeutic interventions are considered in terms of the therapeutic goals and context, patient-therapist interaction, and patient as well as therapist characteristics. Benefits provided by the technique to the client, client-therapist interaction, and therapist respectively are briefly discussed. The specific methodology of this technique is described according to seven steps: (1) permission request: (2) client observation: (3) session structure: (4) client confidence: (5) therapist trance: (6) feedback: and (7) subsequent utilization. Relevant clinical examples are provided.

Fourie, David P. (1983). Width of the hypnotic relationship: An interactional view of hypnotic susceptibility and hypnotic depth. Australian Journal of Clinical and Experimental Hypnosis, 11 (1), 1-14.

Efforts have been reported in the hypnosis literature to correlate measurements of hypnotic susceptibility with measurements of hypnotic depth. Not only have the findings not been consistent, but recently the whole issue of hypnotic susceptibility and depth and their measurement has become controversial, as evidenced by Weitzenhoffer's (1980) and Hilgard's (1981) statements. This paper offers a different perspective on the issue and introduces the concept of the width of the hypnotic relationship as a useful indication of the degree of hypnotic involvement. The width of the hypnotic (paradoxical) relationship refers to the scope of the relationship within which certain involuntary behaviors can occur. The larger the number of such behaviors that are possible within the bounds of the paradoxical relationship, the wider that relationship shall be considered to be. This is an investigation of the relationship between the width of the relationship and the depth of hypnosis experienced. The SHSS: A, as a measurement of the width of the relationship, was applied to 18 volunteer female subjects. A 10-point self-report scale was applied before and after a procedure to widen the relationship. The correlations between the SHSS: A scores and both sets of self-report scores were positive and significant, as expected. The widening procedure had a definite deepening effect, but it seemed possible that this effect was not uniform.

Silverman, Lloyd H.; Lachmann, Frank M.; Milich, Robert H. (1982). The search for oneness. New York: International Universities Press.

NOTES

1:

This book summarizes research on preconscious activation (subliminal psychodynamic activation) of fantasies of oneness, following tachistoscopic presentation of words like, "Mommy and I are one." It represents an attempt to test and validate, through experimental investigation, psychoanalytic concepts. The authors show how such fantasies can improve psychosocial adaptation for people with varying kinds of psychopathology.

1980

Sheehan, Peter W. (1980). Factors influencing rapport in hypnosis. Journal of Abnormal Psychology, 89 (2), 263-281.

The phenomenon of countering expresses the tendency of some highly susceptible subjects to favor the intent of the hypnotist when placed in a conflict situation where social influences of another kind dictate an alternative response. The present research explored the parameters of this objective index of involvement with the hypnotist to investigate the special relevance of rapport processes to the hypnotic setting. Rapport was manipulated in five different experiments, varying either the warmth or genuineness of the hypnotist. It was predicted from transference theorizing that countering would decrease in the negative context and increase in the positive one. Results confirmed predictions for highly susceptible subjects tested in the former context but not the latter. In the negative setting, subjects were inhibited in their rate of countering, but maintained their previous level of response to the hypnotist when rapport was facilitated. Results highlighted the relevance of interpersonal processes to theorizing about hypnosis.

1976

Hodge, J. R. (1976). The contractual aspects of hypnosis. International Journal of Clinical and Experimental Hypnosis, 24, 391-399.

No generally accepted theory of the essence of hypnosis is currently available, nor are any specific responses uniquely associated with hypnosis. A necessary, though not sufficient, aspect of hypnosis involves the subject's preconceived expectations and selective attention to a series of agreements ("contracts") which are developed between patient and therapist before the induction, during the induction and deepening procedures, and during the operational phase. These contracts may be either implicit or explicit, but they can be identified in all hypnotic interactions. The skillful therapist will make the contracts explicit by defining, at least in general terms, what he expects. If the patient agrees, i.e., "sings the contract," he is likely to comply with suggestions.

1969

Blatt, Sidney J.; Goodman, John T.; Wallington, Sue Ann (1969). Is the hypnotist also being hypnotized?. International Journal of Clinical and Experimental Hypnosis, 17, 160-166.

Noted that 2 hypnotists had cognitive and affective experiences similar to those expected in the S as a function of the hypnotic manipulation when they were conducting hypnotic inductions. Though the hypnotists may have been responding to the mood tone of the Ss or responding on the basis of their expectations about the effect of the hypnotic manipulation, it seemed equally possible that the hypnotists may have experienced mild forms of the trance state they had induced in their Ss. These observations seemed consistent with prior notes of such a phenomenon. This phenomenon has important implications for the clinical and experimental use of hypnosis and for concepts such as transference and countertransference, empathy, demand characteristics, and E bias. Suggestions are

made for the systematic evaluation and study of this phenomenon. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Small, Maurice M.; Kramer, Ernest (1969). Hypnotic susceptibility as a function of the prestige of the hypnotist. International Journal of Clinical and Experimental Hypnosis, 17, 251-256.

Administered 40 undergraduates the Harvard Group Scale of Hypnotic Susceptibility, Form A. On the basis of the scores, Ss were divided into 20 "better" and 20 "poorer" Ss. A wk. later Ss were rehypnotized by a tape recording of the above induction procedure. On the 2nd induction, 1/2 of the Ss were told that the hypnotist on the tape was an expert; the other 1/2 were told the hypnotist was a novice. Results indicate that only the better Ss given novice instructions showed a change (decrement) in hypnotic susceptibility. 1964

Black, Stephen (1964). Mind and body. London: Kimber.

NOTES

1:

Defines psychosomatic disease as one that responds to psychotherapy. Believes only 5% are highly hypnotizable, that hypnosis is learnable in 1/2 hour, that hypnosis is not a useful treatment for psychosomatic disorders because you can't use interpretation [of unconscious]. The 'unconscious' is "... a complex of informational systems derived from such primaevial mechanisms" (p. 133). "Primaevial mind is involved in these mechanisms of genetics and immunology" (p. 133). "There is thus a 'somatic mind' which is unconscious and presumably without any means of verbalization of experience--and a 'cerebral mind' which is conscious" (p. 133). The dividing line is not clear.

Rapport is discussed on pp. 160, 169 as one of the spontaneous characteristics of hypnosis, in the absence of suggestion. The same for posthypnotic suggestion (rapport and amnesia). Spontaneous physiological changes in hypnosis relate to mind-body relationships (p. 169)

Conditioned reflex is discussed on p. 161

"...the subjective evidence indicates that a perceptual change involving any sensory modality can be produced by DSUH" [direct suggestion under hypnosis] p. 178. Suggestion can selectively affect different parts of the body p. 197.

Research: "Hypnosis is not only the most important and practical way of proving the existence of the unconscious--which is still in doubt in some circles--but is in fact the only way in which unconscious mechanisms can be manipulated under repeatable experimental conditions for purposes of investigation" (p. 152).

Mind-body is "amenability to control" Catatonia, which characterizes both animal and human hypnosis, seen in hypnosis, is induced by constriction (i.e. disorientation). The Cartesian concept of mind and body tends to confuse the issue p. 157.

Rapport is discussed (p. 157).

Suggestion (p. 159) "It was this concept of 'suggestion'--which so obviously parallels 'amenability to control' in animals--that eventually established hypnosis in the French schools of psychiatry as a state of increased suggestibility. ... still the standard definition of hypnosis in most medical psychiatric textbooks and in lay dictionaries" (p. 159).

Black (1969) did some biochemical sleuthing to learn how information transmitted by words becomes information encoded somatically, as when psychosomatic allergies flare and recede or disappear. What accounts for suggestion "curing" an allergic skin reaction in one part of the body while another part not included in the suggestion remains reactive? What accounts for the instantaneous skin allergy cure which sometimes occurs with suggestion (in 24 hours)?

Skin sensitivity tests in highly hypnotizable Ss who were also very allergic were inhibited by direct suggestion under hypnosis under highly controlled experimental conditions--and in one subject the effect (inhibition) was relatively permanent--ruling out (he suggests) a neurological mechanism. He did further experiments to examine whether the result was due to an instant neurological mechanism and a long-term endocrinal mechanism.

p. 212 He ruled out peripheral blood flow as the cause of diminished skin sensitivity (there was no change in blood flow with suggestions of heat or cold). Therefore decrease in blood flow couldn't explain in neurovascular terms the 'instant' inhibition of skin sensitivity (allergy) tests. Was it due to systemic--especially adrenal-- changes? He demonstrated increases in plasma cortisol under hypnosis with suggestions of fear. On p. 230 he summarizes the facts he established by skin sensitivity tests, plasma- cortisol studies, and histology - endocrinological.

Bowers, Margaretta K. (1961). Theoretical considerations in the use of hypnosis in the treatment of schizophrenia. International Journal of Clinical and Experimental Hypnosis, 9, 39-46. (Abstracted in Psychological Abstracts, 62,: 2 II 39B)

The author presents her views on the hypnotic state and its relationship to schizophrenia. She feels that the most effective use of hypnosis in the treatment of schizophrenia is the rapid achievement of rapport with the repressed, healthy self of the patient. Hypnosis is compared with sensory deprivation, with the difference that the hypnotist remains the patient's only contact with outer reality. Schizophrenia is likened to a perpetual state of auto-hypnosis. Hypnosis is of value in teaching the patient healthy uses of his own skill in autohypnosis. From Psyc Abstracts 36:02:2II39B. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1955

Meares, Ainslie (1955). A note on the motivation for hypnosis. Journal of Clinical and Experimental Hypnosis, 3 (4), 222-228. (Abstracted in Psychological Abstracts 57: 1129)

NOTES

1:  
"Summary. The logical reasons of the patient for desiring hypnosis, and of the therapist in advising it, operate on a background of unconscious mechanisms. These mechanisms are important factors in determining whether or not the logical reasons become effective. An understanding of such motivation helps the therapist in the selection of cases and the choice of the particular form of hypnotherapy to be used" (p. 228).

Patient motivations for hypnosis include magical expectations, paranoid belief that one is under the control of a malevolent influence, a (paradoxical) belief that hypnosis will be ineffective with neurotic symptoms and therefore justify continuation of the symptoms, latent aggression ("hypnotize me if you can" attitude) or an excess of passivity ("humiliate me"), erotic motivation or a wish for a more

intimate relationship with the therapist, search for new or unusual experiences in life, a last ditch effort to cope with chronic pain and illness, etc.

Patient motivations against hypnosis include fear of being overpowered or the threat of authority, aggressive feelings that would be motivated if the hypnotist seems to be an authority, or association of hypnosis with the erotic. The author has observed "a surprising number of people" with the latter association. "With these people, it is more of an attitude of mind in which any close or intimate relationship is regarded as erotic. They see in hypnosis an intimate relationship with the therapist, and they avoid it without being aware of their reasons for doing so" (p. 226).

Therapist motivations for hypnosis include unconscious mechanisms as well, such as a drive for power (sometimes manifested in desire to demonstrate the technique to a wider audience than simply colleagues in a workshop). When tinged with eroticism the drive can become sadistic. Also, erotic drives can find vicarious expression as "The intensity of the rapport between patient and psychotherapist in waking psychotherapy, is increased many times in hypnosis" (p. 227).

Therapist motivations against hypnosis include fear of failure (which is more obvious when a patient doesn't follow a suggestion than in lack of response to medicine), fear of erotic involvement, fear of one's own aggression, etc.

1954

Meares, Ainslie (1954). History-taking and physical examination in relation to subsequent hypnosis. Journal of Clinical and Experimental Hypnosis, 2 (4), 291-295.

NOTES

1:

"Summary. The history-taking and physical examination of the initial interview can be so structured as to facilitate the subsequent induction of hypnosis. Rapport is established, and negative transference feelings are not allowed to develop. There must be no holding back or hiding of the real complaint with screen symptoms. Physical examination is a symbolic surrender and paves the way for the real surrender of passive hypnosis. If induction by an active method is anticipated, authoritative attitudes are introduced into the history-taking and physical examination" (p. 295).

Watkins, John G. (1954). Trance and transference. Journal of Clinical and Experimental Hypnosis, 2 (4), 284-290.

NOTES

1:

The author proposes that [hypnotic] trance and transference are essentially the same phenomena. "Yet while the hypnotherapist is often unaware he is dealing with transference, the psychoanalyst is often equally oblivious to the fact that he is interacting with his patient in a light trance ego state. ... Perhaps a re-examination of the entire problem of ego states and hypnotic trance is due" (p. 290).

READING

1970

Donk LJ. Vingoe FJ. Hall RA. Doty R. The comparison of three suggestion techniques for increasing reading efficiency utilizing a counterbalanced research paradigm. *International Journal of Clinical & Experimental Hypnosis* 1970;18(2):126-133. Reports an experiment in which both Barber-type and alert-trance procedures significantly increased reading speed while maintaining comprehension when compared to a control group; a traditional hypnotic procedure followed by the specific suggestions failed to obtain these results. 32 volunteer undergraduates were randomly assigned to 4 groups in terms of a counterbalanced design. 2 groups were administered trance inductions (traditional and alert) followed by specific suggestions, a 3rd simply the suggestions, while the 4th served as control.

Reading suggestions were to eliminate specific problems, increase speed, and increase or maintain comprehension. (Spanish & German summaries)

## RECEPTIVITY & OPENNESS

### 2000

Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)

This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; (3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

### 1998

Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..

## NOTES

1:  
"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-be patient/client that he or she has something to offer that can help take away pain and bring back more pleasure. This challenge is negotiated through the

therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

**1997**

Patterson, David R.; Adcock, Rebecca J.; Bombardier, Charles H. (1997). Factors predicting hypnotic analgesia in clinical burn pain. International Journal of Clinical and Experimental Hypnosis, 45 (4), 377-395.

The use of hypnosis for treating pain from severe burn injuries has received strong anecdotal support from case reports. Controlled studies provide less dramatic but empirically sound support for the use of hypnosis with this problem. The mechanisms behind hypnotic analgesia for burn pain are poorly understood with this patient population, as they are with pain in general. It is likely that, whatever the mechanisms are behind hypnotic pain analgesia, patients with burn injuries are more receptive to hypnosis than the general population. This article postulates some variables that may account for this enhanced receptivity, including motivation, hypnotizability, dissociation, and regression.

**1995**

Malinoski, Peter; Martin, Daniel F.; Aronoff, Jodi; Lynn, Steven Jay; Gedeon, Scott (1995, November). Hypnotizability, individual differences, and interpersonal pressure to report early childhood memories. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

1:

Infantile amnesia is attributed to developmental issues before 24 months. This study indicates non-hypnotic influences can shape early memories that cross the amnesia barrier.

227 Ss completed Harvard Scale and personality measures in Session 1. In Session 2 182 completed a suggestibility scale. In Session 3 they were selected, as if independent of earlier sessions - 143 [may have misheard number] Ss.

Interviewers told the selected Ss that they were experiencing something like psychotherapy, and they were asked to recall their earliest memory (independent of photos, what people had told them, etc.) Then Experimenters probed for earlier memories; that continued until Ss denied any more memories after 2 consecutive probes. Then Ss were asked to close their eyes and get in touch with more memories. Then they were told most Ss can remember more, including sometimes their second birthday party. After 1 minute, Ss were asked about memories of their second birthday. Then they were asked to focus on even earlier memories, implying it was expected and receiving complements for reporting earlier memories. Finally, Ss completed a post-study questionnaire.

Memory report was a verbal description of an event, person, or object. Initial memory mean age was 3.7; it correlated with Openness to Experience Scale and with Fantasy Proneness. Mean age of the last earliest memory report before the close eyes instruction was 3.2 years. After receiving visualization instructions, 59% reported a memory of their second birthday. Compliance correlated .33 with this. Subjective response, nonvoluntariness, and [missed words] also correlated.

Compliance scores correlated .28 with at least one memory at or before age 24 months. Yielding to leading questions correlated also with memory for an event at or before 24 months.

Clarity of memories decreased between conditions of initial memory, earliest query, birthday, and earliest memory. Mean confidence rating on 5 point scale for second birthday memory was 3.3; mean

confidence rating for earliest memory was 3.6. Mean accuracy rating was 4.0, and 94% said their memory reports were accurate to at least a moderate degree.

The post study questionnaire, totally anonymous, indicated Ss did not feel much pressure to recall (2.9 on scale of 1-5). Only 9.8% indicated they felt a lot of pressure. Subjects also usually denied that they made up memories to satisfy the experimenter. On average, the reports of memory under visualization conditions occurred two years earlier than their first reported memories.

1993

Glisky, Martha L.; Kihlstrom, John F. (1993). Hypnotizability and facets of openness. International Journal of Clinical and Experimental Hypnosis, 41 (2), 112-123.

Absorption, a correlate of hypnotizability, is related to a broader dimension of openness to experience, one construal of the "Big Five" structure of personality. But openness itself is very heterogeneous, and some of its facets may be unrelated to hypnotizability. A total of 651 subjects completed a questionnaire measuring three different aspects of openness -- absorption, intellectance, and liberalism -- before receiving the Harvard Group Scale of Hypnotic Susceptibility, Form A. The three dimensions were only modestly related to each other, and only absorption was significantly related to hypnotizability. Adding intellectance and liberalism to absorption did not enhance the prediction of hypnotizability. The results indicate that the various facets of openness are rather different from each other and that the "Big Five" structure may need to be expanded. Absorption and hypnosis share a kind of imaginative involvement that is not necessarily part of other kinds of openness, such as intellectance and liberalism.

1992

Goodman, Linda; Holroyd, Jean (1992). Ego receptivity and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 40 (2), 63-67.

Ego receptivity has been described as important for the psychotherapy process and as a characteristic of hypnosis (Deikman, 1974; Dosamantes-Alperson, 1979; Fromm, 1979). Receptivity also has been associated with a measure of absorption (Tellegen, 1981). In the first pilot study with 6 dance/movement therapy students, higher observer ratings of receptivity were associated with greater hypnotizability ( $r = .79$ ,  $df = 4$ ,  $p < .05$ , 2-tailed test). In the second pilot study, the correlation was replicated ( $r = .51$ ,  $df = 12$ ,  $p = .06$ , 2-tailed test) with 14 dance/movement therapy students. In the second pilot study, receptivity did not correlate with absorption. Receptivity and absorption, however, accounted for 54% of hypnotizability population variance in a step-wise multiple regression. Receptivity accounted for a unique part of the variance after the effects of absorption were removed. It was concluded that receptivity should be explored as a potential predictor of hypnotizability, and that a reliable scaled measure of receptivity should be developed.

NOTES

1:

Receptivity was rated by dance instructor on the following scale. "TABLE 1 Criteria for Ranking Ss on Receptivity A. Individuals were rated high if they could consistently do the following most of the time:

1. If they moved with emotional involvement.
2. If they could readily verbally describe their movement experience in terms of sensations or feelings.
3. If they were able to image while moving. That is, their movement experience could be transformed into representational visual images.
4. In their describing their movement experience verbally, if they readily alluded to the images which were generated from their body movement.

5. If they could relate their movement experiences to other contexts outside of the therapeutic one.
6. If they could develop a working alliance with the therapist (based on students' capacity to risk experiencing self with increased emotional depth). B. Individuals were rated low, if they were not able to do the above most of the time. C. Individuals were rated in the mid-range if they were able to do the above some of the time" (p. 65).

## NOTES

1:

Balthazard (1993) states that the research suggests that absorption might splinter into a number of subconstructs. Also, different components of "absorption" may be differentially related to different components of hypnotic performance.

Radtke, H. Lorraine; Stam, Henderikus J. (1991). The relationship between absorption, openness to experience, anhedonia, and susceptibility. International Journal of Clinical and Experimental Hypnosis, 39, 39-56.

Examination of the absorption (Tellegen Absorption Scale [TAS] of Tellegen & Atkinson, 1974), openness to experience (OTE Inventory of Costa & McCrae, 1978), and anhedonia (ANH Scales of L. J. Chapman, J. P. Chapman, & Raulin, 1976) scales suggested that they might be conceptually related. Given the reliable relationship between TAS and hypnotic susceptibility, the authors were interested in studying OTE and ANH as possible personality correlates of hypnotic susceptibility. 2 studies, 1 involving a community sample and the other a sample of university students, were conducted to assess the relationships between the TAS, OTE, and ANH scales and hypnotic susceptibility. As predicted, in Study 1 (community sample) the TAS and OTE inventories were positively correlated with one another and both were negatively correlated with the ANH scale. This pattern of correlations was replicated in Study 2 (university sample), but only TAS correlated significantly with hypnotic susceptibility. Factor analyses further confirmed these findings. It was concluded that the conceptual relationship among the TAS and the OTE and ANH scales resides in some dimension other than hypnotic susceptibility.

## NOTES

1:

Two studies used Tellegen Absorption Scale (TAS), Costa & McCrae's (1978) Openness to Experience Inventory (OTE), and Chapman, Chapman, & Raulin's (1976) Anhedonia scales (ANH). One involved a community sample, the other involved university students.

OTE and TAS  $r = .42$  and  $.62$

TAS and HGSHS:A  $r = .22$  ( $p < .10$ ) in one study "Thus, while there is a significant overlap in variability between TAS and the other person variables, the variance shared between TAS and hypnotic susceptibility is unique to those two measures. Further research is needed to determine the role of expectancies in contributing to this pattern of findings and the extent to which item overlap may be responsible for the observed correlations (Nicholls et al., 1982). Inspection of the items included in the three scales indicated that only TAS assesses involvement in experiences; items on the ANH and OTE instruments focus on interest or willingness to engage in various experiences" (p. 51). "Notably, the correlations between TAS and the 2 subjective indices of hypnotic susceptibility, SUB and O-I, were slightly stronger than the correlations between TAS and the two indices reflecting overt behavior (OBJ and HGSHS:A scores). This pattern of relationships is consistent with recent

arguments that objective indices alone do not fully capture the hypnotic experience (e.g., Spanos et al., 1983).

"Interestingly, the correlations among the three personality scales tended to be stronger in Study 1 where a community sample was assessed in a nonhypnotic context than in Study 2 where a sample of university undergraduates was assessed in a hypnotic context. The two samples differed significantly on all three scales both in terms of mean level and variability, indicating possible ceiling effects and restricted range problems in the university sample. Given that almost all of the research on hypnotic susceptibility and its correlates has been conducted on university students, these findings point to the utility of obtaining research participants from a greater cross-section of the population" (pp. 51- 52).

"Of particular importance, these results indicate that the relationships among TAS and the OTE and ANH scales do not depend upon the hypnotic context and are not the product of expectancies generated by the anticipation of being hypnotized. Nevertheless, the conceptual relationship among the three scales resides in some dimension that is unrelated to hypnotic susceptibility. At this point, we can only speculate as to what this dimension might be. One possibility is that TAS and the OTE and ANH scales reflect an openness to various experiences; what absorption and hypnotic susceptibility uniquely share is the willingness to become involved in imaginal and sensory experiences" (p. 52).

## 1990

Barber, Theodore Xenophon (1990, August). Some things I've learned about hypnosis after 37 years. [Audiotape] Presented at the annual meeting of the American Psychological Association, Boston.

### NOTES

1:

"We are a unity of cells. Every cell is a citizen with it's own jobs, communicating all the time; cells send messages; the way we communicate with them is by suggestions. Each \_cell\_ is a mind-body.... When I do it now [hypnotic inductions], I say, 'We're going to go into hypnosis, we're \_both\_ going to go into hypnosis. I'm going to close my eyes (etc.)' - modeling hypnosis for them."

Hoyt, Irene P.; Nadon, Robert; Register, Patricia A.; Chorny, Joseph; Fleeson, William; Grigorian, Ellen M.; Otto, Laura; Kihlstrom, John F. (1989). Daydreaming, absorption and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 37, 332-342.

### NOTES

1:

It appears that the consistent correlation between hypnotizability and positive-constructive daydreaming is carried largely by three subscales--Acceptance of Daydreaming, Positive Reactions to Daydreaming, and Problem-Solving. Number other subscales consistently correlated with hypnotizability.

When absorption was taken into account, daydreaming activity made no independent contribution to the prediction of hypnotizability. "The present results differ from Crawford's (1982) somewhat, however, in terms of the specific aspects of daydreaming activity that are associated with hypnosis. Crawford found that hypnotizability correlated consistently (i.e., in both men and women) with three subscales tapping imagery variables: the presence of visual and auditory imagery in daydreams and the hallucinatory vividness of daydream imagery. In the present study, the imagery subscale, including both visual and auditory items, did not correlate significantly with hypnotizability; unfortunately, the hallucinatory vividness subscale is not represented on the short form (SIPI) of the daydreaming questionnaire used in this study. Crawford (1982) did not find consistent correlations between hypnotizability and scales measuring acceptance, positive reactions, and problem solving--the subscales that consistently yielded significant correlations in the present study. Not too much interpretive weight should be given to any of the correlations between hypnotizability and daydreaming subscales, until a full replication with reliable subscale measurements (such as those

provided by the long, original IPI) has been completed. The important point made by Crawford (1982), and confirmed in the present study, is that hypnotizability is related to positive-constructive rather than guilty-dysphoric daydreaming" (p. 338). The two studies agree that absorption and hypnosis are not correlated with daydreaming scales reflecting poor attentional control. Given the theoretical emphasis in both domains on the narrowing of attention and exclusion of potentially distracting input, negative correlations with this aspect of daydreaming might have been expected.

## **NOTES**

1:

This article is cited by Spanos & Flynn (1989) as indicating that high hypnotizability requires imaginative skills that some people do not possess in sufficient degrees.

Kirmayer, Laurence J. (1988). Word magic and the rhetoric of common sense: Erickson's metaphors for mind. International Journal of Clinical and Experimental Hypnosis, 36 (3), 157-172.

Milton Erickson did not produce a systematic theory of psychotherapy. His talent was as a storyteller, inventing metaphors and more extended healing fictions for his patients. A great many of Erickson's cases did not involve hypnosis in any conventional sense of the term. He used a wide range of persuasive rhetorical forms to encourage behavioral change in his patients. Nevertheless, taken together his work represents a significant shift in paradigm from prevailing schools of psychotherapy. Erickson captured the power of word magic in the language of common sense. This coupling of magical power with folk psychology accounts for much of his current popularity. Attempts to experimentally test his techniques are likely to be unsuccessful because these techniques were unique inventions tailored to the individual idiosyncrasies of patient and context. Although regularities in his work can be found, Erickson's most important contributions are not techniques but changes in the values or ethos under which psychotherapy is conducted.

## **NOTES**

1:

This paper focuses Erickson's implicit models of mind and the values they carry. "It is here that Erickson made his most significant contribution to the general practice of psychotherapy . Erickson avoided systematization. His writing is unusually anecdotal, even for psychotherapy (Erickson, 1980; Vol IV, passim). Erickson's writing format consists of 'thin' case descriptions, freely recycled in parable or homiletic form to serve his immediate rhetorical purpose. ... For Erickson, flexibility and eclecticism were not signs of a lack of coherence but a spirited rejection of rigid dogma that needlessly limited therapeutic possibilities" (pp. 158-59).

Erickson used language of the common man rather than a technical vocabulary, even when speaking of 'hypnosis' or 'trance' or 'the unconscious.' He called his approach 'naturalistic' and viewed hypnotic phenomena as an extension of normal experience and behavior. His common sense descriptions of events and techniques are easily understood in general terms. "Erickson took magic and dressed it in the familiar clothes of common sense. Some of his less critical followers, however, seem intent on taking common sense and dressing it in the cloak of magic" (p. 163).

Erickson used metaphors as a way of actively involving the patient in conceptual, affective, and sensory qualities of experiences, i.e. as a "tool for thought" (p. 164).

In attempting to understand Erickson's psychotherapy, one must note his "elastic use of the word 'hypnosis.' Sometimes Erickson uses the term narrowly with a focus on the elicitation of trance or

dissociative phenomena, but more often he uses it broadly to mean any state of absorption" (p. 165). For him, this was "\_a state of special awareness characterized by a receptiveness to ideas\_" [Erickson, 1985, p. 223, emphasis in original]. By this he does not mean exclusively the classic suggestion effect where motor acts are experienced as involuntary (Evans, 1967). ... The hypnotic subject exhibits a "\_special willingness to examine ideas for their inherent values\_" [p. 224, emphasis in original]. ... For Erickson, any move in the direction of increased absorption is an instance of hypnosis. Dissociation accounts for a great deal but not all of hypnotic behavior" (p. 165). That is why he used the word hypnosis to describe heightened attention that might occur when someone is surprised. But in fact, his published cases include many other kinds of interventions, such as reframing, symptom prescription, etc.--forms of influence and persuasion used by many therapists who do not consider themselves working with hypnosis.

Erickson also emphasized that hypnosis enables one to work with 'the unconscious.' "Ordinarily, we view our consciousness as the causal agent of doing while our unconscious is the place where things just 'happen to us.' Erickson reversed this attribution, emphasizing the unconscious as the agent of active control working for the benefit of the patient while consciousness adopts the attitude of 'wait and see.' This leads consciousness into reverie--the state where images and events move of their own accord, animated by emotion, before the 'passive audience' of consciousness" (p. 167). So Erickson viewed hypnosis as liberating the unconscious. There was healing potential in helping the ego to relinquish "rigid control over the creative and benevolent processes of the unconscious" (p. 168). From this theoretical position, the patient and therapist are seen as allies and psychotherapy is a collaboration; there is no need for the Freudian concepts of resistance and defense.

"Erickson's metaphors for hypnotherapy link it with normal processes of learning and imagining. His image of the unconscious as a storehouse of creative potential supports a non-pathologized view of man amid all his troubles and craziness. In contrast to psychiatry's current preoccupation with nosology, and the emphasis of psychoanalysis on the dimensions of human frailty, Erickson adopted a non-pathologizing attitude. He did not deny his patient's difficulties but neither was he excessively fascinated by them. He recognized that healing depends not on cataloguing deficiency but on fully mobilizing the person's intelligence, imagination, and integrity. This message of therapeutic optimism was balanced by his own example of the benefits and limitations of hypnotherapeutic practice" (p. 170).

1981

Dosamantes-Alperson, Erma (1981). Experiencing in movement psychotherapy. American Journal of Dance Therapy, 4, 33-44.

Experiencing is a process variable in psychotherapy which deals with the manner with which individuals use their internal, ongoing bodily-felt flow of experience to gain self-awareness and to communicate about themselves. A consistent finding across research process studies in psychotherapy is that successful clients start, continue, and end therapy at higher experiencing levels than do less successful clients. The implication of this finding for all therapists, irrespective of their theoretical framework, is that they need to help their clients process the content they raise in therapy at a high level of experiencing throughout the course of therapy. This paper discusses and demonstrates several body movement based procedures that enhance clients' experiencing level while working within the context of experiential movement psychotherapy, a form of psychotherapy which emphasizes the acquisition of personal meanings by clients from any of the following three experiential and expressive modalities: body movement, kinetic imagery, or verbal communication.

Fromm, Erika; Brown, Daniel P.; Hurt, Stephen W.; Oberlander, Joab Z; Boxer, Andrew M.; Pfeifer, Gary (1981). The phenomena and characteristics of self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 189-247.

Self-hypnosis and hetero-hypnosis were compared, and self-hypnosis was studied longitudinally. Results indicated that absorption and the fading of the general reality orientation are characteristics of both hetero-hypnosis and self-hypnosis. The differentiating characteristics lie in the areas of attention and ego receptivity. Expansive, free-floating attention and ego receptivity to stimuli coming from within are state-specific for self-hypnosis, while concentrative attention and receptivity to stimuli coming from one outside source--the hypnotist on whom the subject concentrates his attention--are state-specific for laboratory defined hetero-hypnosis. Attempts to produce age regression and positive or negative hallucinations are markedly more successful in hetero-hypnosis. Imagery is much richer in self-hypnosis than in hetero-hypnosis. Self-hypnosis requires adaptation to the state: in the beginning of self-hypnosis there is a good deal of anxiety and self-doubt. As the subject feels more comfortable in the self-hypnotic state, he spends less time worrying about failures in self-suggestion, his ability to enter trance quickly and easily increases, as does the fading of the general reality orientation, trance depth, and absorption. An attempt was also made in the present study to find personality characteristics related to the ability to experience self-hypnosis.

1980

Weitzenhoffer, Andre M. (1980). What did he (Bernheim) say? A postscript and an addendum. International Journal of Clinical and Experimental Hypnosis, 28 (3), 252-260.

When Bernheim (1917) made his pronouncement, "There is no hypnotism, there is only suggestibility" at a scientific congress in London in 1892, he shocked the scientific community, which turned against him for what amounted to heresy. Clearly, his colleagues understood him to deny existence to hypnosis as a state. That he only meant to shock them into viewing suggestion as being the primary agent and hypnosis as being one of its products rather than the other way around, as then held, was made fully clear by him in 1917 in one of his last writings. Recognizing there had been a misunderstanding, Bernheim made this very point and explained further that although hypnosis is sleep, it is only so in an incomplete form, one allowing the subject to be responsive and suggestibility to be elicited. From there he went on to develop the thesis that hypnotic behavior is the result of an integration of elicited automatisms (nonvoluntary acts) and conscious voluntary behavior, and not entirely a pure, non-conscious, nonvoluntary automatism. Bernheim also proposed in this later work that suggested behavior results from automatisms rendered possible by the "credivity," that is, the implicit belief of suggestible persons in the reality of whatever the suggestor states, a belief which is limited to the suggestor. (In contrast, the credulous person believes everyone.) Credivity is a particular outgrowth of the hypnotist-subject relationship. In his final writings, Bernheim thus called attention to the importance of interpersonal factors in hypnotism.

1979

Dosamantes-Alperson, Erma (1979). The intrapsychic and the interpersonal in movement psychotherapy. American Journal of Dance Therapy, 3, 20-31.

The adaptive function of two states of consciousness and corollary movement experiences is described. Movement in which a relaxed state of attention is maintained on inner kinesthetic sensations and imagery is contrasted with movement which is characterized by conscious, active interacting with the external world of people and events. Clinical examples from individual and group psychotherapy

sessions are cited to demonstrate how meaning and conflict resolution may be achieved by clients while moving in either mode.

1976

**King, Dennis R.; McDonald, Roy D. (1976). Hypnotic susceptibility and verbal conditioning. International Journal of Clinical and Experimental Hypnosis, 24, 29-37.**

18 Subjects highly susceptible to hypnosis and 18 Subjects refractory to hypnosis were studied in a verbal conditioning task modeled after the one used by Taffel (1955). Results indicated that the highly susceptible group showed significantly greater conditioning than the low group. Awareness of the reinforcement contingency by S was not related to the learning task nor to hypnotic susceptibility. A measure of S's attitude toward the reinforcement cue during learning showed that the highly susceptible group had a more positive set toward the cue, whereas the low group tended to respond to it in a neutral or negative manner. Results were interpreted in terms of the theoretical nature of hypnotic susceptibility.

## NOTES

1:

They review literature on attempts to correlate hypnotizability with verbal conditioning ability.

Volunteer students participated; screened by HGSHS:A: highs 10-12, lows 0-4.

Verbal conditioning procedure: S viewed 100 3x5 cards on which were a two-syllable, past tense verb, below which typed in upper case letters on one line were the pronouns I, WE, HE, SHE, THEY, and YOU (randomly assigned to different orders). E was blind to hypnotizability. E instructed S to make up a sentence using the verb and a pronoun; gave no response for first 20 trials; said "good" to usage of I or WE during conditioning.

Afterwards, S filled in an Awareness Questionnaire (What was purpose? If E gave cues, what were they? If you noticed cues, what do you think they indicated?) and attitude toward the reinforcement cue (Did you notice that I did anything special? What? Did I say "good" for a special reason? What was the reason for my saying "good"? How did hearing the word "good" affect you during the experiment? IN a positive, negative, or neutral way?

Results. Groups did not differ at baseline but did differ at Blocks 2 (highs 9.7 vs lows 6.3;  $p < .05$ ) and 3 (highs 10.4 vs lows 6.3;  $p < .05$ ). Although the High group continued to maintain a somewhat higher level of responding than the Low group during extinction (9.8 vs 7.6), this difference did not reach statistical significance. (The graph shows an increase for Lows during extinction!)

Using a liberal definition of awareness and a learning index computed for each S by subtracting his operant level of response from the mean number of correct responses shown during the 3 blocks of acquisition trials, Subjects were ordered and a median test applied; contingency coefficient of .28 not significant ( $p < .10$ ).

Attitude significantly differentiated High and Low hypnotizability groups (see Table 2) with Highs more often responding in positive manner to reinforcement cue and Lows giving a neutral rating. Awareness of reinforcement contingency was equally represented in High and Low groups. The Aware High Positive groups learning index differed significantly from Aware Low Neutral group ( $p < .01$ ); the Unaware Low Positive group ( $p < .05$ ); and the Unaware Low Neutral group ( $p < .001$ ).

Thus, the Aware High Positive group's learning index score was significantly higher than that of the 3 Low groups. Also, the Unaware High Positive group differed significantly from the Unaware Low Neutral group ( $p < .05$ ). No other High groups differed from the Low groups and none of the High groups differed among themselves.

Among the Low groups, only the Unaware Low Positive group differed significantly from the Unaware Low Neutral group ( $p < .05$ ).

**Discussion.** Data show that hypnotizability is important in response to verbal conditioning, extending findings of Das (1958) by showing that primary suggestibility is associated with operant as well as classical conditioning but also those of Weiss et al. (1960) in illustrating that higher hypnotic susceptibility leads to enhanced verbal conditioning, using an improved measure of hypnotic susceptibility.

Awareness of reinforcement contingencies is not sufficient to account for subject differences in verbal conditioning; the characteristics tapped by HGSHS:A produce conditioning which cannot be accounted for by awareness alone.

The fact that high susceptible Subjects here rated E's cue more positively than low susceptible Subjects is further consistent with some of the personological descriptions associated with hypnotic susceptibility which have been offered by Hilgard (1968). In addition, Cairns and Lewis (1962) and Spielberger et al. (1962) found that persons who assigned more positive value to the kind of reinforcement present in verbal conditioning experiments produced greater conditioning than Subjects whose attitudes were less favorable or non-committal toward the reinforcement. This relationship is not clear-cut in the present data in that although the High groups had an overall more positive attitude regarding reinforcement, only the Aware High Positive group learned better than all the Low groups, while the only other High group learning better than a Low group was the Unaware High Positive which had a significantly better learning index score than the Unaware Low Neutral group. Moreover, positive attitude did not differentiate learning within the High groups or the Low groups. Thus, the present data are unclear regarding the role attitude plays in the acquisition of verbally conditioned responses.

The roles of awareness and attitude could probably be better defined in future research using larger experimental groups. The attitude measure employed here was a gross one and a more sophisticated assessment of the valence characteristics of reinforcement cues could reveal more complex relationships in subsequent research. In addition, a more careful assessment than was done here of the role of cooperation and demand characteristics would contribute substantially to understanding more completely the effect of awareness on these phenomena.

The general indications regarding attitude may in part account for the increased interest in production of conditioned responses in Figure 1 shown by the Low group (graph) during the extinction phase of this experiment. Although highly susceptible Subjects show a decrease in the correct response with nonreinforcement, low susceptible Subjects begin to evidence an increase in the correct response. The attitude measure indicates that Subjects in the Low group did not respond positively to the reinforcement cue, and one of these Subjects reported in the interview that he did not like being told what to do by the E. It can be speculated that these Subjects were aware of the reinforcement contingency but did not "cooperate" until the reinforcement was absent. This follows the interpretation of Farber (1963) who found that aware Subjects who conformed to the demand characteristics of the experimental situation showed greater verbal conditioning than those who were aware and nonconforming. It thus appears that a willingness to go along with E's expectations and a positive, cooperative attitude are common features in individuals who make good hypnotic Subjects and who evidence an enhanced propensity for verbal conditioning.

## **REFLEX**

**1998**

Danziger, N.; Fournier, E.; Bouhassira, D.; Michaud, D.; De Broucker, T.; Santarcangelo, E.; Carli, G.; Chertock, L.; Willer, J. C. (1998). Different strategies of modulation can be operative during hypnotic analgesia: A neurophysiological study. Pain, 75 (1), 85-92.

Nociceptive electrical stimuli were applied to the sural nerve during hypnotically-suggested analgesia in the left lower limb of 18 highly susceptible subjects. During this procedure, the verbally reported pain threshold, the nociceptive flexion (RIII) reflex and late somatosensory evoked potentials were investigated in parallel with autonomic responses and the spontaneous electroencephalogram (EEG). The hypnotic suggestion of analgesia induced a significant increase in pain threshold in all the selected subjects. All the subjects showed large changes (i.e., by 20% or more) in the amplitudes of their RIII reflexes during hypnotic analgesia by comparison with control conditions. Although the extent of the increase in pain threshold was similar in all the subjects, two distinct patterns of modulation of the RIII reflex were observed during the hypnotic analgesia: in 11 subjects (subgroup 1), a strong inhibition of the reflex was observed whereas in the other seven subjects (subgroup 2) there was a strong facilitation of the reflex. All the subjects in both subgroups displayed similar decreases in the amplitude of late somatosensory evoked cerebral potentials during the hypnotic analgesia. No modification in the autonomic parameters or the EEG was observed. These data suggest that different strategies of modulation can be operative during effective hypnotic analgesia and that these are subject-dependent. Although all subjects may shift their attention away from the painful stimulus (which could explain the decrease of the late somatosensory evoked potentials), some of them inhibit their motor reaction to the stimulus at the spinal level, while in others, in contrast, this reaction is facilitated.

Abstract from National Library of Medicine, PubMed

1998

Schauble, Paul G.; Werner, William E. F.; Rai, Surekha H.; Martin, Alice (1998). Childbirth preparation through hypnosis: The hypnoreflexogenous protocol. American Journal of Clinical Hypnosis, 40 (4), 273-283.

A verbatim protocol for the "hypnoreflexogenous" method of preparation for childbirth is presented wherein the patient is taught to enter a hypnotic state and then prepared for labor and delivery. The method provides a "conditioned reflex" effect conducive to a positive outcome for labor and delivery by enhancing the patient's sense of readiness and control. Previous applications of the method demonstrate patients have fewer complications, higher frequency of normal and full-term deliveries, and more positive postpartum adjustment. The benefit and ultimate cost effectiveness of the method are discussed.

1993

Lindsay, Suzanne; Kurtz, Richard M.; Stern, John A. (1993). Hypnotic susceptibility and the endogenous eyeblink: A brief communication. International Journal of Clinical and Experimental Hypnosis, 41, 92-96.

This study investigated the relationship between hypnotic susceptibility, hypnotic state, and the endogenous eyeblink with 36 undergraduates, who were assigned to four independent groups (waking-low, hypnotized-low, waking-high, and hypnotized- high susceptibles) on the basis of combined cutoff scores on both the Creative Imagination Scale and the Stanford Hypnotic Clinical Scale for Adults. The auditory vigilance task required subjects to discriminate between 200 ms and 300 ms tones over a 35-minute period. Hypnotic depth was controlled across trials using the Long Stanford Scale of Hypnotic Depth. As predicted, high-susceptible subjects had a significantly lower blink rate than low-susceptible subjects. The predicted interaction between susceptibility and hypnotic state was also confirmed. High-susceptible subjects showed a significant decrease in blinking for the hypnotized

condition, whereas low-susceptible subjects did not. The need for replication with more adequate measures of susceptibility is discussed.

## NOTES

1:

"In a preliminary study, Weitzenhoffer (1979) found significant differences between high- and low-susceptible subjects following a hypnotic induction. The highs showed a 66% decrease in blink rate from a baseline reading. More recently, Tada, Yamada, and Hariu (1990) reported a series of studies suggesting that blink rate was dramatically reduced during the hypnotic state, as well as finding a relationship between high susceptibility and decreased blink rate. Although these studies tend to support Weitzenhoffer's (1979) research, they are poorly controlled and report no quantitative data" (p. 93).

In the present study, "to assure that subjects kept their eyes open, they were required to maintain their gaze on a dimly lighted box (12" x 12") placed one meter in front of them. Subjects in both conditions were asked to rate their hypnotic depth by using the Long Stanford Scale of Hypnotic Depth (Tart, 1970) before being given a practice trial of 20 tones. Following the practice trial, participants were again asked to rate their hypnotic depth, and the trial period began. Subjects gave subsequent depth ratings every 10 minutes for the remainder of the 35-minute trial. The hypnotic state was maintained across time periods by using deepening instructions when necessary" (p. 94).

In their Discussion, the authors noted that "High-susceptible subjects in the hypnotized state have a significantly lower blink rate and presumably greater attentional focus than lows. Although the interaction was significant and in the predicted direction, it accounted for only a small portion of the overall variance, suggesting that trait differences are more robust than those for state" (p. 95).

1992

Gainer, Michael J. (1992). Hypnotherapy for reflex sympathetic dystrophy. American Journal of Clinical Hypnosis, 34, 227-232.

Reflex sympathetic dystrophy (RSD) is an unusual, debilitating, chronic pain syndrome thought to be the result of a continuous excessive discharge of regional sympathetic nerves. Supportive and stress-reduction psychotherapies are commonly recommended as adjunctive treatments. Biofeedback is a more direct symptomatic treatment. Although hypnotherapy is effective in altering sympathetic reflex and pain responses, there are no reports of its use for the treatment of RSD. This article reviews some promising results of hypnotherapy with three RSD sufferers. I discuss the role of hypnotherapy as a supportive adjunct to medical treatment. I also explore the possible role of hypnotherapy as a complementary treatment.

## NOTES

1:

"Hypothetically, RSD represents a continuous excessive discharge of the regional sympathetic nerves. Such discharge normally occurs in response to an injury. In RSD this reflex response is unremitting despite the cessation or absence of an external stimulus" (p. 227).

The psychosomatic aspects of RSD are highly disputed. Some studies suggest a relationship between RSD and various psychopathological conditions. Also proposed is a predisposing character type, sometimes termed 'Sudeck personality' ... patients who are generally anxious, inactive, and hypertensive. ... Others cite chronic pain as the cause, not the result, of certain 'typical' behavior patterns and emotional responses (Abram, 1990; Ecker, 1984)" (p. 228).

"Reports of four cases described RSD treatment with temperature biofeedback. These studies suggest that the patients learned to warm the affected limb through increasing cutaneous circulation. The temperature change was associated with decreased regional sympathetic activity and decreased pain.

Complete remission of symptoms is reported in three of these cases; significant improvement is reported in the fourth" (p. 228).

"Abram (1990) reported that in two independent studies the incidence of RSD was 6.3% and 10.7% of patients admitted to pain clinics" (p. 228).

"I hypothesized that hypnotic interventions could facilitate a decrease in local sympathetic nervous discharge. This would result in vasodilation and warming of the affected limb, decreased spasticity, and decreased pain. The following is a report of the effective treatment of three RSD cases with hypnotherapy" (p. 228).

Case #1. "The eventual resolution of her RSD symptoms was due, in part, to resolution of psychodynamic conflicts. ... She had a grade-four profile on the Hypnotic Induction Profile (Spiegel & Spiegel, 1978). In later sessions she readily demonstrated superior hypnotic capacity, achieving such phenomena as spontaneous amnesia, negative hallucination, and somnambulism" (p. 229).

Case #2. ... "She had a grade-three profile on the Hypnotic Induction Profile (Spiegel & Spiegel, 1978) Because of the success with the first patient, I used visualization techniques initially. ... She responded more readily to kinesthetic and tactile suggestions. ... These interventions produced dramatic improvement in the RSD symptoms" (p. 230).

Case #3. ... "He had a grade-three profile on the Hypnotic Induction Profile (Spiegel & Spiegel, 1978). He was readily able to use visualization techniques. He was able to affect dramatic temperature changes (8-10 degrees F) by visualizing 'warm' vacation scenes and imagining the feeling of the 'warm sun' on the affected limb" (p. 231).

DISCUSSION mentioned, "The patients presented in this report were all highly motivated and demonstrated an above-average to superior hypnotic capacity. Despite the obvious limitations of such a selective sample, the actual treatment results support the initial hypothesis. The treatment results of these three cases indicate that hypnotherapy can be an adjunctive treatment to alleviate pain. Moreover, these results indicate that hypnotherapy can be a complementary treatment in RSD.

1991

Kleinhaus, Moris (1991). Prolonged hypnosis with individualized therapy. International Journal of Clinical and Experimental Hypnosis, 39 (2), 82-92.

A therapeutic approach is presented which involves the use of prolonged hypnosis for the treatment of diverse medical and/or psychological conditions, including intractable pain. This approach may be indicated either as a complementary tool used in conjunction with other treatment approaches or as the only method of intervention. The technique is based on achieving a prolonged hypnotic response, during which hypno- relaxation serves as the foundation for the delivery of an individualized therapeutic plan which includes self-hypnosis, suggestive procedures, metaphors, and constructive imagery techniques. In debilitated patients, medical supervision and nursing care are essential, and hospitalization is recommended if necessary. Theoretical assumptions underlying this approach are presented, and clinical implications are discussed. The method is illustrated through case presentations.

NOTES

1:

The general procedure involves: 1. A flexible plan concerning the duration of treatment: days, weeks, or longer. 2. Information is given to the patient, the family and the medical staff if in hospital. Emphasize that while the patient may be in a 'twilight-like' state, most of the time he/she is able to fulfill his or her basic physiological needs, (drinking, eating, taking care of personal cleanliness, etc.). 3. The method of hypnotic induction is individualized. 4. The patient is trained in self- hypnosis, and for using signals for induction and dehypnotization either for self hypnosis or for the hypnotist to use. Thus if there is a physiological or emotional need for self-hypnosis the patient can do it. Suggestions

and training are given and reinforced concerning the patient's capability to fulfill his/her basic physiological needs. 5. The family and/or the medical staff are instructed and trained in induction and dehypnotization, until the patient responds to them satisfactorily. 6. At this stage, therapeutic suggestions aimed at ego-boosting and a change of attitudes and meanings towards the symptom and symptom removal/amelioration/substitution are added. 7. Metaphoric constructive imagery is introduced when indicated. 8. If required, other hypnotic phenomena are elicited and used (e.g. dissociation, time distortion, age regression, rehearsal, hypno/analgesia, change of muscular tonus, displacement of emotions, abreaction, etc.). 9. An audio cassette which contains the wording of the therapeutic intervention is used with some patients. 10. The family and/or the medical staff are instructed to supervise the patient properly and to avoid potential complications. 11. Termination of prolonged hypnosis with individualized therapy is gradual to permit appropriate re-orientation towards reality. 12. Treatment is evaluated and a posttreatment plan is outlined.

They provide case reports and discuss precautions. All the cases reported were treated while the patients were hospitalized for their physical condition (although in Case 3, prolonged hypnosis with individualized therapy was also continued at home after the patient's discharge from the hospital), and the patients were monitored by the medical staff. In very debilitated patients, special care should be taken to avoid potential complications arising from their passivity, mainly the development of decubitus ulcer and of aspiration/choking while drinking or eating. Although precaution is taken routinely with these patients, these measures should be emphasized while the patient is in a state of prolonged hypno-relaxation.

1989

Santarcangelo, E. L.; Busse, K.; Carli, G. (1989). Changes in electromyographically recorded human monosynaptic reflex in relation to hypnotic susceptibility and hypnosis. Neuroscience Letter, 104, 157-160.

The aim of the present experiment was to study how hypnotic susceptibility and hypnosis affect motor neuron excitability. In the first trial, human Ss were selected according to their hypnotic susceptibility. In a second trial, the Hoffman (H) reflex amplitude of the soleus muscle was studied in three groups: (1) highly susceptible subjects during hypnosis with standardized suggestions of simple relaxation, anesthesia, analgesia and paralysis (group I); (2) highly susceptible subjects (group II); and (3) nonsusceptible subjects (group III) during long-lasting control conditions. Surface Ag/AgCl electrodes were used to stimulate the posterior tibial nerve using a constant current stimulator and to record the soleus EMG. The H reflex amplitude decreased significantly during the recording session in groups I and II and there was no change in group III. In group I the effect of the different suggestions could not be distinguished from the effect of hypnotic relaxation. The decrements in H amplitude did not differ between groups I and II, suggesting that the effect was related to personality traits rather than hypnotic induction.

1988

Hawkins, Russell; Le Page, Keith (1988). Hypnotic analgesia and reflex inhibition. Australian Journal of Clinical and Experimental Hypnosis, 16, 133-139.

The major change in thinking about models of analgesia over the last decade or so may be seen as a shift away from the earlier emphasis on a one-way afferent transmission sequence. Analgesia was effected, according to the older models, by a simple blocking of afferent impulses at some level (as achieved by local anaesthesia). Recent models suggest that there are at least two CNS analgesia control systems, each operating via an active mechanism for the inhibition of nociception which includes reciprocal \_efferent\_ impulses able to respond to input from lower centres by sending control signals

which modify their output. One CNS analgesia system has now been quite well described. This "opiate" analgesia system has proved to be naloxone reversible and seems to be mediated by reciprocal pathways between brain stem structures and the dorsal horn and trigeminal caudalis. This is not likely to be the system responsible for all cases of hypnotic analgesia, since the common experience of continued awareness of some elements of a normally painful stimulus, in spite of a freedom from pain, implicates a higher level involvement such as input from the prefrontal cortex.

## NOTES

The authors present a surgery case (of a cystoscopy and urethrotomy performed under hypnotic analgesia, with a highly hypnotizable patient) as an illustration of their position. The patient grimaced when the urethrotome was inserted into the urethra and dilated, but she denied discomfort and did not exhibit a reflex adduction of the thighs that is often observed even under standard general anaesthesia. She had spontaneous amnesia for the entire surgery. Later, under hypnosis, the patient could remember "discomfort and a sharp pain" which lasted for "seconds, if that" (p. 134).

The authors refer to Melzack and Wall's (1965) gate control theory as well as Hilgard's (1973) neodissociation interpretation of pain reduction in hypnosis. They review research by Hardy and Leichnetz (1981) with monkeys, in which they "traced the projections of the periaqueductal gray (PAG) to determine the extent of any possible cortical involvement in the endogenous analgesic system. Their work showed that the prefrontal cortex was the principal source of projections to the PAG" (p. 136). They quote the latter as writing that, "Patients who have had prefrontal lobotomies for relief of chronic pain report that while they still feel the pain they are no longer bothered by it ... the prefrontal cortex by virtue of its projections to the PAG may play a role in modulating nociception at the spinal level" (Hardy & Leichnetz, 1981, p. 99).

"Hardy and Leichnetz have also suggested that there may be more than one analgesic system within the CNS. The first system is a naloxone-reversible mechanism which can be activated by opiates (presumably both endogenous and exogenous) and by acupuncture. Since hypnotic analgesia has shown itself not to be naloxone-reversible (Goldstein & Hilgard, 1975) it may have little to do with the opiate reception analgesia system. Instead the mechanism of hypnotic analgesia may lie in Hardy and Leichnetz's second system which is sensitive to affective and cognitive influences" (pp. 136-137).

The authors include a review of the work by Mayer and Price (1976) which established the importance of brain stem structures in analgesia, especially for eliciting stimulation-produced analgesia. They cite Mayer and Price as drawing a distinction between "analgesia achieved by incapacitating a component in a pain transmission system or by activating a pain inhibition system" (p. 137). They also report that Mayer and Price conclude that stimulation-produced analgesia does not result from a "functional lesion" in the brain stem, but results from stimulation of a pain-inhibiting mechanism, suggesting the dorsal horn and trigeminal nucleus caudalis may be involved. This would be consistent with the inhibition of spinal reflexes (the adductor reflex) observed in their urethrotomy case, and the spinal reflex to nociception has also been reported by Finer (1974).

"The concomitant inhibition of reflexes in humans during hypnotic analgesia can be interpreted as evidence that nociception is probably not ascending to the cerebral cortex and that therefore the source of analgesia can be localized to the brain stem areas. It may be the case, however, that the locus of effect of hypnotic analgesia is not uniform across cases and may be identified by the overall pattern of subjective reports and physiological responses. Hypnotic analgesia may be experienced in more than one way subjectively and these differences may be attributable to differing underlying physiological mechanisms. On some occasions the relevant body part may be experienced as totally anaesthetised and all sensation (not only painful sensation) may be lost. This experience matches well with a brain stem involvement, which presumably inhibits any further afferent action. On other occasions, however, and more commonly, patients are still aware of a variety of sensations, which might include pressure in the case of childbirth or even cutting in the case of surgery, but these sensations are not

described as painful. This is reminiscent of the effect of frontal lobotomy and it is tempting to focus on the frontal lobe as the locus of hypnotic analgesia effects in such instances" (p. 138).

Eli, I.; Kleinhauz, M. (1985). Hypnosis: A tool for an integrative approach in the treatment of the gagging reflex. International Journal of Clinical and Experimental Hypnosis, 33 (2), 99-108.

The extreme exaggerated gag reflex can be an enormous obstacle to routine dental treatment. In some patients, extreme gagging may be a learned avoidance reaction; in others, it may act as a defense mechanism which inadequately compensates for an internal psychodynamic conflict. The most frequent areas of conflict encountered are those concerning the symbolic meaning of the mouth, fear of loss of control, and problems in the dependence/independence vector. In the Consultative Outpatient Clinic for Behavioral Dysfunctions at the School of Dental Medicine of Tel Aviv University, a multidisciplinary team of dentists, psychiatrists, and psychologists has been working on treatment modalities for such patients including hypnorelaxation and other hypnotic techniques. Hypnosis is incorporated in the framework of psychodynamic, behavioral, relaxation, and suggestive approaches that are integrated in the shaping of the therapeutic strategy. Clinical cases are described and treatment philosophies discussed.

1975

Carli, G. (1975). Some evidence of analgesia during animal hypnosis [Abstract]. Experimental Brain Research, 23, 35.

The purpose of this study was to investigate the response to painful stimuli during animal hypnosis. The experiments were performed on unanesthetized, free-moving rabbits carrying implanted electrodes for recording the EEG and EMG activity and nerve stimulation. Injection of formaline into the dorsal region of the foot produced long lasting EEG desynchronization and motor pain reactions. In some rabbits a procedure of habituation was used to reduce hypnosis duration below 45 sec. Hypnosis was induced by inversion. The following results were obtained: 1) Polysynaptic reflexes elicited [sic] by electrical stimulation of cutaneous and muscle afferents were depressed during hypnosis. 2) Hypnosis transitorily suppressed all the painful manifestations due to formaline injection and was characterized by high [sic] voltage slow wave activity in the EEG, 3) In habituated rabbits, a significant increase in hypnotic duration and EEG synchronization was observed when hypnosis was preceded by formaline injection. Hypnosis duration was not potentiated by painful stimuli when Naloxone (5mg/Kg i.v.) was injected before hypnosis induction. 4) In habituated rabbits a recovery in hypnotic duration coupled to EEG synchronization was obtained, in absence of painful stimuli, following subanalgesic injection of Morphine (1mg/Kg). It has been previously shown that in the rabbit administration of 5-20 mg/Kg of Morphine produces EEG synchronization and strong reduction of pain reactions. It is suggested that, during animal hypnosis in a condition of continuous nociceptive stimulation, the pain response is blocked by a mechanism which exhibit [sic] similar effects of Morphine both at spinal cord (polysynaptic reflexes) and at cortical levels (EEG synchronization).

Weitzenhoffer, Andre M. (1969). Eye-blink rate and hypnosis: Preliminary findings. Perceptual and Motor Skills, 28, 671-676.

Tests the validity and reliability of certain features of the outer appearance of hypnotized individuals which have long been popularly and clinically considered good indices of "hypnosis." The present report focuses on eye-blink rate. 19 Ss were administered a slight modification of the Stanford Scale of

Hypnotic Susceptibility, Form A. Samples of their blink rates were obtained prior to the induction of hypnosis and some time after the induction of hypnosis procedure had been terminated, but before the dehypnotization procedures began. The results support the popular and clinical belief that hypnotic-like behavior is accompanied by a decrement in blink rate to the extent that Ss scoring 6 or more points on the Stanford Scale showed a marked and statistically significant mean reduction in blink rate of over 60% following the induction procedure and some testing of their suggestibility. In contrast, Ss scoring 5 or less and presumably not hypnotized but merely suggestible to non-suggestible, did not show a statistically significant decrement. As a possible index of "hypnosis," such a decrease in rate was found to have a test-retest reliability of .86. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Bartlett, Esther E. (1968). A proposed definition of hypnosis with a theory of its mechanism of action. American Journal of Clinical Hypnosis, 11, 69-73.

A definition of hypnosis as a control of the normal control of input (information) for the purpose of controlling output (behavior) is proposed. A theory of the mechanism of action of hypnosis as an increasing integration of the neocortex and the subcortical areas of the brain, with the subcortical areas activated to a greater extent than normally, is postulated.

Mishchenko, M. (1961). The hypnotic condition as a process of nervous excitation. In Proc. Third World Congress of Psychiatry, Montreal, Canada, I. (pp. 704-708). (Abstract in American Journal of Clinical Hypnosis 1964, 7, 101.)

Subjects were selected with certain predispositions for the hypnotic state and studied in the waking, hypnotic and experimental sleep states by motor conditioned reflexes modified to a specific function of the frontal system. Excitable, active students of music and literature were found most excitable as subjects, subjects tending to be passive showed no hypnotic responses. Experimental sleep abolished the motor-conditioned reflexes, quite contrary to hypnotic findings. (M.H.E. abstract in AJCH).

Stolzenberg, Jacob (1961). Technique in conditioning and hypnosis for control of gagging. International Journal of Clinical and Experimental Hypnosis, 9, 97-104.

(Author's Conclusion) "The practitioner who is competently trained in hypnosis will find that there is a diminished need for the use of hypnosis per se, with most of his patients. His understanding of the psychodynamics will aid immeasurably in establishing rapport with his patients, and develop an excellent patient-dentist relationship. His semantics will be a vocabulary of positive words which will not trigger off negative reactions in his patients. The dentist as a rule, who has been exposed to hypnosis indoctrination, usually displays kindness and understanding, and treats his patients with tender loving care.

"The highest achievement in a dentist-patient relationship is attained when the parent says, "You know, doctor, I would almost think you had hypnotized my daughter when I see how nicely she cooperates"" (p. 104).

Hernandez-Peon, R.; Dittborn, J.; Borlone, M.; Davidovich, A. (1960). Changes of spinal excitability during hypnotically induced anesthesia and hyperesthesia. American Journal of Clinical Hypnosis, 3, 64. (From 21st International Congress of Physiology, Buenos Aires, 1959, pg. 124, Abstracts)

Although hypnosis is well established, the physiological mechanisms of the hypnotic state and their related sensory phenomena are far from clear. Hernandez-Peon and Donoso have found that the magnitude of photic evoked potentials in the optic radiations of awake human subjects changed in response to previous verbal suggestions concerning the intensity of the expected photic stimulus. This striking observation led the cited authors to propose that certain hypnotic sensory phenomena might be explained, at least partially, by changes occurring as far down as second-order sensory neurons by centrifugal mechanisms controlling the sensory input to the brain. In the intact subject it is impossible to record uncontaminated electrical indexes of afferent impulses from those lower sensory neurons. However, it is possible to gain indirect evidence of tactile sensory inflow to the spinal cord by recording cutaneous reflexes. In young males, a forearm skin reflex evoked by a single square pulse of 0-.1 msec. duration was recorded with cathode- ray oscilloscope. The amplitude of the evoked potentials was often reduced during the hypnotic state, and it was further reduced by verbally suggesting to the hypnotized subject complete anesthesia of the forearm. Reciprocally, during hypnotically suggested hyperesthesia the cutaneous reflex was enhanced. It is concluded that during hypnotic anesthesia and hyperesthesia excitability changes occur at the spinal level, and it is suggested that these changes probably involve the spinal internuncial system interposed between the dorsal root ganglion cells and the motoneurons. (From Abstracts, 21st Internat. Cong. Physiol., Buenos Aires, 1959, p. 124.)

Dorcus, Roy M.; Kirkner, Frank J. (1955). The control of hiccoughs by hypnotic therapy. Journal of Clinical and Experimental Hypnosis, 3 (2), 104-108.

NOTES

1:

"The present paper is devoted to a discussion of 18 cases ... of hiccoughs that were treated by hypnosis at the Long Beach Veterans Hospital during the course of the past five years. Aomost all of these cases had received some kind of medical therapy before hypnosis was employed. ...

"The age range of the patients (27-75 years) indicates that age is not a factor either in the onset of the spasm or in the termination of it by hypnosis. ... While there are some differences in the number of patients in the various [age] decile groups, these differences are in all probability due to sampling. The kinds of physical disorders fit into the table of causes abstracted from Samuels' article and it is evident that hiccough may be associated with a wide variety of physical diseases. With respect to the onset of the hiccoughs, the major number of the spasms seem to be initiated after the central nervous system has been depressed by an anesthetic. When the diaphragm is set in reflex action by some other cause such as vomiting, hiccoughs may be initiated and continue. The hypnotic treatment stressed two points in procedure: (a) an attempt to obtain complete muscular relaxation, and (b) an attempt to relieve the patient of anxiety concerning the spasm and his physical disorder. The number of hypnotic sessions required varied from one session to as many as 8 or 10 sessions. The number of sessions required could not be predicted in advance. No criteria of whether hypnosis would be successful have been evolved other than whether the patient is, generally speaking, a good hypnotic subject. Of the eighteen patients treated by this method fourteen were permanently relieved of their symptoms; three received no benefit and one received temporary benefit. Since other therapies had been tried on most of these patients, it is quite apparent that this form of treatment is very useful and should be applied as soon as possible after the advent of the spasm. This statement is not based on the fact that hiccoughs of shorter duration respond more readily to hypnotic therapy. However, hypnosis should be utilized early to control hiccoughs so that the hiccoughs will not add to the distress of otherwise seriously ill patients" (pp. 107-108).

1954

Koster, S. (1954). Experimental investigation of the character of hypnosis. Journal of Clinical and Experimental Hypnosis, 2, 42-54.

NOTES

1:

In waking, hypnosis, and sleep states 6 subjects were tested for knee-jerk height, key pressing to metronome signal, doing sums, recalling a story, etc. The Summary states:

"1. The height of the knee-jerk of all 6 subjects both in T and in "S" was much lower than in (W), the average height of all knee-jerks computed of the 6 subjects was both in T and in "S" only 39% of the average height in (W).

2. The [arm] catalepsy in T and in "S" continually existed.

3. The subjects in T and in "S" could hear well and perform active movements, though they reacted somewhat more slowly, and less forcibly than in (W) and sometimes only after some provocations.

4. The subjects both in T and in "S" could not only hear well, but could also present more or less complicated psychic impressions, reproducing them later again in "S" and also after the end of the experiment" (p. 50).

The author concluded, "Hypnosis is a sleeping-condition, but a special one. The specific difference consists of the fact that the subject's many impressions, which he would observe in a waking-condition, he does not observe now, and does not react to, aside from impressions coming to him through the hypnotist. It can then be said that there is not an absence but a decrease of the active relation with the outer world. This is exactly the same state as the one during sleepwalking and the writer must repeat after all his investigations, what has already been stated: Essentially there is no difference between the condition of a hypnotized person and that of a sleepwalker" (p. 51).

1953

Guze, Henry (1953). The phylogeny of hypnosis. Journal of Clinical and Experimental Hypnosis, 1 (3), 41-46.

NOTES

1:

"The continuity of hypnotic phenomena from infrahuman through human organisms has created an array of problems in interpretation" (p. 41). "Unfortunately, most investigators in animal hypnosis

have concerned themselves mainly with states of immobility. Because of this, they have neglected to recognize that hierarchical and group reactions of animals are just as fit in the category of hypnotic behavior" (pp. 41-42). "It is postulated in this paper that hypnosis or hypnotizability is a phylogenetically derived characteristic strongly akin to emotional readiness. It differs in expression from organism to organism within a species and from species to species" (p. 45).

## **REGRESSION**

**2002**

**Edwards, Lynn; Sapp, Marty (2002). Reoperationalizing adaptive regression during hypnosis. Australian Journal of Clinical Hypnotherapy and Hypnosis, 23 (3), 115-129.**

Employing a non-randomized two-group pre-test post-test design, this study found that a regression hypnotic transcript produced a greater reduction in conflict responses than a relaxation transcript. Finally, this study re-operationalized the concept of regression.

**GOW, MICHAEL (2002). Treating dental needle phobia using hypnosis. [Paper] Presented at IFDAS/SAAD 10th International Dental Congress on Modern Pain Control, Edinburgh, June 2003, also at BSMDH (Scot) meeting December 2003.**

"This case illustrates the effectiveness of short-term hypnosis treatment for a dental needle phobia. What is significant is the dental history of the patient and the longstanding effect of her dental phobias and how quickly hypnosis was able to remove this problem.

**Aim:** To manage dental needle phobia using hypnosis integrated into an anxiety management treatment plan."

**Case History:** Female, 48, had traumatic and painful experience at the dentist when 5, developed phobia of dental injections and treatment. Has had a dozen General Anaesthetics for dental treatment. Experiences psychosomatic pain prior to treatment.

**Methods:** Medical, dental and phobia history explored. Pre-treatment questionnaire assessed dental anxiety, reasons for anxiety, and ascertained management options. Post-treatment questionnaire assessed changes in dental anxiety and attitudes.

**Anxiety management techniques:** Needle Desensitisation, Relaxation, and Hypnosis (Regression, Progressive Muscular Relaxation, Glove Anaesthesia, Future Rehearsal etc.).

**Results:** Pre-treatment questionnaire revealed high level anxiety (26 out of high of 30 modified Corah score; and high anticipation of future pain during dental treatment (10 out of high of 10 on a Visual Analogue Scale. Post-treatment questionnaire revealed low level anxiety (12/30) and low anticipation of future pain (4/10).

**Conclusion:** Hypnosis was an effective adjunct to anxiety management in this case, demonstrating how a non pharmacological approach can find long term solutions by addressing the causes of the anxiety. Previous pharmacological approach had only addressed the symptoms of the immediate anxiety. Successful completion of prescribed dental treatment plan and changes in patient's attitudes highlight positive outcome.

Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)

This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies;

(3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

Elter-Nodvin, Edeltraud (2000). Computerized content analysis: A comparison of the verbal productions of high hypnotizable, low hypnotizable and simulating subjects (Dissertation). (<http://www.televid.com/elternodvin/dissertation/>)

This research was designed to investigate the domain of hypnosis and to explore how the "'state"' of hypnosis, along with the susceptibility to hypnosis relate to lexical choice in verbal productions as well as to primary/secondary process mentation. ... College students were screened for level of hypnotic susceptibility ... [yielding] 32 high hypnotizable subjects and 57 low hypnotizable subjects [randomly assigned to two groups] ... 29 low hypnotizable subjects and 28 low hypnotizable simulating subjects.

Responses to six Thematic Apperception Test (TAT) cards and responses to five free speech story-openings were collected and tape-recorded during [counterbalanced waking and hypnosis conditions].... verbal productions were transcribed and [computer] analyzed by ... the Dartmouth Adaptation of The General Inquirer ... and COUNT with the Regressive Imagery Dictionary ... .

To summarize, findings suggest that the changes in SECONDARY PROCESS and THOUGHT, as well as the DAGI-III-variable EMOTION and the COUNT-RID-variable EMOTION, may be a result [sic] other than hypnotic ability or the hypnotic experience. The possibility has been raised, that subjects who had been instructed to simulate hypnosis were successful in discerning the experimental, implicit

demands to respond with decreased SECONDARY PROCESS and THOUGHT as measured by the DAGI-III and COUNT-RID respectively and to present the appearance of a genuinely hypnotized subject. The same was true for the increase in EMOTION as measured by the DAGI-III as well as by the COUNT-RID. The interaction between the condition (baseline vs. hypnosis) and the group (level of hypnotic susceptibility) would have provided the strongest support for the assertion that hypnosis changes a dimension (e.g. enhances primary process responding or decreases secondary process mentation) in highly hypnotizable subjects.

The likelihood that the hypnotic main-effect can be attributed at least to some extent to demand characteristics has been supported by the current results. The hypnotic state, even though it can be measured through behavioral measures such as the HGSHS and the CAH, cannot be measured by content measures of verbal productions.

Findings are discussed in regard to previous literature suggesting a link between primary process and hypnosis and suggestions for future research are made. In addition, theoretical and practical implications are discussed. - From dissertation at web site <http://www.televid.com/elternodvin/dissertation/>

1997

Patterson, David R.; Adcock, Rebecca J.; Bombardier, Charles H. (1997). Factors predicting hypnotic analgesia in clinical burn pain. International Journal of Clinical and Experimental Hypnosis, 45 (4), 377-395.

The use of hypnosis for treating pain from severe burn injuries has received strong anecdotal support from case reports. Controlled studies provide less dramatic but empirically sound support for the use of hypnosis with this problem. The mechanisms behind hypnotic analgesia for burn pain are poorly understood with this patient population, as they are with pain in general. It is likely that, whatever the mechanisms are behind hypnotic pain analgesia, patients with burn injuries are more receptive to hypnosis than the general population. This article postulates some variables that may account for this enhanced receptivity, including motivation, hypnotizability, dissociation, and regression.

1993

Watkins, Helen H. (1993). Ego-State therapy: An overview. American Journal of Clinical Hypnosis, 35, 232-240.

Ego-state therapy is a psychodynamic approach in which techniques of group and family therapy are employed to resolve conflicts between the various "ego states" that constitute a "family of self" within a single individual. Although covert ego states do not normally become overt except in true multiple personality, they are hypnotically activated and made accessible for contact and communication with the therapist. Any of the behavioral, cognitive, analytic, or humanistic techniques may then be employed in a kind of internal diplomacy. Some 20 years experience with this approach has demonstrated that complex psychodynamic problems can often be resolved in a relatively short time compared to more traditional analytic therapies.

1989

Zamore, Neal; Barrett, Deirdre (1989). Hypnotic susceptibility and dream characteristics. Psychiatry Journal of the University of Ottawa, 14 (4).

This study examined the relationship of hypnotic susceptibility to a variety of dream characteristics and types of dream content. A Dream Questionnaire was constructed synthesizing Gibson's dream inventory and Hilgard's theoretical conceptions of hypnosis. Several dream dimensions correlated significantly with hypnotizability as measured by the Harvard Group Scale of Hypnotic Susceptibility and the Field Inventory. For Ss as a whole, the strongest correlates were the frequency of dreams

which they believed to be precognitive and out-of-body dreams. Ability to dream on a chosen topic also correlated significantly with hypnotic susceptibility for both genders. For females only, there was a negative correlation of hypnotizability to flying dreams. Absorption correlated positively with dream recall, ability to dream on a chosen topic, reports of conflict resolution in dreams, creative ideas occurring in dreams, amount of color in dreams, pleasantness of dreams, bizarreness of dreams, flying dreams, and precognitive dreams.

1988

Nash, Michael R. (1988). Hypnosis as a window on regression. Bulletin of the Menninger Clinic, 52, 383-403.

Examines the empirical evidence for temporal and topographic regression during hypnosis--which Freud explicitly defined as regressive. A review of more than 100 studies spanning 60 years of research found no convincing evidence that developmentally previous psychological structures are reinstated during hypnosis (temporal regression). In contrast, there is evidence that hypnosis enables subjects to elicit more imagistic, primary process, and affect-laden material (topographic regression). The author recommends a careful reexamination of two core assumptions underlying the concept of temporal regression: (1) that early structures in human development are imperishable, and (2) that regression necessarily involves reinstatement of infantile psychological structures.

1983

Eisen, Marlene R.; Fromm, Erika (1983). The clinical use of self-hypnosis in hypnotherapy: Tapping the functions of imagery and adaptive regression. International Journal of Clinical and Experimental Hypnosis, 31 (4), 243-255.

The authors present a new method of interweaving hetero-hypnotic psychotherapy and self-hypnosis. In the hetero-hypnotic sessions, the hypnotherapist acts as a dependable parent figure who is supporting and available when that is desirable, but who also encourages and fosters the patient's efforts to develop his/her inner resources and ability to function autonomously. Self-hypnosis is utilized for its rich idiosyncratic imagery. The hypnotherapist uses and elaborates on this rich, affect-loaded imagery. At other times the therapist takes a guiding role in producing therapeutic metaphors of positive valence. The patient uses and enlarges on these during self-hypnosis between the weekly therapeutic hours. In addition, the hypnotist may counteract any negative strong self-hypnotic images during hetero-hypnosis. Self-directed self-hypnosis allows patients to experience openness and receptivity to internal and unconscious processes against which they may defend themselves in the dyadic relationship with the therapist. For patients struggling with issues of control and for patients fighting their own regressive pull towards dependency, this mode of therapy appears to be particularly effective. The emphasis in this paper is on imagery and on the inter-twining of the two modalities, hetero-hypnosis and self-hypnosis.

1976

Kampman, R. (1976). Hypnotically induced multiple personality: An experimental study. International Journal of Clinical and Experimental Hypnosis, 24, 215-227.

The purpose of the study was to clarify the frequency of appearance of a hypnotically induced secondary personality and to compare Ss who were able to create secondary personalities in hypnosis to control Ss who could enter a deep hypnotic trance but were unable to produce secondary personalities.

The sample of 1,200 pupils was made up of the 3 highest grades of the secondary schools in the city of Oulu, Finland. A total of 450 students volunteered to participate in the study. All those who could enter a deep hypnotic state, 78 in all, were selected for closer study. 32 Ss were able and 43 were unable to create multiple personalities in hypnosis.

Ss also underwent a psychiatric interview. In addition, the identity of Ss was measured.

Both the psychiatric interview and identity examination gave parallel results to the effect that Ss capable of producing secondary personalities were clinically healthier and more adaptive than the group without secondary personalities. This finding is at variance with results presented in previous studies.

Procedure for induction of multiple personalities involved re-hypnotizing Ss, suggesting, "You go back to an age preceding your birth, you are somebody else, somewhere else," and repeating the suggestion many times. Other suggestions were given that everything was completely normal, nothing miraculous was happening. A multiple personality was counted if the S then said he was a human being, was able to give his name and where he lived, could describe the social environment and his own personality.

Lavoie, Germain; Sabourin, Michel; Ally, Gilles; Langlois, Jacques (1976). Hypnotizability as a function of adaptive regression among chronic psychotic patients. International Journal of Clinical and Experimental Hypnosis, 24, 238-257.

The Rorschach and the Stanford Hypnotic Susceptibility Scale, Form A (SHSS:A) were administered to a sample of 56 chronic psychotic patients, mainly schizophrenics (N = 48). Verbatim transcriptions of tape-recorded Rorschach protocols were scored according to the Holt system (Holt et al., 1963), which provides an index of adaptive regression. Experimental procedures were conducted single blind. With one exception, all the patients high on SHSS:A were among those obtaining a higher adaptive regression index, while 50% of those obtaining higher adaptive regression index were high on SHSS:A. A systematic investigation of ego functions was proposed for a better understanding of this asymmetry, although the results already gave ostensible positive support to the Gill and Brenman (1959) theory, and to the theory of ego autonomy.

Levin, L. A.; Harrison, R. H. (1976). Hypnosis and regression in the service of the ego. International Journal of Clinical and Experimental Hypnosis, 24, 400-418.

28 highly hypnotizable female Ss were selected to test the hypothesis that hypnosis is characterized by regression in the service of the ego (adaptive regression). 2 tasks, producing a hypnotic dream and telling a TAT story, were administered individually under hypnotic and normal waking conditions. Scoring for adaptive regression yielded 2 factors, one for the regressive aspects of the fantasies produced, the other for cognitive mastery of those fantasies. An increase in primary process thinking was found in hypnosis, particularly in the hypnotic dream. There was a relationship between S's capacity for adaptive regression and the amount of adaptive regression found in hypnosis. Although facilitating regression from secondary to more primary process thinking, hypnosis does not inherently provide mechanisms by which primary process manifestations can be utilized adaptively by the ego. Such mechanisms are ego functions which tend to be amplified by hypnosis only in Ss who demonstrate good capacity for adaptive regression.

## NOTES

2:

This document reports on a U.S. Army research project using hypnosis to collect high fidelity samples of the voice under "combat stress" conditions in the laboratory. Using hypnotic regression, combat veterans "re-experienced" their own, actual high stress combat situations. Besides subjective reports of stress levels by subjects, physiological stress measures were obtained from polygraph recordings of heart, respiration and GSR activity. The voice samples were later analyzed by spectrographic techniques to determine which factors remain invariant to identify and authenticate the speaker in a military communications situation. Hypnotic techniques were shown to be useful in establishing controlled emotional states for laboratory research purposes. (Richard Bloom)

1970

Shor, Ronald E. (1970). The three-factor theory of hypnosis as applied to the book-reading fantasy and to the concept of suggestion. International Journal of Clinical and Experimental Hypnosis, 18, 89-98. Maintained that many of the conflicting viewpoints in theories of hypnosis parallel the descriptive complexity of the phenomena. A 3-factor theory of hypnosis is surveyed in which hypnotic depth is conceived as a complex of 3 separate but complementary processes or dimensions. The theory is used to illuminate the book-reading fantasy and the concept of suggestion. (Spanish & German summaries) (16 ref.) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

1968

Meares, Ainslie (1968). Hypnotherapy without the phenomena of hypnosis. International Journal of Clinical and Experimental Hypnosis, 16, 211-214.

A clear distinction must be drawn between the phenomena of hypnosis and the hypnotic state itself. Hypnosis is a state of mind characterized by regression to atavistic mental functioning. The phenomena are produced as a result of this regression. The production of phenomena in either the induction or the therapeutic process is generally undesirable. Hypnosis may be used for reduction of anxiety or as a therapeutic experience without the production of any hypnotic phenomena. (French & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1960

Schneck, Jerome M. (1960). Comment on a theory of hypnosis. International Journal of Clinical and Experimental Hypnosis, 8 (4), 231-236.

(Author's Summary) I presented, in previous reports, a holistic, biological theory of hypnosis which emphasized the core element in the nature of hypnosis, to which other theoretical propositions appear to serve as embellishments and secondary detail, valid as the various observations may be. The proposed theory states, "The hypnotic state, in terms of its basic ingredient, is that condition represented by the most primitive form of psychophysiological awareness of individual-environmental differentiation attainable among living organisms." An explanation of the theory, its ramifications, and the ontogenetic and phylogenetic implications have been disclosed elsewhere. Meares regarded the theoretical proposal as too complex, with clarity obscured. A review of the material tends to affirm the opposite, I believe. Meares presents his own ideas regarding the nature of hypnosis as a regression to the archaic mental function of suggestion. Suggestion is recognized as verbal and non-verbal. The ontogenetic and phylogenetic features of this concept are included among other ramifications of his discussion. I have offered the opinion that Meares' ideas about hypnosis do not contradict my theory. On the contrary, his experience is quite consistent with the theoretical concepts I have offered, and his understanding of the nature of hypnosis fits in quite easily with my own. His stress on archaic mental function is not, however, as far reaching as the proposals I have made, but it does constitute one proper aspect of the broader spectrum of hypnosis. Of this there is a definite core as outlined. Secondarily, there are manifold, complex, superimposed ingredients and embellishments with psychological, physiological, and sociological determinants.

1957

Schneck, Jerome M. (1957). Hypnoanalytic observations on the psychopathology of fainting. Journal of Clinical and Experimental Hypnosis, 5 (4), 167-171. (Abstracted in Psychological Abstracts 62: 3 II 67S)

Varieties of fainting have been described as hysterical syncope, vasodepressor syncope, and carotid sinus reactions, among others. Fainting has been linked in general with personality problems, emotional instability, and immaturity. It has been called a mechanism for blocking of ego functions in its role of primitive defense against overwhelming stimuli. The present paper gives in greater detail the specific dynamics in a patient with fainting episodes. A crucial event incorporating major dynamic ingredients was an operative procedure in childhood. The psychological impact of this trauma was revived during a spontaneous hypnotic regression. The personality matrix significant for this patient in relation to the fainting episodes consisted of passive, masochistic submission to a dominant, highly influential mother whose pressure was felt by the patient as pervasive and stifling. Circumstances associated psychologically with this feeling apparently triggered the fainting reactions. As he matured through the years and cast off increasingly this type of maternal influence, the tendency toward fainting reactions diminished" (p. 170).

## NOTES

1:  
The hypnotic state has four attributes: "an effect of emotional stabilization, a retrogression to an infantile psychological functioning, suggestibility, and transmissibility of the hypnotic relationship" (p. 82). "SUGGESTIBILITY is a special motivation to accept, incorporate within one's self, and execute direct or implicit propositions, which is equivalent to the motivation of a child to accept, assimilate and carry out the propositions of its parents" (p. 84). The authors propose that verbal and non-verbal suggestions are incorporated during the course of education, lasting years and thus becoming in effect

post-hypnotic suggestions. "The person will have in the future a special responsiveness, that may be more or less pronounced according to the circumstances, for those data (coming from books, movies, conversations, etc.) which agree with his emotionally-incorporated post-hypnotic suggestions" (p. 85). If while in an auto-hypnotic condition he comes in contact with someone "who appears to be the embodiment of the convictions or prejudices that on being stimulated started the process of emotional activation that led to the development of the hypnotic state, there may be a transformation of the auto-hypnotic condition into an interpersonal hypnotic relationship" (p. 86).

According to the authors, this theory can explain post-hypnotic (negative) sequellae. It also accomodates explanations of both Natural or Direct Orientation inductions and Indirect Orientation inductons, and explains phenomena such as patients entering hypnosis rather automatically while awaiting the appearance of Mesmer in his waiting room.

"To conclude, we will stress that the psychological mechanism of hypnotic induction is exactly the same in everyday life and in the experimental environment. The apparent differences like [sic] in the behavior of the subject in the hypnotic state, and are due to the motivation that arises from the circumstances and to the convictions, capacities, psychological maturity, and degree of retrogression of the individual" (p. 96).

Solovey, Galina; Milechnin, Anatol (1957). Concerning the nature of hypnotic phenomena. Journal of Clinical and Experimental Hypnosis, 5 (2), 67-76.

## NOTES

1:

The authors write about the place of the hypnotic state in general psychology: "the study of the psychological mechanisms that make the appearance of the phenomenon possible, which need not be different from the normal and current psychological mechanisms in everyday life\_" (p. 67). They classify hypnotic phenomena into three groups:

"I. Phenomena which are a function of the state of psychological retrogression (hypnotic depth), appearing in spontaneously [sic] or when proposed by the operator.

II. Phenomena which appear without any specific suggestion, as a side issue of other suggestions, capable of originating emotional states in the subject.

III. Phenomena which are independent of all suggestion, being a constituent part of the hypnotic state itself, in its 'positive' or 'negative' forms" (p. 68).

Using this framework, the authors describe several aspects of hypnosis: catalepsy, anesthesia, retrogression, the taking of a role, negativism and resistance, visceral changes, emotional stabilization, psychotherapeutic benefits (indirect). They observe that direct suggestions are often not necessary for therapeutic benefit, and give as an example the tendency for less bleeding when dentists suggest that patients will not feel less pain.

"For the elucidation of this point, the authors carried out an experiment in a dental clinic, taking six easily hypnotizable subjects in whom dental extractions were to be performed. They were given only the suggestions that they would feel the doctor working, but not experience pain ... that they would pay no attention to it ... or even if they felt a little pain, this would not trouble them and they would bear it perfectly ... Nothing was said about the loss of blood. As a result, in all the cases the loss of blood was slight, practically insignificant, though technically difficult extractions of roots were included" (p. 74).

"The explanation of hypnotic phenomena as natural and normal consequences of the hypnotic emotional state, and of the state of psychological retrogression, eliminates the supposed mysterious powers of suggestion. Suggestion is thus relegated to the modest role of a litmus paper which reveals the psychological functioning of the individual in an experimental environment. On the other hand, in everyday-life hypnosis, in the principal hypnotic relationships of parents with their children, of teachers with their pupils, etc. (11), suggestibility plays an important role in education or re-education" (p. 75).

1956

Guze, Henry (1956). Kline, M. V. A scientific report on 'The Search for Bridey Murphy' [Review]. Journal of Clinical and Experimental Hypnosis, 4 (3), 127-130.

This book contains chapters by scientists who are critical of the book on Bridey Murphy written by Morey Bernstein. The critiques discuss the following phenomena in relationship to reports of 'past lives':

idea of traveling back in time, glossolalia or speaking in tongues, ecstatic states in certain religious sects, physiological regression (Babinski), medical hypnosis, mysticism, reincarnation theories in religion and philosophy, miraculous healing, and supernatural phenomena.

Kline describes a parallel case described by Professor Flourney (Helene Smith) in which previous life on other planets and use of Martian language was claimed.

Solovey, Galina; Milechnin, Anatol (1956). Concerning a theory of hypnosis. Journal of Clinical and Experimental Hypnosis, 4, 37-45.

#### NOTES

1:

"The essential attributes of the hypnotic condition may be understood to derive from three sources:

- 1) The hypnotic emotional state per se
- 2) The resultant motivation of the 'subject' to comply with the desires of the 'operator' (reinstating a child-like responsiveness).
- 3) The RETROGRESSION to an earlier form of psychological functioning that takes place under a hypnotic state of growing intensity" (p. 43).

"Although the retrogressive process is a general response to emotions and probably exists in some toxic states as well, it has a remarkable feature in the hypnotic state: THE COALESCENCE OF MOTIVATION AND RETROGRESSION, which exists in hypnotized people, permits a peculiar manipulation of the retrogressed condition. The peculiar responsiveness of the subject may be tested and molded by means of propositions which act as suggestions. In this manner, the so-called HYPNOTIC PHENOMENA are elicited" (p. 44).

Solovey de Milechnin, Galina (1956). Concerning the attributes of the hypnotic state. Journal of Clinical and Experimental Hypnosis, 4 (3), 115-126.

#### NOTES

1:

This article considers four areas:

- "1) The essential attributes of the 'positive' ('empathetically-induced') hypnotic emotional state.
- 2) The distinguishing features of the 'negative' ('authoritarian') hypnotic emotional state.
- 3) 'Suggestibility' -- as a motivation to comply with the desires of the person who has induced either of these emotional conditions.
- 4) The retrogression to a more primitive form of psychological functioning: a phenomenon which is common to all sufficiently intense emotions.
- 5) 'Hyper-suggestibility' -- as the peculiar behavior that is made by the coalescence of the motivation to comply with the operator's desires and the retrogressed condition" (p. 115).

Wagner, Frederik F. (1956). A dynamic approach to the problem of hypnotic induction. Journal of Clinical and Experimental Hypnosis, 4, 93-98.

#### NOTES

1:

The author discusses inductions in a broadly psychoanalytic framework. "In keeping with the terminology, hypnotic induction can be defined as a deliberate attempt to disturb the psychic [sic] equilibrium leading to a reorganization on a regressed level. This process takes place in a structured,

goal directed interpersonal relationship to which the subject attempts to adjust himself. The outcome of this potential conflict determines whether or not the subject can be hypnotized. Hypnotizability can consequently be formulated as the degree of motivation to regress in this transference-like relationships with the hypnotist" (p. 95). He suggests that the thoughts and fantasies about the hypnotist are very important, as well as the kind of physical setting the subject would prefer, to assure adequate induction.

"With such information at hand the hypnotist would probably, to a greater extent, be able to phrase his suggestions in the patient's lingo and assume a proper attitude according to the patient's needs. By avoiding suggestions which stir up fearful fantasies about hypnosis he will try to keep anxiety at a minimum. By assuming a protective parental role he may stimulate infantile needs and give the patient a maximum of security; anxiety, and consequently, defenses may thereby be minimized. He may even assume an authoritarian role, deliberately stirring up anxiety, if he expects the subject will respond with regression" (p. 97).

1955

Rosen, Harold (1955). Regression hypnotherapeutically induced as an emergency measure in a suicidally depressed patient. Journal of Clinical and Experimental Hypnosis, 3 (1), 58-70.

#### NOTES

1:

After cautioning that regressive techniques are only to be undertaken by very experienced therapists, the author states in conclusion, "However, if the therapist have a thorough grounding in dynamic psychiatry, he may as an emergency measure, through the adjunctive use of hypnotic techniques of the type described in this article even induce regressive phenomena in the potentially homicidal or suicidal psychotic patient, in order that they may be integrated and utilized in the service of the ego, at first by blotting out ego-boundaries between patient and therapist, so that later on during the course of the therapeutic process these self-same ego-boundaries may be re-defined and re-constituted on a more mature emotional level and with much healthier personality functioning.

de Milechnin, Galina Solovey (1955). Concerning the concept of hypnotic depth. Journal of Clinical and Experimental Hypnosis, 3 (4), 243-252.

#### NOTES

1:

The author discusses the following:

A. "Two basic aspects of hypnosis which do not appear to be in a direct relationship to the traditional concept of hypnotic depth:

1) the effectivity of suggestions

2) the psycho-therapeutic (or psycho-prophylactic effects of hypnosis)" (p. 243)

B. "the problem about the nature of the hypnotic state and its levels of 'depth,' ...

1. What is the hypnotic state?

2. What is the meaning of the traditional levels of 'hypnotic depth?'" (p. 244).

C. Three hypothetically 'pure' points of reference:

1. The waking state as it is seen in the normally developed adult person in our present civilization.

2. The 'deep' somnambulistic hypnotic state in its most characteristic aspect.

3. The still 'deeper' stuporous hypnotic state" (p. 245).

D. "three periods from the continuum of a normal person's maturation:

1. The hypothetically 'psychologically completely mature' adult

2. The normal child from 1 to 3 years of age

### 3. The newborn infant" (p. 247).

She relates C and D. "If we compare: 1) the 'somnambulistic' hypnotic behavior of the adult to the normal behavior of the child from 1 to 3 years of age approximately, and 2) the 'stuporous' behavior under hypnosis to the normal behavior of the neonate, their general mechanisms appear to coincide" (p. 250). "The so-called light and medium stages of hypnosis can be understood as an overlapping of the 'adult' and 'childhood' psychological mechanisms with a progressive reduction of the former and increase of the latter, in a reversion of the progress of normal psychological maturation" (p. 250).

"Summary.

1. The hypnotic state is a special emotional state, the intensity of which varies similarly to that of other emotional states and cannot be graduated.

2. The traditional 'hypnotic depth' is nothing else than a 'retrogression' to a more primitive psychological mechanism. This retrogression constitutes one of the basic phenomena of the hypnotic state" (p. 251).

### 1953

Conn, Jacob H. (1953). Hypnosynthesis III. Hypnotherapy of chronic war neuroses with a discussion of the value of abreaction, regression and revivication. Journal of Clinical and Experimental Hypnosis, 1, 29-43. (Abstracted in Psychological Abstracts, 53: 6687)

Author's Summary - Three examples of chronic war neuroses which were successfully treated by hypnotherapy are presented. The clinical material would seem to indicate that the patient in the trance state is greatly influenced by the attitude and goal of the therapist and tends to produce the type of material which is expected of him. The protocols reveal that the hypnotized patient responds to a permissive, calm, attitude with relatively little emotional display, and by talking about harrowing war experiences in a matter-of-fact manner.

It would appear that merely to recall the traumatic experience without a personalized, constructive, emotional relation to a supporting, understanding therapist is of little therapeutic value. The crux of the therapeutic problem in every approach, whether it be narcosynthesis, narco-analysis, hypnosynthesis, or the hypnotic intensification of an emotion is to bring about the integration of unbearable experiences which previously had been dissociated and obliterated from memory or which automatically reappear and disrupt smooth ego functioning.

It is postulated that the hypnotic trance state provides a unifying, integrating inter-personal experience which is of value in the treatment of chronic war neuroses.

Schneck, Jerome M. (1953). A theory of hypnosis. Journal of Clinical and Experimental Hypnosis, 1 (3), 16-17.

"This theory of hypnosis proposes then, that the hypnotic state, in terms of its basic ingredient, is that condition represented by the most primitive form of psychophysiological awareness of individual-environmental differentiation attainable among living organisms. The capacity to move in the direction of functioning which would bring to the fore this most primitive state to the greatest degree possible probably varies among different organisms. The retention of some degree of such capacity probably obtains among all biological forms" (p. 17).

Mauer, Magaly H.; Burnett, Kent F.; Ouellette, Elizabeth Anne; Ironson, Gail H.; Dandes, Herbert M. (1999). Medical hypnosis and orthopedic hand surgery: Pain perception, postoperative recovery, and therapeutic comfort. International Journal of Clinical and Experimental Hypnosis, 47 (2), 144-161.

Orthopedic hand-surgery patients experience severe pain postoperatively, yet they must engage in painful exercises and wound care shortly after surgery; poor patient involvement may result in loss of function and disfigurement. This study tested a hypnosis intervention designed to reduce pain perception, enhance postsurgical recovery, and facilitate rehabilitation. Using a quasi-experimental research design, 60 hand-surgery patients received either usual treatment or usual treatment plus hypnosis. After controlling for gender, race, and pretreatment scores, the hypnosis group showed significant decreases in measures of perceived pain intensity (PPI), perceived pain affect (PPA), and state anxiety. In addition, physician's ratings of progress were significantly higher for experimental subjects than for controls, and the experimental group had significantly fewer medical complications. These results suggest that a brief hypnosis intervention may reduce orthopedic hand-surgery patients' postsurgical PPI, PPA, and anxiety; decrease comorbidity; and enhance postsurgical recovery and rehabilitation. However, true experimental research designs with other types of controls must be employed to determine more fully the contribution of hypnosis to improved outcome.

1998

Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that

can help take away pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

Dane, Joseph R. (1996). Hypnosis for pain and neuromuscular rehabilitation with multiple sclerosis: Case summary, literature review, and analysis of outcomes. International Journal of Clinical and Experimental Hypnosis, 44 (3), 208-231.

Videotaped treatment sessions in conjunction with 1-month, 1-year, and 8-year follow-up allow a unique level of analysis in a case study of hypnotic treatment for pain and neuromuscular rehabilitation with multiple sclerosis (MS). Preparatory psychotherapy was necessary to reduce the patient's massive denial before she could actively participate in hypnosis. Subsequent hypnotic imagery and posthypnotic suggestion were accompanied by significantly improved control of pain, sitting balance, and diplopia (double vision), and a return to ambulatory capacity within 2 weeks of beginning treatment with hypnosis. Evidence regarding efficacy of hypnotic strategies included (a) direct temporal correlations between varying levels of pain relief and ambulatory capacity and the use versus nonuse of hypnotic strategies, (b) the absence of pharmacological explanations, and (c) the ongoing presence of other MS-related symptoms that remained unaltered. In conjunction with existing literature on hypnosis and neuromuscular conditions, results of this case study strongly suggest the need for more detailed and more physiologically based studies of the phenomena involved. - Journal Abstract

**1993**

Everett, John J.; Patterson, David R.; Burns, G. Leonard; Montgomery, Brenda; Heimbach, David (1993). Adjunctive interventions for burn pain control: Comparison of hypnosis and Ativan. Journal of Burn Care and Rehabilitation, 14, 676-683.

Thirty-two patients hospitalized for the care of major burns were randomly assigned to groups that received hypnosis, lorazepam, hypnosis with lorazepam, or placebo controls as adjuncts to opioids for the control of pain during dressing changes. Analysis of scores on the Visual Analogue Scale indicated that although pain during dressing changes decreased over consecutive days, assignment to the various treatment groups did not have a differential effect. This finding was in contrast to those of earlier studies and is likely attributable to the low baseline pain scores of subjects who participated. A larger

number of subjects with low baseline pain ratings will likely be necessary to replicate earlier findings. The results are argued to support the analgesic advantages of early, aggressive opioid use via PCA or through careful staff monitoring and titration of pain drugs.

1992

Alden, Phyllis (1992, October). The use of hypnosis in the management of pain on a spinal injuries unit. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

NOTES

1:

[Author is at Royal National Hospital in England]

To have a spinal injury is one of the most devastating injuries that can happen, reducing you suddenly from a normal life to situation of loss of control, helplessness, etc.- -with nothing to say about what is being done in surgery or other aspects of treatment.

In UK patients come for acute care and rehabilitation all in one place. Over 2 1/2 yrs we had 46 referrals. 7 refused hypnosis ("witch doctoring"). 30 benefitted.

Appel, Philip R. (1992). Performance enhancement in physical medicine and rehabilitation. American Journal of Clinical Hypnosis, 35, 11-19.

Performance enhancement or mental practice is the "symbolic rehearsal of a physical activity without any gross muscular movements" to facilitate skill acquisition and to increase performance in the production of that physical activity. Performance- enhancement interventions have been well known in the area of sports psychology and medicine. However, clinical applications in physical medicine and rehabilitation have not flourished to the same extent, though the demand for improved physical performance and the acquisition of various motor skills are as important. In this paper I will describe how hypnosis can potentiate mental practice, present a model of mental practice to enhance performance, and describe how to help patients access an ideal performance state of consciousness.

Weber, Alison Mary (1992, October). Hypnosis with brain-injured patients. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

NOTES

1:

INTRODUCTION. The purpose of this paper is a consciousness-raising one. The use of hypnosis with brain-injured people has been relatively neglected with respect to its potential benefit for the patients themselves and also for increasing our knowledge of hypnotic ability. Occasional reports concerning the use of hypnosis with brain-injured patients have appeared (e.g., Crasilneck & Hall, 1970 & 1975; LaClave & Blix, 1989; Manganiello, 1986). However, clinicians often assume that such patients are not able to utilise hypnotic techniques. This assumption appears to derive from three mistaken beliefs: 1. The belief that hypnotic trance ability requires an intact brain. Actually, a fully intact brain is not necessary for entering a hypnotic trance. 2. The belief that brain damage means that the person is totally mentally incompetent, a "vegetable." In reality there are degrees of brain injury that vary from coma or vegetative state through to relatively mild changes in ability that may not be immediately obvious yet significantly impact the person's functioning in everyday life. 3. The belief that brain-damaged individuals are identical with respect to their type of cognitive disability. In actual fact, the cognitive and other effects of brain injury vary according to location within the brain's functional systems.

CASE EXAMPLES. All four cases are people of apparently average or better ability prior to injury as judged from their educational and vocational history. Before discussing these examples, I should point out that the basic induction technique used has generally been the same one that I use with non-brain-

injured people. This technique is one that encourages mental and physical relaxation and a mental attitude of passivity and dissociation (Weber, 1981). All were taught to use self-hypnosis as a means of making the benefits available as needed. No hypnotizability scales were used and the issue of using such scales with brain-injured people will be commented upon later.

CASE 1 is a 39 year-old man who fell hitting his head and sustaining a closed head injury. The main effect of that injury was severe slowing of information processing speed. This problem is a common one in cases of closed head injury, is thought to be related to diffuse microscopic axonal injury, and causes experiences of mental fatigue, overload, and stress. The mentally passive, relaxed dissociative state offered through hypnosis helps prevent and reduce these overload problems. In this patient's case, his use of the hypnotic technique enabled him to increase his daily activity level from one of mainly sleeping and resting in darkened rooms to one that included a live-in relationship with his former wife and engaging in hobbies and social activities.

CASE 2 is a 22 year-old man who had a malformation of blood vessels in the left temporoparietal area of the brain. He was undergoing surgical correction of this malformation when it hemorrhaged and he was left aphasic and paralysed down the right side of his body. At the time of hypnotic treatment, he had switched to using his left hand for writing, was able to walk though with a limp, and was able to converse intelligibly but with some underlying language difficulties. He particularly complained of right-sided pain and general numbness of his body. Post-hypnotic suggestions about his body feeling normal and solid together with imagery related to swimming were effective in eliminating the pain and reducing the numbness so that he experienced his body as comfortable and "more normal." He was so comfortable physically that he started earning a living by mowing lawns.

CASE 3 is a 40 year-old man who fell at work, sustained a closed head injury, was unconscious for 1.5 hours, and had no recall of events for 2.5 days after injury. Five years later he still showed a very disorganised and fragmented memory that was suggestive of frontal system dysfunction. He was also able to recall very little of his life prior to injury and this lack of autobiographical memory was very disconcerting to himself and to his family. He was able to benefit from post-hypnotic suggestions concerning his ability to form associations to pictures in the family photo album. These associations were then used as a basis for his making a written autobiographical outline to which he could refer as needed.

CASE 4 is a 47 year-old man who was showing subtle changes in personality over about 10 years, suddenly had a severe grand mal seizure during which he stopped breathing, and was found to have a large meningioma arising from the falx and extending bilaterally over the top of his brain. There was also evidence of recent hemorrhage within the tumor. The tumor was surgically removed but due to its previous pressure on the brain and to possible anoxia when he stopped breathing, he was left with cognitive problems of poor planning and organizing, slowed mental processing, and memory problems secondary to these other problems. He also showed emotional lability and disinhibition and physical problems that at first involved paralysis but later improved to leg weakness and spasticity and arm weakness and incoordination. Hypnotic techniques helped this patient in several ways: (a) Mental relaxation and dissociation resulted in better emotional control and some relief of the painful knotting of his leg muscles. (b) Age regression was successful in improving his manual coordination for the purpose of accordion playing, an activity of great emotional significance to this patient and his wife. During regression to age 15 years, he reported a twitching of his arm muscles (also observed by the therapist), a feeling that his arms and hands could "move more freely and flexibly as if a resistant force had been removed," and a feeling like "electrical recharging and reconnecting." His accordion playing noticeably improved from about 15 percent to about 90 percent competency and he was able to play again from memory for the first time since his surgery. (c) Post-hypnotic suggestions about his brain connecting to his leg muscles and these muscles working smoothly resulted in his being able to walk around the block without cramping for the first time since his surgery and a few weeks later he was able to walk for four or five hours in the mall instead of being limited to 30 minutes. (d) The

patient also reported generally improved well-being as "having more energy, like another veil has been taken off so that things look sharper and more in focus."

These four cases represent just a few of the ways brain-injured people can be helped by hypnosis. There are sure to be more ways just as there are for people with normal brains. In order to adapt hypnotic techniques to the needs of brain-injured people, some understanding of their particular brain-function problems is important.

**HYPNOSIS AND BRAIN FUNCTION.** Because of time limits only a very quick and simplified overview of brain function can be provided but it should serve to give a general "feel" for a neuropsychological orientation to hypnosis with brain-injured people. It is based partly on Luria's model of brain function (Luria, 1973).

**1. Arousal and Some Physiological Functions.** These functions involve the brain stem. Arousal functions include sleeping/waking, consciousness/coma, and level of general alertness. The brainstem also controls various physiological functions such as breathing, heart rate, and blood pressure.

**2. Knowledge.** Information from auditory, visual, and somesthetic path ways generally goes to the posterior half of the brain on the side opposite that of stimulus presentation. There are three levels of processing: (a) Primary processing involving initial registration and consciousness of stimuli; (b) Secondary perceptual elaboration of sensory input so that it makes perceptual sense. For example, in the visual modality the lines and colors registered in the primary area are organized into cohesive shapes in the secondary area. (c) Tertiary processing involves integration of input across modalities, for example, the ability to associate an auditorally heard word with the visually presented object it symbolizes.

**3. Action.** This aspect of brain function includes both motor and mental performance and embraces physical action, speech, and active thinking such as generating ideas and problem-solving. It is located in the anterior half of the brain and also has three levels: (a) Primary control of discrete muscle groups which mainly involves one side of the brain controlling the opposite side of the body; (b) Secondary areas underlie the ability to organize discrete muscle groups into a sequence such as brushing one's teeth; (c) Tertiary executive areas which are critical to the generation of purposive behaviour, goals, plans, self-monitoring and adaptation.

**4. Lateralization of Cognitive Function.** The two cerebral hemispheres are usually specialized in the following way for most right-handed people: (a) Left Hemisphere language; symbolic, analytic, sequential type thinking; and probably motor planning. (b) Right Hemisphere visuospatial, melodic, holistic, synthetic thinking.

**5. Information Processing Speed.** This aspect of mental function seems to depend on the axonal connections that form the white matter of the brain. Speed of information processing refers to the amount of information that can be attended to and processed within a given amount of time and includes both external stimuli like sights and sounds and also internal ones such as thoughts and memories.

**6. New Learning and Memory.** This feature of our abilities involves moving initially registered information into long term storage. The hippocampus is particularly critical in this process. The thalamus is thought to play a part in cued recall. General strategies for encoding and retrieval are probably influenced by frontal system function.

**7. Emotional and Motivational Function.** These functions appear to relate to the limbic system and basomedial frontal areas of the brain. These areas influence emotional intensity, emotional and social self-control, and motivation to initiate action.

**8. Attention.** Attentional function involves several brain areas. The brainstem is responsible for general arousal and level of alertness, white matter connections contribute to how much information a person can attend to and process within a given time, and the frontal cortex and its connections direct and organize the purposive focus of attention.

Any given mental or behavioral ability depends upon a complex system of brain areas and levels of processing. The effects of brain injury vary according to location and severity of damage, and also the person's pre-injury condition and life style.

Obviously, the induction and suggestion techniques of hypnosis need to be based upon a neuropsychological understanding of the patient's cognitive strengths and weaknesses. These factors also need to be considered when interpreting hypnotizability scores on standard scales and perhaps special scales need to be devised for work with such patients. The most common cognitive deficits encountered when working with brain-injured patients in the post-acute rehabilitation programs with which I have been associated have been those impacting memory, information processing speed, and executive function. Specific comments about these areas of deficit as they impact hypnosis are now given

**Memory.** A person with a defective ability to store new information (related to hippocampal dysfunction) is going to do well with post-hypnotic suggestions of amnesia but is probably not going to recall the items even when the amnesic suggestion is removed or if positive post-hypnotic suggestions are given. The patient with thalamic based memory difficulty may later be able to recall information but only provided a cuing structure of prompts or reminders is built into the suggestions. Whether or not memory ability in those with organically based memory deficit can be enhanced through hypnosis remains unclear. The patient presented earlier whose autobiographical memory difficulties were helped by hypnotic techniques did not have a storage problem per se but rather a very disorganized memory that probably stemmed from frontal type problems.

**Information Processing Speed.** Reduced speed of processing may necessitate giving instructions more slowly or in such a repetitive and redundant manner that some gaps in the patient's registering what is said don't matter. It is also important for such patients not to mentally overload them. For example, case #1 benefitted from the mental relaxation/ dissociation aspects of hypnosis and was able to mentally block out noise to which he was hypersensitive but the mental effort involved in such blocking-out resulted in his feeling mentally exhausted and stressed.

**Executive Function.** Patients with frontal system dysfunction show some deficits that are similar to hypnotic phenomena in people without brain dysfunction. From this point of view, they may be the most promising group to work with to clarify the nature of hypnosis. The hypnotized patient's responses in conforming to suggestion resemble the stimulus-bound and concrete focus and time-distortive aspects of frontally dysfunctional behavior and perhaps also its confabulatory tendencies. The frontal patient may also show a dissociation between knowing and doing that is similar to the split reported by some people in being aware of and observing their own behavior at the same time as they respond to hypnotic suggestions. There is a sense in which the hypnotist acts as the "frontal lobes" of the hypnotized person, giving direction to their perceptions and behavior. The similarities between the two groups certainly invite further exploration and research.

21 studies that met the criteria of having both an adequate control and a mental practice alone group were included. The 44 separate effect sizes resulted in an overall average effect size of .68 (SD = .11) indicating that there is a significant benefit to performance of using mental practice over no practice. A series of General Linear Models revealed that the use of "internal" imagery produced a larger average effect size than the use of "external" imagery, and that mental practice sessions of less than one minute or between ten and fifteen minutes in length produced a larger average effect size than sessions of three to five minutes in length. These findings suggest the complexity of the relationship between variables that influence mental practice.

Sapp, Marty (1991, August). The effects of hypnosis in reducing anxiety and stress in adults with neurogenic impairment. [Paper] Presented at the annual meeting of the American Psychological Association, San Francisco.

A repeated measures design was utilized to investigate the effects of hypnosis in reducing anxiety and stress in 16 adults with neurogenic impairment. Seven sessions were used to measure the efficacy of hypnosis. Session one was used to obtain a baseline level of anxiety and stress and to initiate hypnosis. Sessions three and six were used to obtain repeated measures of these emotions. Sessions two, four, and five were the treatment sessions. Session seven was used to conduct a four week follow-up on the effects of hypnosis. Levels of anxiety were measured by the State-Trait Anxiety Inventory, while stress was measured by the State-Trait Anger Expression Inventory. The results indicated a statistically significant decrease in anxiety and stress. Hypnosis also significantly increased levels of self-esteem. Finally, follow-up data demonstrated that the treatment gains were maintained.

NOTES

1:

Hypnotizability was not related to treatment outcome. The average Barber Susceptibility Scale score was 3, which indicates that the subjects were fairly low in hypnotizability level.

1990

Appel, Philip R. (1990). Clinical applications of hypnosis in the physical medicine and rehabilitation setting: Three case reports. *American Journal of Clinical Hypnosis*, 33 (2), 85-93.

Hypnosis is useful in the rehabilitation setting to help patients master skills, to increase their sense of self-efficacy and self-esteem and, in general, to facilitate and accelerate their rehabilitation program. I used hypnosis with three patients where patient behaviors and beliefs were interfering with the rehabilitation treatment goals set by the patient and the health care team. Collectively, these cases demonstrate the use of hypnotic techniques in diagnosing and treating problems with patient compliance and assisting patients to gain greater benefit from their rehabilitation regimen. - Journal Abstract

## NOTES

1:

Reports results of a survey of speech therapists trained in the use of hypnosis. The majority use hypnosis in treating voice or fluency disorders to achieve relaxation and encourage self-esteem and also in the treatment of acquired neurological disorders. Respondents were less inclined to use hypnosis with children. Problems encountered in the use of hypnosis are explored.

Holroyd, Jean; Hill, Alexis (1989). Pushing the limits of recovery: Hypnotherapy with a stroke patient. International Journal of Clinical and Experimental Hypnosis, 37, 189-191.

Hypnotherapy was used to assist recovery of left arm function following stroke in a 66-year-old woman. Treatment protocol is described, and results are discussed in terms of how hypnosis may facilitate voluntary motor movement. Recent literature on cortical changes in hypnosis and motor improvement during hypnosis is discussed in relation to the present results.

The patient was 6 months post-stroke and physicians did not expect much additional improvement. She improved despite the fact that she measured as a low hypnotizable on the Stanford Scale, Form C. However, she appeared very absorbed in the hypnotic imagery, and she was highly motivated and exhibited much hope or positive expectation. Also, the author notes that "remarkable improvements in brain functioning have been reported through the use of sophisticated behavioral technology," (p. 124), as in the use of EEG biofeedback to treat untractable seizures (Sterman & Lanz, 1981).

In rehabilitation cases, hypnotic dissociation may enhance pain control during the performance of exercises; more vivid hypnotic imagery may facilitate mental rehearsal of movements; attitudes may be reframed using hypnotic suggestion; and focusing attention on bodily sensations may be enhanced with hypnosis. Hypnosis also may improve expectancy, reduce anxiety, increase hope, provide general relaxation (reducing involuntary spasticity), increase cerebral blood flow, or in other ways promote healing.

Research by Pajntar, Roskar, & Vodovnik (1985) has demonstrated improved motor response during hypnosis for patients with hemiparesis. They attributed EMG changes under hypnosis "to a facilitory influx from supraspinal motor centers. They hypothesized that new motor units of paretic muscles were being activated or that there was an increased recruitment of the motor units already active, and they suggested that relaxation of the spastic antagonist muscle permits the paralyzed muscle to move" (p. 125).

## 1988

Borgens, Richard B. (1988). Stimulation of neuronal regeneration and development by steady electrical fields. In Waxman, S. G. (Ed.), Functional recovery in neurological disease (47, pp. 547-564). New York: Raven Press.

At the end of the review, author notes that a combination of electromyography and computer modeling of agonist-antagonist, flexor-extensor muscle contraction patterns in the functional body parts of hemiparetic patients, artificially imposed on the paralyzed portions of the body using repetitive electrical stimulation to effect more normal movement, sometimes leads to functional recovery. Such recovery has been observed in some chronic cases of paralysis associated with head injury, stroke, and cerebral palsy. These clinical observations challenge the way we should view paralysis in general. Perhaps there are many redundant pathways in the CNS that will support certain kinds of functional return in the absence of the original pathways destroyed by trauma. Perhaps CNS-associated paralysis is a problem, at least in part, of too much competing signal in spared pathways, not one of impoverished signal. Can use of these neuronal pathways be entrained or retrained? Is the return of function in patients who experience repetitive functional electrical stimulation due to a reorganization

within the CNS? These are exciting questions whose answers will possibly lead to our ability to further modify the plasticity of the brain and spinal cord.

[This would fit with the inhibition model of hypnosis, and with the high theta power findings during hypnosis, the implication being that hypnosis facilitates filtering out non-essential competing stimuli.]

Houge, Donald R.; Hunter, Robert E. (1988). The use of hypnosis in orthopaedic surgery. Contemporary Orthopaedics, 16, 65-68.

Some patients postpone or refuse indicated orthopaedic surgery because of fear or a medical contraindication to anesthesia. Clinical hypnosis previously has been used mainly as an adjunct to chemical anesthesia. However, hypnosis was shown to be entirely effective when used as the sole anesthesia in three of four orthopaedic cases. These four procedures included a radical head resection, the removal of a sideplate and Richard's screw from the hip, and two cases of arthroscopic knee surgery. The preparation required for the surgery and the experiences of the patients during these procedures are described, and the kinds of patients most likely to benefit from the use of hypnosis in orthopaedic surgery are reviewed.

1983

Spiegel, David (1983). Hypnosis with medical/surgical patients. General Hospital Psychiatry, 5, 265-277.

The role of hypnosis as a tool in the treatment of problems commonly encountered among medical and surgical patients is examined. Hypnosis is defined as a change in state of mind far more akin to intense concentration than sleep. Diagnostic implications of differences in hypnotic responsivity are explored, and scales suitable for use in the clinic are examined. Uses of hypnosis in treating anxiety, pain, childbirth, psychosomatic symptoms, seizure disorders, neuromuscular dysfunction, and habits are described and evaluated. The phenomenon of hypnosis is presented as a means of exploring the mind-body relationship in a controlled fashion, providing information of diagnostic importance while at the same time allowing hypnotizable patients to intensify their concentration and interpersonal receptivity in the service of a therapeutic goal

## NOTES

1:

This fourth volume of four has 9 sections, with chapters as follows. I. General Introductions to Hypnotherapy

1. The applications of hypnosis to psychiatry
2. Hypnosis in medicine
3. Hypnotic techniques for the therapy of acute psychiatric disturbances in war
4. Hypnotic psychotherapy
5. Hypnosis in general practice
6. Hypnosis: Its renaissance as a treatment modality
7. Hypnotic approaches to therapy II. Indirect Approaches to Symptom Resolution
8. A clinical note on indirect hypnotic therapy
9. The hypnotic and hypnotherapeutic investigation and determination of symptom- function
10. Experimental hypnotherapy in Tourette's Disease
11. Hypnotherapy: The patient's right to both success and failure
12. Successful hypnotherapy that failed

13. Visual hallucination as a rehearsal for symptom resolution III. Utilization Approaches to Hypnotherapy
14. Special techniques of brief hypnotherapy
15. Pediatric hypnotherapy
16. The utilization of patient behavior in the hypnotherapy of obesity: Three case reports
17. Hypnosis and examination panics
18. Experiential knowledge of hypnotic phenomena employed for hypnotherapy
19. The burden of responsibility in effective psychotherapy
20. The use of symptoms as an integral part of hypnotherapy
21. Hypnosis in obstetrics: Utilizing experimental learnings
22. A therapeutic double bind utilizing resistance
23. Utilizing the patient's own personality and ideas: 'Doing it his own way' IV. Hypnotherapeutic Approaches to Pain
24. An introduction to the study and application of hypnosis for pain control
25. The therapy of a psychosomatic headache
26. Migraine headache in a resistant patient
27. Hypnosis in painful terminal illness
28. The interspersal hypnotic technique for symptom correction and pain control
29. Hypnotic training for transforming the experience of chronic pain V. Hypnotherapeutic Approaches in Rehabilitation
30. Hypnotically oriented psychotherapy in organic brain damage
31. Hypnotically oriented psychotherapy in organic brain disease: An addendum
32. An application of implications of Lashley's researches in a circumscribed arteriosclerotic brain condition
33. Experimental hypnotherapy in a speech problem: A case report
34. Provocation as a means of motivating recovery from a cerebrovascular accident VI. Hypnotherapy with Psychotics
35. Hypnotherapy with a psychotic
36. Symptom prescription for expanding the psychotic's world view VII. Sexual Problems Hypnotherapeutic Reorientations to Emotional Satisfaction
37. Posthypnotic suggestion for ejaculatio praecox
38. Psychotherapy achieved by a reversal of the neurotic processes in a case of ejaculatio praecox
39. Modesty: An authoritarian approach permitting reconditioning via fantasy
40. Sterility: A therapeutic reorientation to sexual satisfaction
41. The abortion issue: Facilitating unconscious dynamics permitting real choice
42. Impotence: Facilitating unconscious reconditioning
43. Latent homosexuality: Identity exploration in hypnosis
44. Vasectomy: A detailed illustration of a therapeutic reorientation VII. Self-Exploration in the Hypnotic State: Facilitating Unconscious Processes and Objective Thinking
45. Pseudo-orientation in time as a hypnotherapeutic procedure
46. Facilitating objective thinking and new frames of reference with pseudo-orientation in time
47. Self-exploration in the hypnotic state
48. Self-exploration in trance following a surprise handshake induction
49. The reorganization of unconscious thinking without conscious awareness: Two cases of intellectualized resistance against hypnosis IX. Facilitating New Identity
50. Psychological shocks and creative moments in psychotherapy
51. Facilitating a new cosmetic frame of reference
52. The ugly duckling: Transforming the self-image
53. A shocking breakout of a mother domination

54. Shock and surprise facilitating a new self-image
55. Correcting an inferiority complex
56. The hypnotherapy of two psychosomatic dental problems
57. The identification of a secure reality
58. The hypnotic corrective emotional experience
59. The February man: Facilitating new identity in hypnotherapy

Hart, R. (1980). The influence of a taped hypnotic induction treatment procedure on the recovery of surgery patients. International Journal of Clinical and Experimental Hypnosis, 28, 324-331.

A study of 40 open heart surgery patients assigned to 1 of 2 equal size treatment groups sought to evaluate the efficacy and utility of a tape-recorded hypnotic induction procedure that preoperatively prepared patients for surgery. The dependent variables included daily blood pressure measurements and postsurgical outcome data pertaining to postoperative units of blood required, state/trait anxiety, and locus of control dimensions. Results of the study tended to provide some support for the tape-recorded hypnotic induction procedure in lessening state anxiety and in promoting a more self-directed attitude toward surgical recovery.

Pajntar, Marjan; Jeglic, Anton; Stefancic, Martin; Vodovnik, Lojze (1980). Improvements of motor response by means of hypnosis in patients with peripheral nerve lesions. International Journal of Clinical and Experimental Hypnosis, 28 (1), 16-26.

In order to accelerate rehabilitation of patients with peripheral nerve lesions, hypnosis was employed to encourage them voluntarily to move those muscles with weak re-innervation and to achieve the best possible activity of the affected muscle groups. By measuring muscle force and endurance and by observing the electrical activity of the affected muscles, it was found that the activity of the affected muscles was much better while patients were in hypnosis than when they were in the waking state. The patients were able to contract even paretic muscles having only weak re-innervation with such strength, that clinically perceptible contraction of the muscles and movement of paretic extremities occurred. Such early and improved activation is very important for prevention of much permanent damage.

1970

Crasilneck, Harold B.; Hall, James A. (1970). The use of hypnosis in the rehabilitation of complicated vascular and post-traumatic neurological patients. International Journal of Clinical and Experimental Hypnosis, 18 (3), 152-158.

Hypnotherapy has been found of value in rehabilitation of many patients experiencing difficulty in the usual procedures which follow cerebrovascular or traumatic brain injury. 3 cases are reported to illustrate the approach taken. Of 25 similar cases seen over a 9-year period, 4 were unresponsive to hypnosis. Although an increase in motivation for recovery seemed to be the major change elicited by hypnotherapy, other theoretical possibilities are mentioned. Hypnosis may be a useful way of approaching motivational problems in rehabilitating patients who manifest negativism toward conventional treatment.

1968

Nuland, William (1968). The use of hypnotherapy in the treatment of the postmyocardial infarction invalid. International Journal of Clinical and Experimental Hypnosis, 16 (3), 139-150.

**DEALS WITH THE PSYCHOLOGICAL ASPECTS OF CONVALESCENCE AND REHABILITATION OF PATIENTS FOLLOWING CORONARY INFARCTION. THE FOCUS IS ON THE SITUATIONAL FACTORS WHICH THE PATIENT ENCOUNTERS DURING CONVALESCENCE THAT SERVE TO PROLONG AND REINFORCE THE INVALIDISM. IT IS CONCERNED ESPECIALLY WITH THE VALUE OF HYPNOTHERAPY AS COMPARED WITH OTHER PSYCHOTHERAPEUTIC METHODS IN TREATING THESE CASES. THE ANXIETY AND EMOTIONAL STRESS WHICH CAN BE RELIEVED THROUGH THE USE OF HYPNOSIS IS DIRECTED PRIMARILY TOWARD REDUCING EMOTIONAL TURMOIL WHICH RESULTS FROM THE CORONARY ATTACK WITH THE CONSEQUENT FEAR OF PHYSICAL ACTIVITY AND OF SUDDEN DEATH. SPECIFICALLY, HYPNOSIS IS USED EFFECTIVELY IN REASSURANCE, REEDUCATION, DESENSITIZATION, GUIDANCE, AND OTHER DIRECT SUPPORT TECHNIQUES IN ACCORDANCE WITH THE PATIENT'S SYMPTOMS AND NEEDS. (SPANISH + GERMAN SUMMARIES) (PsycINFO Database Record (c) 2002 APA, all rights reserved)**

**1953**

**Kirkner, Frank J.; Dorcus, R. M.; Seacat, Gloria (1953). Hypnotic motivation of vocalization in an organic motor aphasic case. Journal of Clinical and Experimental Hypnosis, 1 (3), 47-49.**

**Authors' Summary - A 41 year old male patient with a history of mutism on an organic basis for a year and a half failed to respond to speech retraining efforts. Comprehension was good and motivation poor. With the aid of hypnosis, he was induced to vocalize. Following vocalization, oral speech retraining progress was steady. Retraining efforts in writing met with repeated failure.**

**The patient had suffered a cerebral vascular accident, attributed at the time to an embolism.**

## **RELATIONSHIPS**

**1994**

**Adrian, Cheri (1994, August). Sexual feelings in hypnosis: Managing therapeutic boundaries in hypnotic work. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.**

**Therapist countertransference has been little addressed in discussions of hypnosis, particularly the sexual feelings that may be evoked in therapists in the hypnotic context. These are some of the most disturbing and problematic feelings therapists can experience toward patients, and they are little addressed in training. This issue is important both because of our increasing efforts to prevent sexual boundary violations in therapy and because therapist sexual feelings, like other countertransference feelings, can have important clinical meanings that are often avoided or ignored. This discussion defines the nature and purposes of patient-therapist boundaries. It describes the various dynamics which have been identified in therapists who become confused about sexual boundaries and proceed to mismanage them. It then elaborates the ways that using hypnosis may create special vulnerability for the therapist, not only to experiencing sexual feelings toward patients, but to becoming confused about their meaning and relevance to treatment. The discussion focuses attention on the origins and clinical significance of therapist sexual feelings, and acknowledges that such feelings may serve both awareness enhancing and defensive functions in the therapeutic process. A clinical case example illustrates various kinds of sexual feelings therapists may experience, the many meanings therapist sexual feelings may have, the various discomforts they typically generate, and the impulses to avoidance or acting out**

they may provoke. Further discussion addresses both clinically appropriate and inappropriate ways of managing boundaries in the presence of sexual arousal, and of utilizing sexual feelings as a means of deepening clinical understanding and of directing treatment. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall 1994, Vol. 3, No. 3.)

Grant, Carolyn (1994). The Computer-Assisted Hypnosis Scale: Standardization and norming of a computer-administered measure of hypnotic ability (Dissertation). Dissertation Abstracts International, 54 (10/B), 5387.

"In a counterbalanced, within-subjects, repeated measures design, 130 subjects were administered both the Computerized Assisted Hypnosis Scale (CAHS) and the Stanford Hypnotic Susceptibility Scale, Form C (Stanford Hypnotic Susceptibility Scale: C). For each hypnotic procedure responsiveness was assessed along three dimensions: behavioral (CAHS, Stanford Hypnotic Susceptibility Scale: C), subjective depth (Field Depth Inventory), and relational involvement (Archaic Involvement Measure). Subjects also completed a Stanford Hypnotic Susceptibility Scale: C self scoring measure and the Tellegen Absorption Scale. The CAHS was shown to be a psychometrically sound instrument for measuring hypnotic ability. The various dimensions of CAHS hypnotic responsiveness were highly positively related, and the CAHS compared favorably with the Stanford Hypnotic Susceptibility Scale: C across the three dimensions assessed. Results are discussed in terms of the theory and practice of clinical assessment, noting directions for future research" (p. 5387).

1993

Diamond, Michael J. (1993). A question of filling in the gaps: A master class commentary. [Comment/Discussion] .

This is a response to a clinical vignette described as follows: "'Judy,' a professional writer, asked me to use hypnosis to help her 'fill in the gaps' in her knowledge of certain periods in her youth. As she was so keen, getting her into trance was relatively easy. I asked a few questions and she answered in a slurred voice. Then, after a few minutes, she said that she wasn't hypnotized. 'Not to worry, Judy, I'll bring you out' was my reply. With that, a flood of memories, absolutely unstoppable for approximately 4 minutes, came pouring forth. Thereafter, I asked questions relating to an earlier period in her life. Again came the statement that she wasn't hypnotized, and I replied as before. With that, a second flood of unstoppable experiences poured forth. later, on coming out of trance, she was able to recall all she'd spoken about while in trance and often punctuated her recollections with 'I didn't know that they punished me at y by locking me in the cupboard under the stairs!'" (p. 261).

NOTES

1:

Relationship is the area where healing occurs. The basis of the relationship in hypnosis is poorly understood scientifically.

1983 - Freud's hypnosis of a conversion hysteric led him to postulate a "mysterious element" (i.e. sexualized transference) which occurred when the patient threw her arms around his neck. He, and many other analysts, abandoned hypnosis - which was nevertheless continued by some doctors who were working with war neurosis or PTSD.

Freud equated hypnosis to direct suggestion and saw it as a definitive therapy. Today clinicians think it is the context of using hypnosis (not just the hypnotic state) that makes hypnosis useful for psychotherapy.

Example: A borderline patient may become more comfortable, not just because of an altered state (which they may be experiencing all the time anyway) but because of the [containing, comforting] context.

Shor's paper on the "Three dimensions of hypnotic depth" is a useful way to begin a conceptualization of the relationship between hypnotist and patient. See also Michael Diamond (1984), It takes two to tango. *AJCH*, 27, 3-13. The most capable hypnotherapists are able to enter empathic bonds with patients, comforting the patient. This represents the "courage to not understand" (Reik). The therapist should be comfortable with the disintegrated material that is evoked, helping the patient to metabolize the material.

Orne's (1962) concept of "folie a deux" is a precursor to the concept of projective identification: the patient projects onto the therapist an idea that the therapist is all-powerful, and the therapist must buy into that (while at the same time realizing it is a fantasy - using it for the purposes of therapy, but not believing it.)

Spinhoven, Philip; van Wijk, Jorrit (1992). Hypnotic age regression in an experimental and clinical context. *American Journal of Clinical Hypnosis*, 35, 40-46.

Investigated role of a clinical context in the experience of hypnotic age regression. 25 patients experienced hypnotic age regression in an experimental and clinical context in counterbalanced order. Patients obtained significantly lower scores for experimental age regression than for clinical age regression, in particular when the experimental assessment preceded the clinical assessment of age regression. Moreover, scores for clinical and experimental age regression were only significantly and positively correlated when the clinical assessment of age regression preceded the experience assessment. These findings give a tentative indication that more patients are able to experience clinical age regression than can be predicted from their responses to an experimental suggestion for hypnotic age regression where almost no opportunities for patient contact or maximizing of hypnotic responsiveness are provided.

Lynn, Steven Jay; Weekes, J. R.; Neufeld, U.; Ziuney, O.; Brentar, J.; Weiss, F. (1991). Interpersonal climate and hypnotizability level: Effects of hypnotic performance, rapport, and archaic involvement. *Journal of Personality and Social Psychology*, 60, 737-743.

Designed to extend research by McConkey and Sheehan, they tested 24 hypnotizable and 21 un hypnotizable Ss in high interpersonal/high rapport (including education about misconceptions about hypnosis, eye contact, and friendly self-disclosure) and low interpersonal/low rapport testing contexts. Overall, hypnotizable Ss were more responsive to hypnosis, rated the hypnotist more positively, and experienced greater involuntariness and archaic involvement than un hypnotizable subjects. However, results provide support for the hypothesis that low hypnotizable Ss are particularly sensitive to variations of the hypnotist's interpersonal behavior. Only low hypnotizable Ss' objective and subjective hypnotic performance on the SHSS, Form C, was enhanced by hypnotist behavior designed to optimize rapport. Hypnotizable Ss' behavior was stable across testing contexts.

## NOTES

1:

"There are several different ways to classify the model that is expounded in this chapter. One may view it ... as an individual-differences model of hypnosis, because it emphasizes the significance of intragroup differences in the pattern of hypnotic performance. Alternatively, one may view it as a phenomenologically based model.... Invariably, however, single categories fail to do justice to the nature of theories, and hence it is perhaps wisest to view this theory as a means of exploring particular hypotheses about hypnotic phenomena that focus primarily on the meaning of suggestion as perceived by susceptible subjects. This model focuses, in a way that most other theories do not, on the motivational implications of the cognitive involvement of the susceptible subject in the events of the hypnotic setting. It offers a variant of contextual theories of psychological functioning, but is experiential in its emphasis rather than simply behavioral" (p. 537).

## NOTES

1:

"We are a unity of cells. Every cell is a citizen with it's own jobs, communicating all the time; cells send messages; the way we communicate with them is by suggestions. Each cell is a mind-body.... When I do it now [hypnotic inductions], I say, 'We're going to go into hypnosis, we're both going to go into hypnosis. I'm going to close my eyes (etc.)' - modeling hypnosis for them."

Coe, William C. (1990). Are the Conclusions Valid? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 237-239.

## NOTES

1:

The authors confounded variables, e.g. hypnotic susceptibility and monetary incentive (in Study IV), and Study IV was different from the other 3 studies, so that any differences/similarities between these studies can't be attributed to susceptibility level, degree of incentive, or interaction between them.

A simulator design would clarify why 50% of Ss in Study IV did not resist and lost \$100; also, postexperimental interviews focusing on Ss' reasons for resisting or not resisting would be helpful. Did nonresisters actually believe that they would receive \$100 for resisting?

The Subject population was not homogeneous in occupation, and students are financially poorer than others--which would affect incentive strength. Were those who resisted the ones who could use the money the most?

Small sample sizes obviating statistical tests is a problem. Coe nevertheless evaluates 4 variables in terms of the 'power' of their effects on hypnosis: 1. Susceptibility level. Studies I, II, and III all show correlations between hypnotizability and compliance with resistance, suggesting that high hypnotizables are not as susceptible to resistance manipulation; however across studies, highs in one study seem to comply at the same rate as lows in another study, and as many as 50% of high hypnotizables in the strong incentive (\$100) study were able to resist suggestions. 2. View of the Hypnotist. Coe states that one can't evaluate the question with the data given. One would need an experimental condition that would also create a negative view of the hypnotist, as all samples tended to view the hypnotist positively. 3. View of Resistance Instructor. Again, one would need a research design that separates the effects of hypnotic susceptibility from effects of Ss' views of the resistance instructor. "Nevertheless, Study IV suggests that for high susceptibles the view of the resistance instructor has little effect. Three resisters viewed him as positive, whereas the other three viewed him as negative; further, nearly all of the nonresisters viewed him as neutral" (p. 238). 4. Degree of

Incentive. This too was confounded with susceptibility level, as "the higher value was only offered to the very high susceptibles in study IV. Half of them took it, half did not" (pp. 238-239).

Coe also remarks that "the expectational effects on subjects of being in an experiment have not been addressed adequately. It is possible that the experimental paradigm as currently presented is incapable of providing an unambiguous answer to the question of coercion. In naturalistic settings subjects may react quite differently than they do when they know they are participating in an experiment" (p. 239).

**Hoencamp, Erik (1990). Sexual abuse and the abuse of hypnosis in the therapeutic relationship. International Journal of Clinical and Experimental Hypnosis, 38, 283-297.**

In the Netherlands, individuals charged with rape may be prosecuted only in instances in which the suspect could have known that the victim was unconscious or in a state of powerlessness. Hypnosis might be looked upon as a method by which an unscrupulous person could sustain such a state of powerlessness in a victim. As an expert witness, the present author participated in a court case against a lay hypnotist who was accused of abusing 9 women. The methods and strategy used by the lay hypnotist are presented as well as are the diverse reactions of the women involved in the case. Feelings of nonvolition appear to have been a relevant factor in the coercion, especially in women who demonstrated hypnotic phenomena such as arm levitation, catalepsy, etc. The basis for sexual coercion was established only after the interpersonal relationship had been redefined as a therapeutic relationship. Introduction within the pseudotherapeutic relationship of a sexual rationale for the presented complaints helped to provide a framework for actual sexual acts to occur. With certain individual patients, the introduction of hypnosis enhanced the subjective experience of nonvolition and with it the vulnerability for abuse. It may be hypothesized that patients with a tendency for external attribution and high hypnotizability are specifically at risk for this kind of abuse when hypnosis is used in the context of a therapeutic relationship.

## NOTES

1:

This chapter is a reprint of an article published in the *American Journal of Clinical Hypnosis* in 1987. It provides a conceptual framework for understanding psychotherapy processes in the context of a hypnotic state. Based on empirical and theoretical considerations, the author identified nine changes occurring with hypnosis: changes in attention and awareness, imagery, dissociation, reality orientation, suggestibility, mind-body interactions, initiative or volition, availability of affect, and relationship. "This chapter proposes that hypnotherapy exploits hypnotic phenomena-- takes advantage of them--in the service of standard therapy endeavors" (p. 125).

**Levitt, Eugene E.; Baker, Elgan L., Jr.; Fish, Ronald C. (1990). Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 225-236.**

Five experimental approaches to the resolution of the century-old Bernheim/Janet dispute and the issue of involuntariness or coercion (the classical suggestion effect) are presented. Four experiments are reported that follow one of the approaches: attempts to induce hypnotic subjects to resist suggestions made in trance. The design is one in which a "resistance instructor" proposes a reward for the resisting subject. Tentative inferences from the results are that the classical suggestion effect is found with a small number of subjects; for a larger number of subjects there is no classical suggestion

effect, and for many subjects the outcome is equivocal. Relational factors in the hypnotic dyad influence responsiveness in the subject, the effect being least for those whose susceptibility is high.

## NOTES

1:

**Study I.** Used a \$5 bribe, two suggestions, and Ss resisted average of 1.2 suggestions. 9 Ss resisted both, 5 resisted neither, and 6 (30% of Ss) resisted one test suggestion. Resistance appeared to be related to impression of the resistance instructor, suggesting that "neither the monetary bribe nor hypnotic responsiveness was as important to the resistance/compliance dimension as relational factors" (p. 228).  
**Study II.** Used only one suggestion, obtained quantitative ratings of the two instructors, and offered \$10 to resist one suggestion. 19/40 Ss (48%) resisted. The authors wondered whether the difference in impressions of hypnotist and resistance instructor might be due to very limited contact with the latter.  
**Study III.** Ss were greeted by the resistance instructor, who accompanied Ss to the experimental room, discussed the information under 'Establishing Rapport Prior to the Initial Induction' in the SHSS:A and a condensed version of the introduction to the Eye Closure item (10 minutes). Then he left, the hypnotist entered and administered the same 9-item SHSS:A that had been employed in Studies I and II. The resistance instructor then entered and offered \$10 if the S could successfully resist the hypnotist's suggestion on the second try [of an item just passed successfully]. The hypnotist re-entered, repeated SHSS:A instructions for the selected item, brought S out of hypnosis, and then a different experimenter did a structured interview--to give impressions of the hypnotist and the resistance instructor on an Adjective Rating Form (ARF), to estimate depth of their trance on 0-8 scale before and after contact by the resistance instructor. Then S was paid if he/she had resisted. The resisters obtained a mean on the SHSS:A of 4.8 compared to 7.9 for the nonresisters, significant t-test for the difference ( $p < .01$ ).

**Table 1 A Comparison of Interview Ratings of Hypnotists and Resistance Instructors in Two Studies**

\* Not significant

In Table 1 it may be seen that perceptions of the hypnotist and the resistance instructor changed from Study II to Study III. "In summary, the manipulation of time spent in the second experiment increased the proportion of resisters and dramatically improved the impression of the resistance instructor. Nevertheless, the evidence suggests that the hypnotist continued to be perceived positively and, according to our best measure, was still perceived more positively than the resistance instructor" (p. 232).

Because they suspected that the impressions of the experimenters might be confounded by hypnotic susceptibility, and \$10 might not be enough reward for behavior shaping, the experimenters designed Study IV. Study IV used 12 high hypnotizables (scoring 11 or 12 on Harvard Scale; with a group mean of 8.8 on a 9-item version of the SHSS:A). The same procedure as in Study II was carried out, except that four experimenters other than the authors were the hypnotists and resistance instructors; each experimenter worked with three subjects. The incentive was \$100 to resist.

The results of this procedure were that six Subjects resisted and six complied; each group scored 8.8 on the SHSS:A 9-item scale; resisters had 5.7 mean and nonresisters 5.1 mean depth (nonsignificant).

Resisters and compliers were exactly alike in their perceptions of the hypnotist, but appeared different in perception of the resistance instructor (and the N was too small to test statistically).

Table 3

Rated Impression of Hypnotist (%)

\*Lower score is more favorable.

Summary of the Four Studies:

The data in Tables 2-5 reflect a critical finding. "There was a sharp drop in the number of Ss who did not resist, or it may be clearer to put it as a sharp increase in the number of resisters. The change is nearly 40%.

"However, when only responsive subjects were used as in Study IV, the percentage of nonresisters is much the same as it was in Study II" (p. 233). The authors conclude that "relational factors are more important in hypnotic behavior among less responsive subjects" (p. 233).

"The data contrasting resisters and nonresisters are somewhat confusing. There were more positive and negative impressions among subjects who resisted and more neutral impressions and no negative impressions among the nonresisters," (pp. 233-234) though the number of cases involved is quite small. Using the ratings, the nonresisters had a more favorable impression of the hypnotist than did the resisters, which is in accord with the interviewers' ratings.

"A striking finding is that nonresister Ss in Study IV had a less favorable impression of both hypnotist and resistance instructor ... a clear reversal from Study III for the hypnotist, not quite so clear for the resistance instructor" (p.234).

Levitt, Baker, & Fish draw the following inferences: "1. Hypnotic influence is truly coercive for a very small number of what Register & Kihlstrom (1986) have called the 'hypnotic virtuoso,' the most responsive individuals; for them, the classical suggestion effect is a reality; 2. Hypnotic influence, though perhaps not truly coercive, is manifestly strong for a somewhat larger group of highly responsive individuals; the classical suggestion effect may exist for them; 3. For many individuals who behave in accordance with hypnotic suggestions, the classical suggestion effect does not exist; 4. Relational factors in the hypnotic dyad influence hypnotic responsiveness. The influence is strongest among individuals of low-to-moderate hypnotic responsiveness; 5. The more positive the impression of the hypnotist, the greater will be his influence on the hypnotized individual; 6. A subject's impression of a hypnotist will tend to be favorable even though the sole interaction between the two is the induction of the trance; 7. Preliminary efforts to build rapport with the subject will tend to improve the already positive impression created by the hypnotist" (pp. 234-235).

NOTES

1:

"We cannot see how Lynn can allege that in three of the studies there was no relationship between

resistance-nonresistance and perception of the hypnotist. The appropriate correlation coefficients are reported in Studies II and III.

"Coe's point about the confounding of incentive and susceptibility might be valid if we had no prior knowledge of the relationship between resistance and susceptibility. But we already knew that the most susceptible Ss were likely to be the nonresisters. In Study IV, we abandoned susceptibility as an independent variable and made it a sample descriptor. ... [However] we resonate to Coe's suggestion of simulators" (p. 247).

"In our first three studies, we reported no relationship between occupation and resistance, an admittedly crude but unobtrusive approach to the question of whether the most financially needy subjects were the resisters. We usually compared the students in the sample with the employed subjects. We did not report this lack of relationship in Study IV in which only three subjects were students. Two resisted, one did not.

We must accept responsibility for provoking Coe's question about the credibility of the financial incentive in Study IV, by poor reporting. In a postexperimental inquiry, one subject (a resister) was mildly suspicious of the offer. All other Ss found the resistance instructor credible" (pp. 247-248).

"Our own more recent research suggests that offering undergraduate students additional points toward the final class grade can yield more resisters than the money incentive in Study IV (Levitt, Baker, Hacker, Klion, Krause, Lytle, & Vanderwater- Piercy, 1990 in press)" (p. 248).

"We have suggested that the hypnotic phenomenon is apparently experienced differently among subjects, and the critical factors are thus also likely to vary from subject to subject. We would be quite willing to accept Bernheim's estimate that 17% are incapable of resisting hypnotic suggestions, as cited by Weitzenhoffer. We agree with Spiegel that the issue of the coercive potential of hypnosis is 'not really settled by mean differences across groups.' Measures of central tendency are apt to obscure the minority of Ss who may experience coercion in experiments with designs different from ours" (p. 248).

## NOTES

1:

Unlike Levitt, Baker, & Fish (1990), Lynn, Rhue, & Weekes (Psychological Review, 1990 in press) concluded that nonvoluntary behaviors in hypnosis are similar to other spontaneous social behaviors (like conversational response to social stimuli). "Hypnotized subjects, like nonhypnotized subjects, act in terms of their aims, according to their point of view, and in relation to their interpretation of appropriate behavior and feelings" (p. 239).

"Research shows that hypnotizable subjects resist and even oppose suggestions as a function of their expectancies and perceptions about appropriate hypnotic behavior (Lynn, Nash, Rhue, Frauman, & Sweeney, 1984; Lynn, Snodgrass, Rhue, & Hardaway, 1987; Lynn, Weekes, Snodgrass, Abrams, Weiss, & Rhue, 1986; Spanos, Cobb, & Gorassini, 1985). In one study (Spanos et al., 1985), when subjects were informed that deeply hypnotized subjects were capable of becoming involved in suggestions and simultaneously resisting them, subjects resisted 95% of the suggestions. When subjects were told that deeply hypnotized subjects were incapable of resisting suggestions, they passed the majority of suggestions. Thus, knowledge about what constitutes appropriate hypnotic role behavior is a reliable determinant of resistance, apparently more reliable than the monetary lures used by Levitt et al." (P. 240).

These studies by Levitt et al. only used behavioral measures of resistance and hypnotizability, and Ss' perceptions of the resistance instructor and hypnotist. "The ratings of global perceptions are, however, no substitute for measures of subjects' perception of the relationship. ... The failure to measure important variables relevant to the central dimensions of concern--coercion, compliance, involuntariness, and relational factors--precludes meaningful interpretation of the nonresisters' motivation and behavior" (p. 240).

As Orne (1959) has suggested, we should not attribute behavior in the hypnosis context to something unique to hypnosis (such as coercive influence), because other kinds of social context also constrain behavior, e.g. psychotherapy and psychology experiments, with coercive features. Therefore, it seems important in the future to compare the responses of hypnotized subjects with those of subjects in waking-imagination and hypnosis-simulating conditions. In addition to looking at their behavior, it is important to examine their own perceptions of their actions, given the complexity of the social situation entailed in hypnosis.

"Finally, there are statistical grounds to be wary of the authors' conclusions. They assert that 'relational factors in the hypnotic dyad influence hypnotic responsiveness,' yet in three of the studies (I, II, and IV), subjects' ratings of the hypnotist failed to discriminate whether they resisted or responded to the suggestion" (p. 241). Even where Study III was compared with Study II, the difference in the percentage of Ss who resisted failed to reach statistical significance. "In fact, across all studies, differences in overall resistance rates were not documented by statistical tests--despite procedural variations and differing monetary incentives. So contrary to authors' assertion, relational factors in the hypnotic dyad generally had little bearing on resistance behavior. If anything, ratings of the resistance instructor had greater weight" (p. 241).

Mason, Albert A. (1990, January). A psychoanalyst looks at a hypnotist; or, where the elephant skinned boy took me. [Paper] Presented at the Psychoanalytic Center of California Scientific Meeting.

#### NOTES

1:

"The results of working with hypnotism experimentally in the production of anaesthesia for surgery, dentistry and obstetrics; in controlled series of treatments of asthmatics, skin disorders, and allergic manifestations; as well as its clinical use, have convinced me that it is a delusional state akin to mania which depends on the omnipotent denial of mental pain. The mania is stimulated by the hypnotized subject having phantasies of an omnipotent object that it fuses with and shares in the omnipotence. The hypnotist has similar unconscious phantasies about himself. Both subject and hypnotist projectively identify with each others' phantasies, and together produce phenomena like anaesthesia which can be likened to delusional states. In fact, true hallucinations can also be deliberately produced. "I believe that similar psychotic mechanisms can also occur in life between parents and children and in other relationships, and produce delusional states. These form a continuum from intractable narcissism on the one side, through Christian Science and the denial of evolution in the center, to frank folie a deux and transexualism on the other side. The therapeutic course of these states seems quite dissimilar from that of psychosis arising without the encouragement of external objects."

Perry, Campbell (1990). Coercion by hypnosis? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 242-243.

#### NOTES

1:

"A postexperimental inquiry (following Orne, 1959) might have informed the reader of the degree to which operationalization of the coercion in terms of disobedience was successful. Without this additional step, it is difficult to determine whether what was found in the laboratory by these

investigators applies to what has been reported in clinical and field settings for almost 200 years" (p. 242).

"In particular, elsewhere, the authors equate coercion with involuntariness and appear to view involition as a euphemism for coercion. While I agree that perceiving involition of one's own behavior may contribute to the commission of unconsenting acts in hypnosis, the two are easily distinguished at the conceptual level. Laboratory subjects ordinarily report much behavior in hypnosis that is experienced involuntarily, without the issue of it being coerced ever being broached" (p. 242).

Author describes cases in which patients claimed they participated in sex with hypnotist against their wills because they were hypnotized. "What may be happening in both of these reports is that the hypnotized subjects found themselves responding involuntarily; from this, they appear to have adduced that they could not resist the hypnotist's suggestion. That is, they were coerced not by hypnosis but by their belief, which was a direct function of the experience of involuntariness, that they could not resist" (p. 243). "In short, if a hypnotized person equates involuntary behavior with powerlessness, "coercion" may occur in this limited sense. Conceptually, this appears to be a far cry from equating involition with coercion" (p. 243).

Smith, Alexander (1990). The hypnotic relationship and the holographic paradigm. American Journal of Clinical Hypnosis, 32 (3), 183-193.

The holographic paradigm is a recently constructed model of consciousness derived from neuropsychology and quantum physics. It views the processing of mental forms as occurring within the context of a part/whole relationship, where the identified part exists within the code of the whole. In this paper I have applied this paradigm to the hypnotic relationships, viewing the hypnotic process as an undulation of form and transitional states and proposing the holographic paradigm as a cutting edge to understand the curative processes in hypnosis.

## NOTES

1:

The proposed model represents a synthesis of neuropsychology and quantum physics.

"Based on precise neuroanatomical and neurophysiological processes, Pribram was able to account for a distribution of memory across the brain in its entirety. This occurs not within each neuron, but between them. Graded waves of neural potentials, rather than neural impulses, accounted for the structure of interference patterns (Pribram, 1982, p. 32)" (p. 185).

"Pribram then set out to answer these implied questions: What if there is no world of objects 'out there?' What if the world as we know it is a hologram itself? This search led him to David Bohm's work on the quantum theory.

"Bohm's (1980) world view, based upon study of light waves, consists of a primary reality that remains enfolded (within the frequency domain) and unfolded reality (the world of 'objects' and images). Appearances or objects and images are abstractions reconstructed from the frequency domain" (p. 185).

"A holographic interpretation resets the therapy relationship as a shared partnership: 'The sharing emphasizes the whole of which a partner holds a part, but the holographic paradigm makes it clear that each partner holds not just a part, but the whole because each part contains the whole' (Zinkin, 1987, p. 18)" (p. 186).

"Pribram (1983) seems to suggest, in a similar vein, that the unconscious and consciousness are 'opponent processes' of implicate and explicit orderings. Citing Matte Blanco's (1975) concept of unconscious processes as infinite sets (of opponent emotional states, for example), he considers the process relationship between conscious and unconscious: 'Conscious intelligence is manifest when circumscribed sets can be appropriately partitioned into reasonably unambiguous categories. When behavior is guided by sets of variables which cannot be readily partitioned--variables which show

opponent characteristics--we are apt to conclude that behavior is based on intention or that unconscious processes are at work' (Pribram, 1983, p. 10)" (p. 187).

"Tart's (1967) procedure of mutual hypnosis resulted in such an overlapping of experiential detail between participants that the startling, consensually derived reality became too much to tolerate" (p. 187).

"It is possible that during hypnosis, at some point the therapist and patient's organizations of consciousness in some way literally and not metaphorically cross into a wave length or plane in which there is neither reality nor fantasy but the enfolded- implicate-primary reality that is mutually shared? If so, how would these wave length resonances be determined? What would this mean for various psychopathological states?

"To answer these questions we may be catapulted into a whole rethinking of just what hypnosis is in connection to repression, to developmental capacities to form self and object images, and to the shifts to more advanced levels of adaptation. In particular, the hologram will become perhaps a means of exploring this challenging advance, if it can bring the hypnotic relationship more squarely into focus.

"The expansion and contraction of conscious awareness, as a holistic process between therapist and patient within the context of the trance, may provide us with more precise clues to understand altered states of consciousness, rather than the other way around" (p. 191).

Spiegel, David (1990). Theoretical and empirical resistance to hypnotic compliance. Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 243-245.

## NOTES

1:

Does hypnosis bypass the will, facilitate coercion? The hardest thing for trauma victims to do is to admit helplessness. Furthermore, it is interesting that these same dissociative phenomena seem to be elicited by traumatic experience, the stark imposition of involuntariness (Stutman & Bliss, 1985; Spiegel, Hunt, & Dondershine, 1988). What, then, are we to make of experiments that purport to show that hypnotizable and hypnotized individuals comply with hypnotic instructions irrationally? At some level this challenges our comfortable belief that we always act in our enlightened self-interest, unaffected by unwanted influence. If that can happen even once, our pride of self- ownership is reduced.

Taken as a whole, the studies show that high hypnotizables comply with hypnotic instructions, even in the face of resistance instructions, whereas low hypnotizables are less likely to, especially when conditions foster a relatively less negative view of the resistance instructor. As the authors note, subjects always viewed the hypnotist more positively than the resistance instructor, which in itself suggests the nonrational influence intrinsic to hypnosis. Free will is not abrogated, it is simply not exercised. The Ss are fundamentally choosing whether or not to comply. Half of the highs in Study IV resisted the hypnotic instruction. However, hypnotized individuals tend to narrow the focus of attention, thereby reducing their ability to consider alternatives such as the resistance instruction.

William James (1890) believed that all ideas were invitations to action. Why, then, do we not act on every idea we have, he pondered on a snowy morning while lying in bed. He observed that he would try to get himself to arise by picturing himself doing so. "Why, then, am I still in bed?" He realized that he was editing the primary idea, reflecting on how cold it was, how long it would take to light a fire, and how much time he had until his classes. In a state characterized by a narrowing of the focus of attention, we are less likely to edit the primary idea, and therefore more likely to act. In the experiments presented, the resistance instructor attempts to act as an external editor on the primary hypnotic instruction. Those capable of focusing attention sufficiently disattend to the editing and

comply. These studies show that, thankfully, hypnosis is less than automatic submission to instruction but, interestingly, more than simple conscious response to new information.

Weekes, John R.; Lynn, Steven Jay (1990). Hypnotic suggestion type, and subjective experience - the order-effects hypothesis revisited: A brief communication. International Journal of Clinical and Experimental Hypnosis, 38, 95-100.

In a replication and extension of Field, Evans, and Orne's (1965) research, no support was found for the hypothesis that suggestion order is related to hypnotic responding. Confirming earlier findings, subjects were no more responsive to suggestions ordered from easy-to-difficult than they were to suggestions ordered from difficult-to- easy. Measures of subjective involvement in suggestions, involuntariness, and archaic involvement with the hypnotist were no more sensitive to order effects, nor were order effects more apparent with subjects who received direct versus indirect suggestions. Confirming earlier research, direct suggestions did facilitate suggestion-related involuntariness and response to the hypnotic amnesia item after cancellation, whereas indirect suggestions enhanced fears of negative appraisal by the hypnotist. Thus, authoritative suggestions enhance responding to a cognitive-delusional item relative to more permissive suggestions. Finally, female subjects were more involved in suggestions than were males, particularly in response to more difficult tests items.

Weitzenhoffer, Andre M. (1990). Are induced automatisms necessarily coercive? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 245-246.

## NOTES

1:  
"For the sake of maintaining historical accuracy, I would like first to remark that the ability of hypnotized Ss to resist suggestions was probably never a central issue in the Nancy-Salpetriere controversy. The main quarrel was about other fundamental matters (Crocq, 1900; Barrucand, 1967). It also needs to be said that Pierre Janet should not be seen as representing the Salpetriere in the above controversy. Very little of his extensive writings reflect the ideas of Charcot with whom he was associated for only 4 years (1889- 1893) (Barrucand, 1967; Ellenberger, 1970). Lastly, let it be noted that the association of automatism with hypnotic behavior antedates Bernheim. Despine wrote about it at length as early as 1868, and Charcot (1882) clearly stated before Bernheim that automatic responses to suggestions were characteristic of induced somnambulism. This was at least one view they shared. Referring to the material quoted from my 1978 paper, the authors assert Bernheim's definition of automatism implies a subject responding to a suggestion qua suggestion is "unable to resist" it. But all the definition says is that the will does not directly enter into the production of automatisms. It does not say the will cannot effectively intrude at some point or other. This definition, quoted out of context, was part of a more extensive discussion of \_what the nature\_ of an automatism was for Bernheim. The discussion also went into details regarding \_the conditions\_ under which Bernheim understood automatisms can occur and hold sway. In this greater context, Bernheim (1888a, 1888b) viewed the occurrence of automatisms as normally subject to control by the ego processes responsible for volitional activities. He saw the degree to which a person's behavior can be controlled by automatisms initiated by suggestions to be a function of the extent to which certain ego processes become inactive, ineffective, or cooperatively permit the automatisms to occur. Bernheim recognized that both cognitive and relational factors played an important part in the latter case. Bernheim (1888a, 1888b) also stated that data he had collected showed subjects \_could\_ resist suggestions to varying degrees, with only 17%, who made up the class of somnambules, being \_totally incapable\_ of resisting" (pp. 245-246).  
"Stating the matter more concretely, I doubt many people would speak of an individual having been 'coerced' into producing a knee-jerk reflex under appropriate stimulation. Should the situation be any

different in the case of other reflexes and, more particularly, the reflex ideodynamic action presumed to underlay suggested acts (Weitzenhoffer 1978, 1989)? I do not think so. It seems to me that what the authors have really and directly examined in their article is the extent to which the classical suggestion effect can be countered by conscious, voluntary control" (p. 246).

1989

Baker, Elgan L.; Levitt, Eugene E. (1989). The hypnotic relationship: An investigation of compliance and resistance. International Journal of Clinical and Experimental Hypnosis, 37, 145-153.

: The purpose of this investigation was to assess the ability of hypnotic Ss to voluntarily resist a neutral suggestion when a monetary reward was offered for resistance. 19 of 40 Ss (47.5%) successfully resisted after money was offered by the "resistance instructor." The correlation between resistance/compliance and hypnotizability was -.44 (high hypnotizables were more likely to comply). Ss' impressions of the hypnotist tended to be positive; impressions of the resistance instructor tended to be neutral. There was a tendency for nonresistors to have a more positive view of the hypnotist but it is not as marked as was found in an earlier study (Levitt & Baker, 1983).

#### NOTES

1:

Twelve (75%) of the high hypnotizables did not resist; two (16.7%) of the low hypnotizable Ss did not resist.

In their discussion, they state that "these data support the conclusion that hypnotizability or talent accounts for a significant portion of the variance in determining compliance with suggestions during trance. ... [Further], this research may be conceptualized as examining the contributions of a trait variable (hypnotizability) as compared with a variety of situational or state variables (motivation, social perception, environmental contingencies) in determining compliance and suggestibility. Inherent in this model of research is the assumption that many observed hypnotic phenomena (such as suggestibility) are interactive in nature, representing the outcome of the interplay between trait and state variables and between historically determined and contemporary forces. Such a perspective is consistent with the emerging view of trance behavior and experience and validly parallels the phenomenology of experimental and clinical hypnosis which describe both consistency and variability in hypnotic responsiveness for a specific subject or patient across varying conditions and time" (p. 151).

"This study also serves to clarify the important role of positive social perception and a positive sense of alliance with the hypnotist as a correlate of compliance with suggestion. It is clear that Ss who complied despite inducements to resist reported a more positive perception of the hypnotist and a more gratifying sense of relatedness with him than did their counterparts who resisted in response to financial inducement. These data do not indicate whether the positive perceptions contributed to compliance, as transference theories of trance involvement would predict, or whether they were consolidated after the fact due to other variables such as management of potential cognitive dissonance. It does seem reasonable to conclude, however, that the relationship is influential in the process of suggestibility and compliance" (p. 151).

Fine, C. G. (1989). Treatment errors and iatrogenesis across therapeutic modalities in MPD and allied dissociative disorders. Dissociation, 2, 77-82.

Reviews basic transferences and countertransferences that can be monitored in the treatment of MPD and which can, if unchecked, lead to the creation of new alters. It appears that these phenomena rather

than treatment modalities per se provide the major impetus to iatrogenic increases in the complexity of MPD cases. Boundaries violations associated with nurturant transferences, angry transferences, and eroticized transferences are discussed, and boundary violations by the therapist associated with countertransference are elaborated.

**Johnson, Blair; Eagly, Alice H. (1989). Effects of involvement on persuasion: A meta-analysis. Psychological Bulletin, 106 (2), 290-314.**

Defines involvement as a motivational state induced by an association between an activated attitude and the self-concept. Integration of the available research suggests that the effects of involvement on attitude change depended on the aspect of message recipients' self-concept that was activated to create involvement: (a) their enduring values (value-relevant involvement), (b) their ability to attain desirable outcomes (outcome-relevant involvement), or (c) the impression they make on others (impression-relevant involvement). Findings showed that (a) with value-relevant involvement, high- involvement subjects were less persuaded than low-involvement subjects;

**Kihlstrom, John F.; Register, Patricia A.; Hoyt, Irene P.; Albright, Jeanne Sumi; Grigorian, Ellen M.; Heindel, William C.; Morrison, Charles R. (1989). Dispositional correlates of hypnosis: A phenomenological approach. International Journal of Clinical and Experimental Hypnosis, 37, 249-263.**

Attempted to construct and validate a questionnaire measure of hypnotic- like experiences based on Shor's (1979) 8-dimension phenomenological analysis of hypnosis. Separate item pools were developed to measure each disposition: Trance, Nonconscious Involvement, Archaic Involvement, Drowsiness, Relaxation, Vividness of Imagery, Absorption, and Access to the Unconscious. Based on preliminary testing (total Number - 856), a final questionnaire was produced containing 5 items measuring normal, everyday experiences in each domain. Results from a standardization sample (Number - 468) showed that each of the subscales, except for Archaic Involvement, possessed satisfactory levels of internal consistency and test-retest reliability. Factor analysis indicated that 6 subscales loaded highly on a common factor similar to the absorption construct (Tellegen & Atkinson, 1974), while items pertaining to Relaxation and Archaic Involvement formed separate factors. Validation testing on 4 samples receiving the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962) (total Number = 1855) showed that the Absorption and Trance dimensions correlated most strongly with HGSHS:A; the correlations with Drowsiness, Relaxation, and Nonconscious Involvement approached 0. The scales derived from Shor's analysis, however, did not improve the prediction of hypnotizability over that obtained with the absorption scale (Tellegen & Atkinson, 1974).

**Nash, Michael R.; Spinler, Dwayne (1989). Hypnosis and transference: A measure of archaic involvement. International Journal of Clinical and Experimental Hypnosis, 37, 129-144.**

20 Likert-type items were derived directly from Shor's theoretical propositions concerning the occurrence of transference-like experiences among hypnotic Ss. In 3 separate experiments, this 20-item Archaic Involvement Measure (AIM) was administered to 452 Ss following termination of both group and individually administered hypnosis procedures. Results suggest that: (a) AIM is internally consistent, and is significantly correlated with hypnotizability; (b) among high hypnotizable Ss, AIM scores assess an important aspect of hypnotic experience which is relatively unrelated to behavioral response to hypnotic suggestions; (c) there is no change in AIM scores associated with the sex of the hypnotist or S; and (d) there are 3 clusters of AIM items; perceived power of the hypnotist, positive

emotional bond to the hypnotist, and fear of negative appraisal. Possible validation and clinical research applications of AIM are presented, along with a plea for further empirical examination of the relational dimensions of hypnosis.

## NOTES

1:

Relates these findings to 'countering' (Sheehan, P., *Countering preconceptions about hypnosis: An objective index of involvement with the hypnotist. Journal of Abnormal Psychology, 1971, 78, 299-322*). "Countering is the tendency of some highly hypnotizable Subjects to comply with the intent of the hypnotist, even when there are strong nonhypnotic influences (e.g., social influences, expectations derived from previous lectures, perceptual constraints) to perform otherwise. ... Sheehan and Dolby (1979) found that hypnotic Subjects' dreams about the hypnotist were different than nonhypnotic Subjects' dreams, by being more positive and more often containing themes of protection, care, and authority. Interestingly, these themes were especially evident in the dreams of hypnotic Subjects who countered" (p. 130).

The several experiments in this study investigate reliability, concurrent validity, and factor structure of the AIM. In their discussion, Nash and Spinler make the following points. As is the case with hypnotizability, AIM scores may have a bi-modal distribution, at least when administered in the same context as a hypnosis measure. It is possible that these two modes define qualitatively different kinds of involvement with the hypnotist. "For high hypnotizable Ss, behavioral response to hypnotic suggestions appeared unrelated to the extent of archaic involvement with the hypnotist across both Experiments 2 and 3. Considering only the overall correlation between AIM and hypnotic responsiveness, one might argue that both scales measure general behavioral compliance and conformity, and that this explains their degree of association. It may indeed be correct to associate AIM scores with an overall conformity to respond, but only among low hypnotizable Subjects. For high hypnotizable Subjects, behavioral compliance (task performance) was not associated with AIM scores. Just as Sheehan's (1971, 1980) 'countering' studies suggest, among high hypnotizable Ss there appears to be no clear-cut relationship between the ability to perform hypnotic tasks and the special, motivated commitment to the hypnotist evidenced in some Ss. The theory of Shor (1979) and the empirical work of Sheehan and Dolby (1979) strongly suggest that an intense involvement with the hypnotist (archaic involvement) is a distinctive feature of the hypnotizable S's experience. The present work corroborates Sheehan and Dolby's (1979) finding that, among high hypnotizable Ss, this involvement is not equivalent to overt response to the demands of standard test suggestions.

"Three findings further suggest that AIM scores assess an important aspect of the hypnotic S's experience which is relatively unrelated to behavioral task performance. First, AIM scores correlated significantly with a measure of subjective depth during hypnosis (Hypnotic Depth Inventory, Field, 1966). Second, the correlation between hypnotic depth and AIM scores was substantial for both low and high hypnotizable Ss. Thus, for high hypnotizable Ss, AIM scores were significantly correlated with hypnotic depth, even though they were unrelated to behavioral task performance. Finally, regression analysis suggested that AIM scores accounted for variance in hypnotic depth which was not explained by task performance scores. These findings, then, conform to Shor's proposition and Sheehan's (1971, 1980) later observations that archaic involvement with the hypnotist is a fundamental dimension of hypnotic experience which may not be directly related to the extent of behavioral response to hypnotic suggestions (see Shor, 1979, p. 119)."

"It is of some interest that the mean AIM score for low hypnotizable Ss was roughly equivalent to that of control Ss who had listened to a lecture prior to AIM administration. Only Ss who were exposed to hypnosis and who were behaviorally responsive to hypnotic suggestions evidenced elevated AIM scores" (pp. 140).

1989-1990

Spanos, Nicholas P.; Flynn, Deborah M.; Niles, Judy (1989-90). Rapport and cognitive skill training in the enhancement of hypnotizability. Imagination, Cognition and Personality, 9 (3), 245-262.

The role of interpersonal rapport in facilitating the enhancements in hypnotizability produced by cognitive skill training was examined in two experiments. In Experiment 1 low hypnotizable subjects either received skill training or passively oriented training that was designed to facilitate rapport with the trainer without teaching subjects how to generate the responses called for by test suggestions. Subjects in the two treatments reported equivalently high levels of rapport with their trainer, but only those given skill training attained large gains on two hypnotizability posttests. Subjects given passive training did not differ from untreated controls at posttesting. In Experiment 2 subjects received skill training under conditions designed to either heighten or minimize rapport with the trainer. Those in the high rapport condition showed large hypnotizability gains on both posttests, whereas those in the low rapport condition failed to differ from no treatment controls in the regard. Our findings indicate that high rapport is not sufficient for producing training-induced enhancements in hypnotizability. However, the absence of such rapport may interfere with subjects' learning and applying skills that can enhance hypnotizability.

1988

Diamond, Michael Jay (1988). Accessing archaic involvement: Toward unraveling the mystery of Erickson's hypnosis. International Journal of Clinical and Experimental Hypnosis, 36, 141-156.

The "essence" underlying Milton Erickson's unique style and uncommon technical maneuvers inheres in his uncommon skill at eliciting patients' archaic involvement. Archaic involvement, as characterized by perspectiveless overevaluation, is explicated and America's beloved tale, The Wonderful Wizard of Oz, is used to evoke further perspectives. The importance of such regressive object-representations are noted. Erickson's uncanny ability to access archaic involvement and thereby profoundly influence his client is analyzed in terms of his: (a) relationship style; (b) therapeutic "persona"; (c) theoretical orientation; and (d) specific micro-techniques and interventions. Clinical findings derived from a case transcript and videotaped work are employed throughout to substantiate the argument that Erickson fosters regressive interpersonal shifts. Implications of this skill are discussed, and further avenues for investigation are suggested.

NOTES

1:

Shor (1959, 1962, 1979) introduced the concepts of archaic involvement, trance (fading of the generalized reality orientation or altered state of consciousness) and nonconscious involvement (or fulfillment of the role of hypnotic subject, dissociated role taking) to account for experienced hypnotic depth. Shor (1979) defined archaic involvement as "'the extent to which at any given moment in time there are archaic, primitive modes of relating to the hypnotist that echo back to the love relationships of early life [p. 126]' (p. 143)."

Archaic involvement develops as a hypnotist actively encourages the subject to regard the hypnotist with the role of parent, teacher, guru. Charismatic authority, protector, etc. Erickson fostered these attitudes in his patients, and his apparent magical expertise can be attributed to his ability to tap into these archaic ties, which are 'ubiquitous.' "Freud (1919/1955) long ago noted that human beings' irresolution and craving for authority should never be underestimated. Fenichel (1945) stressed the universal yearning for 'omnipotent beings whose help, comfort, and protection he could depend on [ p. 491].' Kaiser (1965) considered the 'universal psychopathology' of attempting to create in real life the fantasy of fusion. Still others (Kohut, 1971, 1977; Kriegman & Solomon, 1985; Newman, 1983) suggested that the motivation to yield to or to create such charismatic leaders stems from the desire to

lose all boundaries and become lost within a greater whole--an experience elsewhere termed a fusional or symbiotic alliance (Diamond, 1987). This 'search for oneness' (cf. Silverman, Lachman, & Milich,, 1982) is engaged by charismatic leaders as we become enticed by our own archaic wishes to avoid uncertainty, ambivalence, and the complexities of maturation, perhaps even creating such leaders to save us from ourselves" (p. 145). There remains the question of how archaic involvement facilitates or impedes psychotherapy.

In addition to archaic involvement, Erickson's behavior as a hypnotherapist during the later years of his career stressed the evocation of nonconscious role-playing, while underplaying the evocation of the trance dimension. He relied on his reputation and interventional skills, stressing 'naturally occurring trance' of everyday life. (In his earlier years he spent more time on developing profoundly altered states of consciousness.)

"Erickson's \_therapeutic 'persona'\_ and style of engaging were consistently parental and authoritative, albeit frequently permissive, supportive, flexible, and benevolent. He always remained in control and typically insisted that his orders be carried out strictly and without question (Hilgard, 1984). ... Archaic wishes are further gratified by Erickson's gentle and soothing parental tone and stance, while control is maintained as he invites his patient to 'enjoy being irritable with me'" (pp. 147-148). To further psychotherapeutic goals, he sometimes assumed the role of surrogate parent, in hypnosis, to supply the patient with needed (childhood) experiences, as in the famous case referred to as the 'February Man.'

Erickson's implicit theory of an autonomous and omnipotent unconscious further encouraged "more primitive modes of perceiving and construing consensual and historical reality" (p. 148). "For example, he tells his patient in the Lustig (1975) videotape that: 'Your unconscious knows all about it; it will inform the conscious mind when it is ready to know'" (p. 149).

Regarding his technical maneuvers (intonation, wording, nonverbal communication, indirect suggestion, metaphor, and anecdote), "contrary to popular belief, he frequently spent long periods of time thinking about and planning his interventions (Hammond, 1986). In addition to using these patterns to evoke both patient resources and archaic alliances, he adopted an exceptionally confident manner, even when prescribing unusual assignments (McCue, 1984). Thus, patient faith and positive expectation in the efficacy of his interventions were maximized" (p. 149).

Erickson's pacing of his speech was slow, at the same rate as President Reagan's speeches. He was tone deaf, which may have contributed to the arrhythmia and unusual intonation observed in his speech. He used the patient's language, typically, which "undoubtedly provides a narcissistically gratifying identification with a hypnotist felt to be inside one's own psychic system (Diamond, 1987)" (p. 150). When he would say to patients, "My voice will go with you," he was inviting a "bodily-level incorporation" (p. 150). When he created mental confusion through his maneuvers, he increased the likelihood that the patient would "respond to subsequent direction in order to bind anxiety" (p. 150). "Thus, an archaic object relationship is recapitulated by an invoked regression to earlier, primary phases of cognitive processing, and in turn, Erickson provides a safe, 'holding environment' (cf. Winnicott, 1965) for his now regressed patient" (p. 150).

Erickson used what Watzlawick (1978) has called 'the language of change'--puns, metaphors, indirect communication, analogies. He finessed the defensive functions of secondary processes (Kalt, 1986) by allying himself with the patient's secondary processes, as when he used anecdotes and teaching tales in the role of a 'Dutch uncle' giving advice. The teaching tales usually affirmed basic American values (common sense, pragmatism, self-sufficiency, resiliency, achievement; Diamond, 1983). However, this kindly grandfather approach "recreates an archaic relational situation wherein adult-level defenses and secondary processes are realigned while Erickson the storyteller permits expression and oftentimes symbolic gratification of instinctual drives. This archaic recapitulation occurs as a result of the relaxing of defenses through metaphorical communication (cf. Schafer, 1983), in addition to the

revival of opportunities for mastery within this safe and often enchanting context (cf. Bettelheim, 1977)" (p. 151).

The author concludes by addressing clinical issues pertaining to an Ericksonian approach that relies on archaic involvement. "An essential question for clinicians concerns the long-term effects on the patient of the therapist's fostering such regressive involvement. There are both pluses and minuses of therapeutic relationships which maximize archaic involvement. Consequently, we need to empirically determine the efficacy of Ericksonian interventions both in offering short-term relief from suffering, and in potentiating developmental maturation in the long run. Not only must we ascertain how much archaic involvement is required for lasting change, but what is done with the regressive involvement (i.e., is it merely evoked, managed, utilized, or ultimately worked through?) is critical in assessing the value of Erickson's contribution" (p. 152).

Greaves, G. B. (1988). Common errors in the treatment of multiple personality disorder. Dissociation, 1, 61-66.

Psychotherapists report widely different experiences in their attempts at treating multiple personality disorder (MPD) patients. Some have deepened their interests and developed full-time specialized practices with this clinical population. Others have declined to have any further contact with them at all, referring possible MPD patients to colleagues when they first suspect that this disorder may be present. Still others have decided against treating more than one or two MPD patients. These diverse decisions are examined with a focus upon the effects of therapists' uneven attention to the formal properties of the dyadic psychotherapeutic experiences as a possible influence upon their future work with MPD. Problems concerning the framework of psychotherapy and the countertransference conflicts which often move the therapist unconsciously and irrationally to alter the canons of psychotherapy in mutually detrimental ways appear to be crucial determinants.

#### NOTES

1:

Discusses countertransference conflicts that often move the therapist unconsciously and irrationally to alter the canons of psychotherapy in mutually detrimental ways.

Lynn, Steven Jay; Weekes, John R.; Matyi, Cindy L.; Neufeld, Victor (1988). Direct versus indirect suggestions, archaic involvement, and hypnotic experience. Journal of Abnormal Psychology, 97 (3), 296-301.

This study examined the effects of direct (Harvard Group Scale of Hypnotic Susceptibility; Shore & Orne, 1962) versus indirect (Alman-Wexler Indirect Hypnotic Susceptibility Scales; Pratt, Wood, & Alman, 1984) suggestions on archaic involvement (Nash & Spinler, in press) with the hypnotists, objective responding, and subjective involvement and involuntariness ratings, when the scales were administered in all possible combinations (direct/indirect, N = 61; indirect/direct, N = 61, direct/direct, N = 57; indirect/direct, N = 95), across two sessions. At the initial testing, subjects who received indirect suggestions reported a greater emotional bond with the hypnotist and increased fear of negative appraisal than subjects who received direct suggestions. Repeated testing resulted in response decrements on measures of objective responding, subjective involvement, and involuntariness that were paralleled by diminished involvement with the hypnotist. The most stable relation between scales was evident when scales were defined as direct hypnosis across both sessions. Although direct and indirect suggestions produced comparable effects in the first session, in the second session, direct suggestions fostered greater subjective involvement and feelings of involuntariness.

Nathanson, Donald L. (1988). Affect, affective resonance and a new theory for hypnosis. Psychopathology, 21, 126-137.

**Suggests new theory of hypnosis based on recent experimental and theoretical work on emotion that shows neurological systems (including structural effectors and chemical mediators affecting specific sites of action). Tomkins' nine innate affects are organizers of the other moieties, genetically determined prewritten subcortical programs that convert quantitative stimuli into qualitative experience. Emotion in the adult involves subtle and complex combinations of innate affect with associations to previous experiences of affect provided by neocortical mechanisms. The infant initially expresses affect in an all-or-none fashion, while the caregiver, usually mother, acts as an external modulator of infantile affect display. All the techniques by which the mother learns to achieve affect mutualization and interaffectivity are analogues of what later may be seen as the techniques of hypnotic induction. Hypnosis may be viewed as the intentional alteration of neocortical cognition made possible by the state of primitive interaffectivity achieved when the hypnotic operator enters the central assembly system of the adult by techniques reminiscent of maternal modulation of infantile affect display.**

**This paper reviews the contemporary status of clinical hypnosis in light of the current emphasis on briefer, pragmatic forms of therapy and consumer demands to demonstrate effectiveness. Conceptual shifts and an expansion of clinical applications are related to changes in hypnotic strategies and technique. Suggestions for future avenues of clinical research are outlined and the importance of the continued integration of scientific rigor, empirical clarity, and clinical acumen and sensitivity is emphasized.**

**Diamond, Michael Jay (1987). The interactional basis of hypnotic experience: On the relational dimensions of hypnosis. International Journal of Clinical and Experimental Hypnosis, 35, 95-115.**

**The ubiquitous interactional basis of hypnosis remains neglected and poorly understood. Vignettes from clinical practice are research are presented to illustrate the significance of hypnotic relational factors and their internal representations. A descriptive theoretical framework is formulated enumerating 4 relational dimensions: (a) transference phenomena in which previous object relationships are enacted; (b) a goal-oriented working alliance comprised of "rational" and "irrational" expectations about the efficacy of hypnotic procedure and its participants; (c) a symbiotic or fusional alliance in which the hypnotist is experienced as a purely internal figure; and (d) a realistic contemporary relationship. Each dimension is considered as it subjectively operates within hypnosis, and a case example is employed to compare the psychotherapeutic operation of these dimensions in waking and hypnotic contexts. Implications of the interactional framework are discussed and further empirical and clinical directions suggested.**

#### NOTES

Includes training materials for improving hypnotizability.

Holroyd, Jean (1987). How hypnosis may potentiate psychotherapy. American Journal of Clinical Hypnosis, 29, 194-200.

Hypnotherapy is defined as doing psychotherapy in the hypnotic state. This article reviews cognitive, affective, and motivational changes associated with hypnotic trance, attempting to demonstrate how the hypnotic state might influence ordinary psychotherapy processes. Nine characteristics of trance probably potentiate psychotherapy: (1) changes in attention and awareness, (2) imagery enhancement, (3) increase in dissociation, (4) decrease of reality orientation, (5) increase in suggestibility, (6) increased accessibility of mind-body interactions, (7) diminution of initiative resulting in a sense of nonvoluntariness, (8) increased availability or manipulability of affect, and (9) development of a fusional relationship (rapport). This article touches upon the psychotherapeutic implications of these hypnosis attributes.

#### NOTES

Hypnosis is discussed in relationship to traditional Indian medical and psychological treatments. The following Table illustrates some of the relationships among Asian approaches, which also include philosophical and religious elements.

1:

1986

Chertok, Leon (1986). Psychotherapeutic transference, suggestibility. Psychotherapy, 23 (4), 563-569.

Discusses suggestion in psychotherapy and defines it as a body-affective process, an indissociable psychosociobiological entity that acts at an archaic unconscious level far beyond that of transference, mediates the influence of one individual on another, and is capable of producing manifest psychological and physiological changes. Present in all types of therapy, indirect (nondeliberate, nonintentional) suggestion is the element that plays an important role in change and can be observed in hypnotic experimentation. It is further argued that transference and suggestion are phenomena that do not altogether overlap. Suggestion is the condition of transference without which transference could not be established.

Diamond, Michael Jay (1986). Hypnotically augmented psychotherapy: The unique contributions of the hypnotically trained clinician. American Journal of Clinical Hypnosis, 28 (4), 238-247.

In the last century, psychotherapists trained in clinical hypnosis have made a number of unique contributions to the psychotherapeutic endeavor, particularly in the areas of psychotherapeutic theory, technique, and practice. Nine factors indexing the contribution of hypnotherapists are

discussed. They are: 1) communication focus; 2) maximizing expectation and belief; 3) mind-body emphasis; 4) handling of resistance; 5) employing trance phenomena; 6) using archaic levels of relationship; 7) stressing healthy, adaptive ego functions; 8) using therapist trance; and 9) permitting responsible creativity. Each factor is considered as it pertains to hypnotic technique and phenomena as well as how it is manifested in clinical treatment.

Diamond, Michael Jay (1986). When the knight regains his armor: An indirect, psychodynamically based brief hypnotherapy of an ego-dystonic sexual impulse disorder. In Dowd, E. Thomas; Healy, James M. (Ed.), Case studies in hypnotherapy.

#### NOTES

1:

This is a case study demonstrating successful treatment of an ego-dystonic sexual disorder, using brief hypnotherapeutic treatment.

Holroyd, Jean (1986). Hypnosis applications in psychological research. Imagination, Cognition and Personality, 5, 103-115.

It is proposed that hypnosis leads to altered cognition, affect, or motivation as reflected by changes in 1) reality orientation, 2) attention and awareness, 3) imagery, 4) dissociation, 5) suggestibility, and 6) mind-body interaction. Hypnosis may be used as an experimental method to effect such cognitive, affective and motivational changes in order to pursue research in learning, personality, physiological, and social psychology. Examples of possible applications of hypnosis are provided. The influence of individual differences in hypnotic responsivity on research also is discussed.

#### NOTES

1:

The author concludes, "Contributions of hypnosis to research in psychology may have been diminished by the confusion inherent in searching for main effects while giving insufficient attention to interaction effects between personality variables and experimental manipulations. As psychology becomes more cognitive in orientation, the phenomena of hypnosis may seem less bizarre and more amenable to inclusion in psychological research. However great care must be taken not to confuse the contributions of hypnosis with the contributions of the hypnotically responsive personality" (p. 109).

#### 1985

Kelly, Paul James (1985, November). The relationship between hypnotic ability and hypnotic experience (Dissertation). Dissertation Abstracts International, 46 (5), 1690-B.

"This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experiences were: dissociation, the experience of involuntariness, altered state effects, such as perceptual alterations and diminished reality sense rapport, transference-like involvement with the hypnotist, and relaxation. A 47-item scale, the Hypnotic Experience Questionnaire was developed to measure types of hypnotic experience. It was given to 484 subjects and then to a subsample of 272 students. When the scale was factored, four stable factors emerged: Nonconscious/Trance, Rapport, Relaxation, and Cognitive Rumination. A Group Profile Scale was also developed to measure students and when it was factor analyzed four factors were extracted: Hallucinations and Fantasies, Amnesias and Post-Hypnotic Compulsions, Motor Inhibition, and Direct Motor Suggestion. "Two statistical approaches were used to investigate the connections between hypnotic ability and hypnotic experience . Canonical analysis was used to identify the main relationships between hypnotic ability and hypnotic experience and factor analysis was used to explore the relationship among measures of hypnotizability and hypnotic experience. Two canonical variates from the canonical analysis were significant. The first variate was characterized by a dissociative-

imaginative involvement process, and the second variate tapped a rapport-social compliance process. "When 25 variables, representing components of hypnotic ability and hypnotic experience, were factored, five factors were extracted. Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. The results of the factor analysis suggested that dissociative experience and altered state experience are related to hypnotic ability but rapport and relaxation are not. "The results of study, taken as a whole, suggest that relaxation and rapport may happen in the hypnotic situation, but neither experience is related to the condition of being hypnotized in any essential way. The results suggest that the hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. From a theoretical point of view, the results strongly supported Hilgard's theory, partially supported Shor's theory, and failed to support Edmonston's theory" (p. 1690).

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott; Frauman, David; Rhue, Judith (1985). Hypnotic age regression and the importance of assessing interpersonally relevant affect. International Journal of Clinical and Experimental Hypnosis, 33, 224-235.

The present study was undertaken to replicate an earlier experiment and to clarify which factors in this previous experiment (Nash, Johnson, & Tipton, 1979) were responsible for the obtained child-like behaviors of hypnotically regressed Ss. As in the previous study, 3 characteristics of the transitional object relationship (spontaneity, specificity, and intensity) were used as the primary criteria to investigate the effects of hypnotic age regression when Ss were regressed to age 3 and placed in 3 home situations. While in the previous study E suggested separation anxiety and isolation during the 3 home situations (mother-absent condition), the present study deleted all references to anxiety and isolation, and replaced them with suggestions of security and maternal proximity (mother-present condition). As expected, the mother-present versus mother-absent conditions led to similar hypnotized- simulating differences. In further accord with predictions, hypnotized Ss and simulating Ss requested a transitional object infrequently in the presence of mother. The importance of using dependent measures which index affective processes germane to interpersonal affect-laden experience is discussed.

1984

Diamond, Michael Jay (1984). It takes two to tango: Some thoughts on the neglected importance of the hypnotist in an interactive hypnotherapeutic relationship. American Journal of Clinical Hypnosis, 27, 3-13.

Hypnotists can vary in their ability to produce meaningful trance experiences. Certain hypnotists produce more meaningful trance experiences than do others. Therapeutic hypnosis is regarded as a "dual phenomenon" occurring within an intense interpersonal relationship. This interactive dimension is important as is the unique contribution made by the hypnotist. A brief historical survey demonstrates the causal attribution of hypnotic effects. The theoretical literature on the reciprocal nature of hypnotic experience emphasizes the importance of the interpersonal functions of hypnosis, the hypnotic relationship per se, and the impact of the hypnotist. Recent research investigating interactional parameters supports these conclusions and suggests future empirical directions. Finally, an emergent interactional theoretical framework is presented which views hypnotherapeutic skill primarily as a function of the hypnotherapeutic ability to create a facilitating "holding" environment for the patient's internal experience.

**Frauman, David C.; Lynn, Steven Jay; Hardaway, Richard; Molteni, Andrew (1984). Effect of subliminal symbiotic activation on hypnotic rapport and susceptibility. Journal of Abnormal Psychology, 93 (4), 481-483.**

**L. H. Silverman's subliminal symbiotic activation paradigm (Silverman, 1982) was used to manipulate unconscious affective factors in hypnosis to determine whether gratification of symbiotic fantasy would enhance hypnotic susceptibility and rapport with the hypnotist. Seventy-two male undergraduates were divided into two groups matched for susceptibility (high, medium, low). The experimental group received symbiotic, MOMMY AND I ARE ONE, subliminal stimulation via tachistoscope in a double-blind design. The comparison group received a psychodynamically neutral stimulus, PEOPLE ARE WALKING. Following subliminal stimulation, subjects were hypnotized individually. Projective tasks that indexed rapport with the hypnotist and the mother were administered during hypnosis. Rapport was also measured by rated intimacy of self-disclosure topics and by valence of topics selected to disclose to the hypnotist. A significant multivariate group selected more positively valenced topics to disclose on. The effect for symbiotic activation on hypnotic susceptibility was not quite significant ( $p < .056$ , two-tailed).**

**2350, Frauman, Lynn, Mare, & Kvaal, 1992 NOTES: [Paper presented by Lynn.] A number of observations and conclusions are based on literature reviews done with Brentar (British Journal of Experimental and Clinical Hypnosis; Chapter in Rhue, Lynn, & Kirsch [Eds.] Handbook of Clinical Hypnosis) and 15 years of training students in hypnotherapy. Some of this may seem elementary to some of you.**

**For half a century there have been reports of negative effects after hypnosis: minor, serious, transient, and chronic. Clinicians need be as wary (but no more wary) of negative effects in hypnosis as in other therapies. There are more negative effects in clinical situations than non clinical situations.**

**Therapists must be prepared to recognize negative effects and intervene.**

**Too often hypnosis is seen as a technique divorced from psychotherapy. The hypnotist must be a competent psychotherapist. What makes you a good therapist will make you a good hypnotherapist.**

**There should be careful assessment of the client for: 1. those with history of unusual experiences following anesthesia or drugs 2. those with a history of dissociation**

**People may recapitulate a previous bad experience with anesthesia, based on the unusual physiological feelings. The dissociative client must be stabilized before using hypnosis. Depressed clients may also have problems, with the imagery becoming dysphoric. Those vulnerable to psychotic decompensation, with paranoid or borderline character structures, must be evaluated carefully. A lot depends on your comfort zone in therapy.**

**Life experiences with parents and authority figures may also play into the reaction.**

**Many clients, and experimental Ss, are ambivalent about hypnosis. This ambivalence must be acknowledged and one must work with the ambivalence before proceeding. One may: - explain hypnosis - reframe in terms of self hypnosis or relaxation - explain as a state of awareness with full consciousness - offer active induction which is just as effective as the passive induction - do induction with eyes open**

**Research clearly shows that Subjects can monitor events outside the framework of a suggestion--especially if you suggest they can do so with ease.**

**We do not use ideomotor suggestions because they aren't necessary. We tell them to open their eyes and communicate with us during hypnosis.**

**We always assess their feelings about hypnosis, have them have a fantasy about what hypnosis would be like, do an informal semantic analysis of the descriptors clients use (and then reframe them), inquire about previous experiences with counseling and psychotherapy, and do a mental status. Don't**

make assumptions. We want to know about early life experiences to know about transference and form an alliance.

Hypnosis procedures employed must have explicit informed consent (cf MacHovic book), which also provides opportunity to demystify the experience. Our research shows the great majority of Ss find it relaxing, invigorating. Even perceptual distortions can be created without hypnosis. Can create confidence by sharing the research information on hypnosis.

Elicit cooperation with easier suggestions, then use graded suggestions. We want to titrate the demands on clients, move at a pace that keeps anxiety low, promote self efficacy and mastery through ... [missed a few words] and graduated tasks.

Carefully monitor clients for frowns, lack of attention, etc. It is important to ask them what they are experiencing. Rarely, a client appears unable to talk, in which case the therapist can offer hypotheses to the hypnotized client.

Don't terminate hypnosis if there is a problem (Orne also says this); instead, offer reassurance to explore/release the feelings. It is beneficial to work through what is being experienced. There is a somewhat higher risk of emotional reactions with age regression or induced dreams. We simply tell people they can tell us at any time about what they are experiencing, without going through any ritual. When we give suggestions about amnesia, we ask what they would like to remember and suggest that they forget what they would like to forget. The usual permissive suggestion doesn't work; find out what it is, exactly, that they want to forget and then devise strategies for it. Follow for 2 weeks after any abreactive experience that may have occurred. Let them know they can contact you.

Forceful suggestions to abandon symptoms can promote resistance and the therapist may generate negative transference. (See their chapter in book edited by Rhue, Lynn, and Kirsch, *Handbook of Clinical Hypnosis*, published by the American Psychological Association.)

Kelly, Paul James (1984, December). The relationship between hypnotic ability and hypnotic experience. Newsletter of Division 30, Psychological Hypnosis, of the American Psychological Association, 5.

This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experience were: dissociation, the experience of involuntariness; altered state effects, such as perceptual alterations and diminished reality sense; rapport, transference-like involvement with the hypnotist; and relaxation. A sample of 230 students was given the HGSHS:A, a group version of the SHSS:C, and the Hypnotic Experience Questionnaire (Kelly, 1984), a 47-item multidimensional scale of hypnotic experience. Items were taken from these tests to form 11 hypnotic ability variables (Positive Hallucinations, Dreams and Regressions, Post-Hypnotic Compulsions, Amnesia (HGSHS:A), Amnesia (SHSS:C), Arm Rigidity, Arm Immobilization, Other Motor Inhibitions, Head Falling, Moving Hands Together, and Hand Lowering). Fourteen hypnotic experience variables were also formed (Generalized Dissociative Effects, Dissociative Inhibition, Trance, Unawareness, Transference-like Involvement, Trust, Friendliness, Physical Relaxation, Mental Relaxation, Imagery Presence, Imagery Vividness, Imagery Detail, Self Consciousness, and Analytic Thoughts). The 25 variables were intercorrelated and factored with principal axis factoring. Five factors with eigenvalues greater than 1 were extracted and rotated to varimax criteria. These factors, which accounted for 54.4 percent of the variance, were called: Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. Hypnotic ability variables loaded significantly on three of the factors (Imaginative Involvement, Ideomotor Response, and Cognitive Inhibition) and these three factors also tapped some aspect of altered state experience and/or dissociative experience. It was concluded therefore that dissociative experience and altered state experience are related to hypnotic ability. The remaining two factors, Rapport and Relaxation, showed significant loadings only for rapport variables and relaxation variables, respectively. Neither of these

two factors were related to any of the traditional measures of hypnotic ability or to the experience of dissociative effects or altered state effects. The results of this study suggest that rapport and relaxation may happen in the hypnotic situation but neither experience is related to the condition of being hypnotized in any essential way. The hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. The results also raise questions about Edmonston's (1981) theory that relaxation is the essence of hypnotic responsiveness. The finding that the experience of relaxation is unrelated to hypnotic ability is more congruent with Hilgard's (1977) view that relaxation is a nonhypnotic process.

## NOTES

1:

This is an abstract of an unpublished Ph.D. dissertation, University of Waterloo, 1984. It won the American Psychological Association Division 30 award for Best Student Paper at the 1984 APA Convention.

Lindner, H. (1984). Therapist and patient reactions to life-threatening crises in the therapist's life. International Journal of Clinical and Experimental Hypnosis, 32 (1), 12-27.

This paper presents an analysis of the transference and the counter-transference factors in both the patient and the therapist arising from the occurrence of a life-threatening crisis in the life of the therapist. Evaluation of these factors includes a description of the role of hypnosis in the elicitation of repressed feelings of denial and hostility in both members of the therapeutic dyad.

## 1983

Diamond, Michael Jay (1983). Therapeutic indications in applying an innovative hypnotherapeutic technique: The client-as-hypnotist. American Journal of Clinical Hypnosis, 25 (4), 242-247.

A novel hypnotic induction technique is described wherein the client reverses roles and serves as hypnotist for the therapist willing to enter trance. Indications and contraindications in employing innovative hypnotherapeutic interventions are considered in terms of the therapeutic goals and context, patient-therapist interaction, and patient as well as therapist characteristics. Benefits provided by the technique to the client, client-therapist interaction, and therapist respectively are briefly discussed. The specific methodology of this technique is described according to seven steps: (1) permission request: (2) client observation: (3) session structure: (4) client confidence: (5) therapist trance: (6) feedback: and (7) subsequent utilization. Relevant clinical examples are provided.

Fourie, David P. (1983). Width of the hypnotic relationship: An interactional view of hypnotic susceptibility and hypnotic depth. Australian Journal of Clinical and Experimental Hypnosis, 11 (1), 1-14.

Efforts have been reported in the hypnosis literature to correlate measurements of hypnotic susceptibility with measurements of hypnotic depth. Not only have the findings not been consistent, but recently the whole issue of hypnotic susceptibility and depth and their measurement has become controversial, as evidenced by Weitzenhoffer's (1980) and Hilgard's (1981) statements. This paper offers a different perspective on the issue and introduces the concept of the width of the hypnotic relationship as a useful indication of the degree of hypnotic involvement. The width of the hypnotic (paradoxical) relationship refers to the scope of the relationship within which certain involuntary behaviors can occur. The larger the number of such behaviors that are possible within the bounds of the paradoxical relationship, the wider that relationship shall be considered to be. This is an investigation of the relationship between the width of the relationship and the depth of hypnosis experienced. The SHSS: A, as a measurement of the width of the relationship, was applied to 18

volunteer female subjects. A 10-point self-report scale was applied before and after a procedure to widen the relationship. The correlations between the SHSS: A scores and both sets of self-report scores were positive and significant, as expected. The widening procedure had a definite deepening effect, but it seemed possible that this effect was not uniform.

Levitt, Eugene E.; Baker, Elgan L. (1983). The hypnotic relationship--another look at coercion, compliance and resistance: A brief communication. International Journal of Clinical and Experimental Hypnosis, 31, 125-131.

The purpose of the present investigation was to assess the ability of hypnotic Ss to voluntarily resist neutral suggestions on a monetary reward incentive. The results were ambiguous; Ss resisted with a mean of 1.2 of 2 suggestions each. Postexperimental interviews disclosed that all Ss felt that the instructions to resist were asking them to be disloyal to the hypnotist or to betray him. Ability to resist was positively correlated with Ss' impressions of the "resistance instructor" and tended to be negatively correlated with the impression of the hypnotist. These findings are interpreted to suggest support for an interactional conception of the hypnotic state.

1982

Chertok, Leon (1982). The unconscious and hypnosis. International Journal of Clinical and Experimental Hypnosis, 30 (2), 95-107.

This paper reviews Soviet approaches to the unconscious and to hypnotic phenomena, before examining psychoanalytic theories of hypnosis which are generally based on transference. The author believes the existing theories are inadequate, arguing that there is a psychophysiological dimension to hypnosis; but what unconscious processes does this conceal? Psychoanalysis opened one road to the unconscious, but affect, nonverbal communication, and psychophysiological process are still uncharted territories towards which hypnosis may yet prove to be another royal road.

NOTES

1:

The author concludes, "hypnosis and the unconscious ... are closely linked. Historically, experiments on posthypnotic suggestion were in fact the starting point for the discovery of the unconscious. Posthypnotic suggestion is in effect one of the most irrefutable proofs that psychical contents can influence behavior, albeit eluding the subject's consciousness.

"In this paper, the present author provides a description of Soviet researchers' conceptions of the unconscious, and of the point of view from which they approach hypnotic phenomena. Psychoanalytic theories of hypnosis are then presented, which are essentially based on transference. It is shown why this notion seems to the present author powerless to account for the specific nature of the hypnotic relationship. There is, in effect, a psychophysiological dimension to hypnosis. It lies at the crossroads between the instrumental and the relational dimension. But nothing is known about what unconscious processes hide at the psychophysiological level. Psychoanalysis has brought to light the laws governing the functioning of unconscious representations. But the realm of the affect, the nonverbal communication, and bodily processes still remain beyond our knowledge. This is a hidden side of the unconscious, in relation to which hypnosis may serve as another 'royal road'" (pp. 104-105).

Hong, G. K.; Skiba, A. H.; Yepes, E.; O'Brien, R. M. (1982). Effects of ethnicity of hypnotist and subject on hypnotic susceptibility. International Journal of Clinical and Experimental Hypnosis, 30 (1), 23-31.

The effect of ethnic similarity of hypnotist and hypnotic S on hypnotic susceptibility was examined in a 2-part study. The first part of the study compared the performance of Anglo versus Chinese hypnotists on Anglo versus Chinese Ss. In the second half of the study, Anglo and Hispanic Ss and hypnotists were compared using the same Anglo hypnotist-S control group. In total, 112 volunteers were administered the Stanford Hypnotic Susceptibility Scale, Form A, of A. M. Weitzenhoffer and Hilgard (1959), with 16 Ss (8 males and 8 females) in each condition. A 2 x 2 ANOVA was performed on the data for each part of the study. Ethnic similarity of hypnotist and S was found not to enhance hypnotic susceptibility. The implications of these results are discussed in relation to the assumed superiority of homoethnicity in psychotherapy.

Silverman, Lloyd H.; Lachmann, Frank M.; Milich, Robert H. (1982). The search for oneness. New York: International Universities Press.

#### NOTES

1:

This book summarizes research on preconscious activation (subliminal psychodynamic activation) of fantasies of oneness, following tachistoscopic presentation of words like, "Mommy and I are one." It represents an attempt to test and validate, through experimental investigation, psychoanalytic concepts. The authors show how such fantasies can improve psychosocial adaptation for people with varying kinds of psychopathology.

1981

Franck, Jerome (1981, August). Therapeutic components shared by all psychotherapies. [Paper] Presented at the annual meeting of the American Psychological Association.

#### NOTES

1:

The author summarizes as follows. 1. Patients who receive any form of psychotherapy do better than controls. 2. Followup studies show most patients who show improvement maintain it; the closing of gap between patients who improve and those who don't is due to those who do less well catching up. Perhaps the main effect is to accelerate improvement which would eventually happen anyway. 3. Determinants of successful treatment are personal qualities of Patient and Therapist. 4. There are a few conditions which have more specific treatment indications. --Behavior therapy - for phobias, obsessive compulsive disorders, sexuality problems --Cognitive therapy - for depression Further advantages of specific treatments for specific conditions may be found.

All patients seek treatment not just for symptoms but because of demoralization. The common elements are: Subjective incompetence, loss of self esteem, alienation, hopelessness, helplessness, a feeling others could help but won't, feeling of loss of control. Demoralization plus distress leads to seeking treatment.

A small percentage without demoralization seek treatment for specific symptoms (e.g., patients with a simple phobia of height). Anxiety and depression (or loss of self esteem) are most frequent symptoms in Outpatient Departments.

Success in treatment often is due to restoration of morale (which removing symptoms can do very well). 1. Citing Doehrenwald research. 2. People seek treatment only 1-2 years after symptoms appear, after trying other ways of dealing with them. 3. Many patients improve rapidly in treatment (Garfield found the Mean = 5 or 6 sessions.) Mean symptom relief is same after 4 sessions and drop-out than after 6 months; also those on waiting list in phone contact improve as much.

Shared components in the various therapies combat demoralization: 1. Emotionally charged and vital relationship with the helping person (or group). 2. Healing setting (which increases Therapist's prestige and promotes healing). (a) Therapeutic rituals (which lead to an external reason for

abandoning the symptom; the more spectacular the reason, the greater the motivation). (b) Therapeutic bond.

Expectation of help is the best predictor of outcome. (Cites his own placebo study.) One problem found was that responsiveness to placebo didn't correlate with response to psychotherapy. (Cites Lieberman's study). Patients receiving psychotherapy role-induction interview improved more. 3. Provision of learning experiences - movement of values toward those of the therapist 4. Emotional arousal. Supplies motivation for change. Cites his experiments on emotional arousal and attitude change, manipulating arousal using ether drip or adrenalin (leads to temporary attitude change). Something else besides arousal may be needed to sustain change. 5. Enhances sense of mastery, control of one's self and internal states. (a) provides conceptual scheme (b) gives experience of success 6. Provision of opportunities (and incentives) to practice

Properties of Patient which assure success: 1. Distress 2. Earlier relationship with parent which leads to capacity to relate. (Molly Harrower's predictors) 3. To profit from specific procedures: capacity for insight for psychoanalysis.

Properties of Therapist which contribute to success:

We haven't gotten farther than Rogers' empathy, warmth, and positive regard; Whitehorn & Betz's Type A and B; and [missed reference name] activity level. He thinks success may be related to Therapist's parapsychological ability, healing power.

Physiology of hope: Placebos for dental pain lead to pain relief for some. Endorphin antagonist made pain re-occur for them.

1980

**Diamond, Michael Jay (1980). The client-as-hypnotist: Furthering hypnotherapeutic change. International Journal of Clinical and Experimental Hypnosis, 28, 197-207.**

A novel hypnotic induction technique is described wherein the client reverses roles and serves as hypnotist for the therapist. Relevant theoretical processes are discussed as are mutual hypnosis, modeling, and the uncommon techniques of Erickson (1964). 3 case illustrations are presented and implications discussed. It is hypothesized that the 'client-as-hypnotist' may in certain special situations further hypnotherapy by: (a) increasing client motivation; (b) enhancing therapeutic rapport; (c) increasing both client trust and skills in utilizing unconscious processes; (d) overcoming resistance and increasing hypnotizability; (e) providing a useful psychodiagnostic and behavior assessment index; (f) presenting a role 'model' for dealing with feelings, alterations in consciousness, and self-control; (g) providing a client-centered framework for subsequent therapeutic interventions; (h) increasing client self-esteem, mastery, and ego strength; and (i) increasing client self-control skills. Potential risks and contraindications for use of the technique are also discussed.

**Sheehan, Peter W. (1980). Factors influencing rapport in hypnosis. Journal of Abnormal Psychology, 89 (2), 263-281.**

The phenomenon of countering expresses the tendency of some highly susceptible subjects to favor the intent of the hypnotist when placed in a conflict situation where social influences of another kind dictate an alternative response. The present research explored the parameters of this objective index of involvement with the hypnotist to investigate the special relevance of rapport processes to the hypnotic setting. Rapport was manipulated in five different experiments, varying either the warmth or genuineness of the hypnotist. It was predicted from transference theorizing that countering would decrease in the negative context and increase in the positive one. Results confirmed predictions for

highly susceptible subjects tested in the former context but not the latter. In the negative setting, subjects were inhibited in their rate of countering, but maintained their previous level of response to the hypnotist when rapport was facilitated. Results highlighted the relevance of interpersonal processes to theorizing about hypnosis.

Sheehan, Peter W. (1979). Expectancy reactions in hypnosis. In Burrows, G. D.; Collison, D. R.; Dennerstein, L. (Ed.), Hypnosis 1979 (pp. 25-32). Amsterdam: Elsevier/North-Holland Biomedical Press.

NOTES

1:

Susceptible Subjects are more likely to follow the hypnotist's nonverbalized suggestion when it is counter to their expectation. But not consistently. His article in April 1979 *Journal of Abnormal Psychology* reports 10 studies of this. Such individual differences that exist relate to styles of performance, parameters which have nothing to do with hypnotizability.

Thompson, Kay F. (1979). The case against relaxation. In Burrows, G. D.; Collison, D. R.; Dennerstein, L. (Ed.), Hypnosis 1979 (pp. 41-46). Amsterdam: Elsevier/North-Holland Biomedical Press.

NOTES

1:

"One wonders why facilitators continue to talk about and insist on relaxation as a precondition for hypnosis. Do we need to see this relaxation to believe our patients are truly in a hypnotic state?" (p. 43). "The advantages of eliminating relaxation as a precondition for trance include the elimination of the need to re-learn the non-relaxed state, the admission of more natural responses to the therapeutic situation, the recognition of spontaneous trance, and a freer communication between the doctor and patient which should result in a more comfortable use of hypnosis and its more widespread acceptance in medicine" (p. 45).

1978

Hearn, Greg (1978, November). Susceptibility and the process of social interaction in the hypnotic context. [Unpublished manuscript] (Submitted as a partial requirement for the B. S. degree with honours in psychology at the Univ of Queensland)

The hypothesis was tested that the process of social interaction between hypnotist and subject is dependent upon the susceptibility level of subjects. Using Interaction Process Analysis (Bales, 1950), the interaction patterns of 16 high susceptibles and 16 low susceptibles were analyzed. Susceptibility level had been pretested with the HGSHS:A. The hypnotist was then instructed on how to control for differences in the process of interaction which were isolated and the initial hypnotic session was repeated on a new sample. This time the performance and interaction patterns of six high susceptibles and six low susceptibles were compared. Results suggested that trait differences give rise spontaneously to differences in the process of interaction and some combination of these effect the subjects final hypnotic performance. Hence it is argued that an interactionist framework would aid the understanding hypnotic responsivity.

1976

Hodge, J. R. (1976). The contractual aspects of hypnosis. International Journal of Clinical and Experimental Hypnosis, 24, 391-399.

No generally accepted theory of the essence of hypnosis is currently available, nor are any specific responses uniquely associated with hypnosis. A necessary, though not sufficient, aspect of hypnosis involves the subject's preconceived expectations and selective attention to a series of agreements ("contracts") which are developed between patient and therapist before the induction, during the induction and deepening procedures, and during the operational phase. These contracts may be either implicit or explicit, but they can be identified in all hypnotic interactions. The skillful therapist will make the contracts explicit by defining, at least in general terms, what he expects. If the patient agrees, i.e., "sings the contract," he is likely to comply with suggestions.

1972

Sacerdote, Paul (1972). The nature of the hypnotherapeutic process. American Journal of Clinical Hypnosis, 15 (1), 1-11

The author presents several clinical cases where hypnosis was successfully utilized. Through detailed description of what takes place during sessions it is shown how various approaches are adapted to the intellectual, cultural, emotional and hypnotic capabilities of the patient and to the progress of therapy. The author analyzes what takes place during and after hypnotic intervention and draws some conclusions about the nature of the hypnotherapeutic process which, he feels, is essentially a convergence of the patient's and therapist's conscious and subconscious expectations and goals. The importance of the therapeutic ego of the doctor is brought into proper focus. One of the clinical cases illustrates how the therapist can convert a therapeutic relationship that may appear sterile or even hostile into a productive one by utilizing the patient's responses, while avoiding stubborn insistence upon expectations of preconceived hypnotic responses. It is suggested that the hypnotherapeutic model may present, in clearer focus, what takes place in other psychotherapeutic exchanges which do not utilize hypnosis.

1970

Shor, Ronald E. (1970). The three-factor theory of hypnosis as applied to the book-reading fantasy and to the concept of suggestion. International Journal of Clinical and Experimental Hypnosis, 18, 89-98.

Maintained that many of the conflicting viewpoints in theories of hypnosis parallel the descriptive complexity of the phenomena. A 3-factor theory of hypnosis is surveyed in which hypnotic depth is conceived as a complex of 3 separate but complementary processes or dimensions. The theory is used to illuminate the book-reading fantasy and the concept of suggestion. (Spanish & German summaries) (16 ref.) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

1969

Blatt, Sidney J.; Goodman, John T.; Wallington, Sue Ann (1969). Is the hypnotist also being hypnotized?. International Journal of Clinical and Experimental Hypnosis, 17, 160-166.

Noted that 2 hypnotists had cognitive and affective experiences similar to those expected in the S as a function of the hypnotic manipulation when they were conducting hypnotic inductions. Though the hypnotists may have been responding to the mood tone of the Ss or responding on the basis of their expectations about the effect of the hypnotic manipulation, it seemed equally possible that the hypnotists may have experienced mild forms of the trance state they had induced in their Ss. These observations seemed consistent with prior notes of such a phenomenon. This phenomenon has important implications for the clinical and experimental use of hypnosis and for concepts such as transference and countertransference, empathy, demand characteristics, and E bias. Suggestions are

made for the systematic evaluation and study of this phenomenon. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Hunt, Sonja M. (1969). The speech of the subject under hypnosis. International Journal of Clinical and Experimental Hypnosis, 17, 209-216.

Attempts to objectify changes taking place in the speech of 12 undergraduates under hypnosis as compared with their waking speech. A series of open-ended questions was asked in the waking and hypnotized states and the responses compared. Results indicate that the latency of response may be longer, the rate of speech slower, and the number of words in the response fewer under hypnosis. The rate of speech of E, however, also differed significantly between Ss in waking and hypnotized conditions. It was therefore not possible to attribute the speech changes only to the hypnotized state. They could have arisen from E's differential verbal treatment of hypnotized and waking Ss. The need for future research and its nature are discussed. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Small, Maurice M.; Kramer, Ernest (1969). Hypnotic susceptibility as a function of the prestige of the hypnotist. International Journal of Clinical and Experimental Hypnosis, 17, 251-256.

Administered 40 undergraduates the Harvard Group Scale of Hypnotic Susceptibility, Form A. On the basis of the scores, Ss were divided into 20 "better" and 20 "poorer" Ss. A wk. later Ss were rehypnotized by a tape recording of the above induction procedure. On the 2nd induction, 1/2 of the Ss were told that the hypnotist on the tape was an expert; the other 1/2 were told the hypnotist was a novice. Results indicate that only the better Ss given novice instructions showed a change (decrement) in hypnotic susceptibility. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Conn, J. H. (1968). Hypnosynthesis: Psychobiologic principles in the practice of dynamic psychotherapy utilizing hypnotic procedures. International Journal of Clinical and Experimental Hypnosis, 16, 1-25.

DEFINES HYPNOSIS AS PRIMARILY A CHANGE IN REALITY TESTING, AND CONSIDERS IT AS BOTH AN ALTERED STATE OF CONSCIOUSNESS AND A MULTILEVEL DYNAMIC RELATIONSHIP IN WHICH THE S IS ALWAYS AWARE OF THE OPERATOR. HYPNOSYNTHESIS EMPHASIZES THE PATIENT'S VALUES AND EXPECTATIONS AND HIS FREEDOM TO CHOOSE WHAT TO SAY AND HOW HE SHOULD BE TREATED. PREFERENCE IS GIVEN TO TERMS OF "MORE OR LESS" CONSCIOUSNESS. THE PATIENT DOES NOT RECEIVE ANY TRAINING IN HYPNOSIS AND THERE IS NO ENCOURAGEMENT OF ACTING OUT IN HYPNOSYNTHESIS. ATTENTION IS DIRECTED TO REPETITIVE PATTERNS, AND THE HYPNOTIC EXPERIENCE IS UTILIZED AS A PRESENT DYNAMIC EXPERIENCE. HYPNOSYNTHESIS DEMONSTRATES THAT SYMPTOM REMOVAL IS POSSIBLE WITHOUT SYMPTOM SUBSTITUTION WHEN THERE IS AN EFFECTIVE WORKING RELATIONSHIP. THE COMMON FACTOR IN EVERY PSYCHOGENIC CURE, INCLUDING HYPNOTHERAPY, IS THE FOSTERING OF SELF-ESTEEM AND ACTIVE PARTICIPATION, BOTH OF WHICH ARE ACHIEVED BY EFFECTIVE COLLABORATION IN THE THERAPEUTIC SITUATION. Sternbach, Richard A. (1968). Pain: A psychophysiological analysis. New York: Academic Press.

## NOTES

1:

**NOTES: Anxiety potentiates pain, no matter what the source of the anxiety ("meaning of the wound, intensity of the stimulus, a personality characteristic or introduced into the situation" (p. 25). "Local muscles show a marked increase in their electrical potentials following localized pain produced by pressure (Simons, Day, Goodell, and Wolff, 1943), and this striated muscle can potentiate and prolong the responses to the original stimulus (Hardy, Wolff, and Goodell, 1952)" (p. 51). Shor (1962) investigated the physiological response to pain during hypnotic analgesia and used procedures to minimize anxiety in both waking and hypnotized conditions. The 'pure pain' physiological response involved a slight increase in heart rate, depth of respiration, and palmar sweating, "little more than an orienting reflex" (p. 54).**

**Because people vary in the degree to which their pattern of response to pain is stereotyped, it is difficult to detect a pattern specific to pain. However, frequently there is inhibition of motility of the gastrointestinal tract and blocking of or more rapid contractions; increased oxygen consumption with hyperventilation; increase in muscle tension and hypermotility; and variable cardiovascular responses-sometimes elevated blood pressure, sometimes increased pulse, stroke volume, or peripheral vasoconstriction. The physiological changes appear to be preparing the person to take action.**

**Personality characteristics have been investigated with respect to pain reactivity and tolerance. Mueller (1962) predicted response to spinothalamic tractectomy for 14 patients with intractable pain due to spinal cord injuries with 85% accuracy using the Rorschach. Field dependence on the rod and frame test is associated with parasympathetic reactivity to pain, and less reaction to pain. "Those who can tolerate pain (intense stimulation) best can tolerate sensory deprivation (minimal stimulation) least, and vice versa" (p. 62). Also, the nondominant hand is more sensitive than the dominant hand.**

**Sternbach distinguishes pain tolerance from willingness to complain about pain. For example, cultural factors (ethnicity) affect not only pain toleration but also physiological response. Voluntary participation in a pain experience can in fact reduce the discomfort of the pain stimulus. "Pain tolerance may be in part a function of their ability to reduce anxiety concerned with the duration of time (a) a noxious stimulus will last, or (b) before a noxious stimulus will be experienced" (p. 67).**

**Phantom pain is an example of centrally occurring pain. It occurs in only a few patients who have a phantom limb, from 2-10% depending on how they are assessed. Scars and neuromas at the stump may reduce thresholds to peripheral stimulation or may themselves act as pain stimuli. Surgery on the neuromas and scar tissues seldom reduces the phantom limb pain. Most investigators assume it is a 'central' phenomenon of some sort, 'superadded sensations' which may be of psychogenic origin (Henderson & Smyth, 1948) or a 'central state of hyperexcitability' (Cronholm, 1951). Affect seems to be involved. The affects, and the individual's style of coping with them, seem to be the equivalents of the 'central' phenomena which result in pain. Two affects in particular seem to be associated with pain: anger, intropunitively expressed; and grief, the phantom pain representing both the loss and the wish to deny it. Both of these are likely to be associated with depression.**

A psychological (rather than neurological) explanation for phantom limb pain is supported by the success demonstrated by three interventions: psychotherapy, electroshock therapy, and sensorimotor task concentration. The latter approach, reported by Morganstern (1984) requires patients to concentrate on sensorimotor tasks while ignoring distracting stimuli, for 2 hours/day. Morganstern attributed their improvement to a combination of concentration and distraction so that central sensory processes gradually are reorganized and the patients become habituated to stimulation of the stump. Sternbach notes that these factors also characterize hypnosis and hypnotic analgesia. He proposes that the Morganstern results should inform our neurological explanation of phantom pain.

Sternbach goes on to discuss hypnosis, particularly as it offers information that could inform us about pain. He notes that hypnotic inductions and the hypnotic state are characterized by "immobility and sensory canalization, a reliance on the hypnotist for information and direction, and an altered state of awareness in which the environs are perceived as suggested by the hypnotist" (pp. 136-137). The Kubie and Margolin (1944) description of a concentrated focus of excitation in the brain with surrounding areas of inhibition is like the description of hypnosis presented by Ivan Pavlov. During this process, the hypnotized subject becomes dependent on the hypnotist for contact with the outside world, but this emotional/motivational response is not central to the induction. "What is essential is the restriction of sensory and motor activity which, in a variety of natural or experimental settings, with or without another person present, will invariably produce hypnoidal states and hypnagogic reverie" (p. 134).

The profound alterations in perception that are observed in hypnosis are relevant to the understanding of pain because pain "involves perception of certain tissue changes." Sternbach notes that the experimental problem of ascertaining whether a subject is faking hypnotic phenomena is similar to the experimental difficulties inherent in evaluating the (internal) experiencing of pain. He suggests that the Orne (1959) test for toleration of logical inconsistencies is an independent means of evaluating for genuine hypnotic response. Other possible indices are less spontaneous behavior (Gill & Brenman, 1959) or alterations in subjective awareness (Ludwig & Levine, 1965). On the Ludwig & Levine questionnaire, subjects reported changes in thinking, time sense, feelings of loss of control, body image changes, changes in sensations, etc.

It has been observed that physiological response depends on presence or absence of a shock, but behavioral and verbal response depends on suggested or not suggested analgesia (Sutcliffe, 1961).

In Sternbach's summary of the section on hypnosis in this book, he states, "Hypnotic analgesia adds to the above [hypnotic induction] the hypnotist's suggestion of pain relief, or the inability to perceive pain. Experimental and clinical data suggest that in most but not all instances, pain responses are then greatly attenuated. The data further suggest the reasonable inference that such hypnotic analgesia is effective either because attention is focused elsewhere, or because anxiety (concern about the stimulus effects) is very low. ...

"It seems to us reasonable to make a further inference from these data, concerning the relative roles of attention focusing and anxiety-reduction. It is our impression, from the studies cited above, that the focusing of attention is not in itself essential to the elimination of pain. It is necessary for the induction of hypnosis, and it is a useful (but not the only) means for a subject or patient to gain control over anxiety concerning pain stimuli. But the data strongly suggest that in hypnotic analgesia, as well as in other conditions, it is the absence of anxiety about the stimulation which is the single necessary and sufficient condition for perceiving the stimulus as a nonpainful sensation. This is suggested by the fact that subjects with hypnotic analgesia are able to attend to (focus attention on) the stimulus, and even describe it accurately as a sensation, and yet not produce pain responses. This is true also of subjects in control conditions without hypnosis. On the other hand, anxious subjects ( or patients), as we have seen elsewhere (Chapter V), typically produce marked pain responses to appropriate stimulation. Thus it seems reasonable to hypothesize that 'focusing attention' serves primarily to reduce a person's anxiety about his current situation, thus making possible either (1) the regression

and altered state of consciousness of a hypnotic trance, or (2) the perception of a noxious stimulus as a nonpainful sensation" (pp. 140-141).

1964

Field, Peter B. (1964). Bales interaction analysis of hypnosis. International Journal of Clinical and Experimental Hypnosis, 12, 88-98.

Sound films of 2 hypnotists, 4 Ss, and 2 simulators of hypnosis were scored by a modification of Bales' interaction process analysis. Comparisons are presented between the interaction profiles of hypnotists and Ss. Both of the hypnotists' transformed interaction percentages fell above the Ss' 95% confidence intervals for agreeing, asking questions, and giving suggestions, and below the Ss' confidence intervals for appearing submissive, giving opinions, showing tension, and giving information. No consistent differences were found between hypnotists and Ss for seeming positive, negative, or dominant, for disagreeing, or for releasing tension. The 2 simulators did not show consistent interaction differences from the real Ss. Both advantages and limitations in applying Bales' method to hypnosis are discussed. It is concluded that interaction process analysis provides a measure of the overt role-differentiation between S and hypnotist, but does not directly reflect some of the unique features of the hypnotic situation (17 ref.) 1963

Levitt, Eugene E.; Lubin, B. (1963). TAT card '12MF' and hypnosis themes in females. International Journal of Clinical and Experimental Hypnosis, 11, 241-244.

Modification of TAT Card 12M, so that the supine figure was a female, did not increase the frequency of hypnosis themes among sophomore student nurses. The hypothesis that difficulty in identifying with a male figure accounted for the card's inability to predict attitudes towards hypnosis in females was, therefore, not supported. The modified card did elicit significantly more identifications of the standing figure as a professional person. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Pulver, Sydney E. (1963). Delusions following hypnosis. International Journal of Clinical and Experimental Hypnosis, 11, 11-22.

Delusions occurring after hypnosis in the nonpsychotic patient are usually a result of the interplay of 3 factors. (a) the development of rapid, tense, transference reactions in hypnosis; (b) the presence of major defects in the patient's character structure; and (c) the occurrence of countertransference

reactions on the part of the hypnotist which touch on a specific area of conflict within the patient. The presence of a chaperon or the use of tape recorders are not satisfactory preventive measures. Rather, the physician using hypnosis should focus upon: (a) preliminary psychological evaluation and selection of patients free from disposition to delusion formation, (b) identification of transference reactions and a willingness to discuss with patients, (c) awareness of his own emotional responses to the patient. Basic courses in psychiatry are recommended. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1962

English, O. Spurgeon (1962). Some dynamic concepts of human emotions in relation to hypnosis. American Journal of Clinical Hypnosis, 4, 135-140.

He describes characteristics of the human personality as having a need for being dependent, tendency to obey or cooperate, need to avoid pain, tendency toward retreating into solitude and silence away from the stimuli of every day living, wish to avoid tension or anxiety; and therefore having a need to regress, in hypnosis.

Kuhner, Arthur (1962). Hypnosis without hypnosis. International Journal of Clinical and Experimental Hypnosis, 10 (2), 93-99.

The traditional concept of hypnosis that seeks a "sleep" state through employment of formal induction techniques seriously limits its general clinical applicability. It fails to fit the special needs of the patient. An approach designed to counteract this shortcoming manipulates the interpersonal relationship factor. Case illustrations from dental practice support the viewpoint that the proper relationship is akin to the hypnotic one and comparable results obtain without resort to ritualistic induction methods. Weitzenhoffer, Andre M. (1962). The significance of hypnotic depth in therapy. International Journal of Clinical and Experimental Hypnosis, 10 (2), 75-78.

It is a common assumption that hypnosis has a quality of degree. While clinicians often state that success is unrelated to depth, the author maintains that depth determines the techniques one can successfully use in hypnotherapy. At the same time he believes that hypnotic behavior is multidimensional and that the major determinant of hypnotherapeutic success is the therapist's ability to establish a meaningful interpersonal relationship. Schneck, Jerome M. (1961). Hidden determinants in deceptive requests for hypnoanalysis. International Journal of Clinical and Experimental Hypnosis, 9, 261-267. (Abstracted in Psychological Abstracts, 62: 4 II 61S)

Evaluation of the motives underlying the request for hypnoanalysis leads to the conclusion that often these patients do not wish for this form of treatment at all. Thus, requests for hypnoanalysis are often deceptive (a method of changing therapists during a period of negative transference). The implications of these hidden determinants are discussed and brief case references are given. From Psyc Abstracts 36:04:4II61S. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1960

Conn, Jacob H. (1960). The psychodynamics of recovery under hypnosis. International Journal of Clinical and Experimental Hypnosis, 8, 3-16.

Defines hypnosis as primarily a change in reality testing, and considers it as both an altered state of consciousness and a multilevel dynamic relationship in which the S is always aware of the operator. Hypnosynthesis emphasizes the patient's values and expectations and his freedom to choose what to say and how he should be treated. Preference is given to terms of "more or less" consciousness. The patient does not receive any training in hypnosis and there is no encouragement of acting out in hypnosynthesis. Attention is directed to repetitive patterns, and the hypnotic experience is utilized as a present dynamic experience. Hypnosynthesis demonstrates that symptom removal is possible without symptom substitution when there is an effective working relationship. The common factor in every psychogenic cure, including hypnotherapy, is the fostering of self-esteem and active participation, both of which are achieved by effective collaboration in the therapeutic situation. Schneck, Jerome M. (1960). Special aspects of hypnotic regression and revivification. International Journal of Clinical and Experimental Hypnosis, 8, 37-42/

#### NOTES

1:  
Author's Summary: "This report delineates a type of hypnotic revivification without the usually expected dramatic behavioral attributes and use of the present tense in verbalization. On the contrary, motor involvement is at a minimum, manifestations of acting out are devoid of dramatic channels, yet emotion is intense and verbalization is absent. Awareness of the existence of such revivification in the hypnotic setting is important for adequate understanding by the therapist and incorporation into hypnotherapeutic or hypnoanalytic procedure. Considerable alteration of temporal and spatial orientations take place and should be appreciated fully. The revivification under discussion was observed in hypnotic settings involving regressions to preverbal age levels. These observations permitted better recognition of similar occurrences for later age periods. Revivification without verbalization may be disclosed subsequently by the patient in spontaneous comments or explored by

the therapist when it has been suspected. The discussion of this phenomenon has centered on the hypnoanalysis of a fifty-four year old woman. The ingredients have been encountered often with others. Additional details pertaining to the revivifications have been described. The psychodynamic implications of the above-mentioned patient's reference to her hypnotic involvements as "vivification" events owing to intensity of the emotional components, have been outlined and linked to previously presented views on emotional insight preceding intellectual insight. The transference elements in revivifications have been given attention and shown to be consistent with a proposed concept of dynamic hypnotic age regression in contrast to chronological hypnotic age regression. The data presented have been correlated with views of a hypnotic-waking state continuum" (p. 41).

Barber, Theodore Xenophon (1958). Hypnosis as perceptual-cognitive restructuring: II. "Post"-hypnotic behavior. Journal of Clinical and Experimental Hypnosis, 6 (1), 10-20.

NOTES

1:

The author presents "experimental evidence indicating that there is no essential difference between 'hypnotic' behavior and 'post-hypnotic' behavior" (p. 11).

"Summary and Conclusions

"When 'somnambulistic' subjects were told to 'wake up' after they were given a 'post-hypnotic suggestion' and 'amnesia for the suggestion' they behaved as follows:

1. They opened their eyes and became relatively more aware of their surroundings.
2. They were aware that the signal for the 'post-hypnotic- behavior had special significance for them.
3. They were 'set' to 'obey the hypnotist's suggestions' from the moment they were told to 'wake up,' until they were convinced that their interpersonal relationship with the operator was no longer that of subject and hypnotist.
4. When the 'post-hypnotic suggestion' was uncomplicated and fitted into the normal pattern of behavior, the subjects carried it out without 'going deeper into trance,' i.e., without becoming relatively more 'detached' from their surroundings. However, when the 'post-hypnotic suggestion' was of such a nature that it was necessary for the subjects to 'go deeper into trance' to properly carry it out, the subjects did 'go deeper into trance.'

"Whether the subjects did or did not have amnesia for the 'post-hypnotic suggestion' was not important. 'Amnesic' and 'non-amnesic' subjects carried out the 'post-hypnotic' behavior in essentially the same way.

"These experiments indicate that:

1. If the operator properly manipulates the situation, the 'good' hypnotic subject is 'set' to carry out the operator's commands in the 'post-hypnotic' period in the same way as during 'hypnosis.'
2. If, in order to properly carry out the 'post-hypnotic suggestions,' it is necessary for the subject to 'go deeper into trance' -- i.e., to become relatively inattentive to stimuli not emanating from the operator -- the good subject will do so.
3. There is no essential- difference between the subject's behavior in the 'hypnotic' period and in the 'post-hypnotic' period.
4. If we are to continue speaking of 'suggestions' to be carried out in the post-hypnotic period we should term them 'post'-hypnotic 'suggestions'" (pp. 19-20).

Schneck, Jerome M. (1958). Relationships between hypnotist-audience and hypnotist-subject interaction. Journal of Clinical and Experimental Hypnosis, 6 (4), 171-181.

"Patients discussing or entering hypnotherapy are frequently influenced in their attitudes by some measure of direct or indirect contact with popular exhibitions of hypnosis. Expectations, interpretations, general behavior, and transference relationships are affected as a result. Previous papers by others have discussed and described popular exhibitions from the view of dangers and deception based on undeclared use of trained hypnotic subjects. The present paper is a study of a popular exhibition of hypnosis by a well known entertainer. Admixtures of good and rewarding entertainment method and poorly managed hypnotic technique are described. Stress is placed on the major approach involving impression by implication rather than elicitation of phenomena and clarification of claims with demonstration by challenge. The result is one of impressing the audience in regard to possible behavior under hypnosis without the actual proof of such claims. This is accomplished through reliance on the suggestibility and gullibility of the audience owing to its lack of experience and information. In most instances then, hypnotist-subject interaction is reduced to the most simple essentials. Stress is placed on the hypnotist-audience relationship. In some of the demonstrations there were varying degrees of subtle interplay between hypnotist-subject and hypnotist-audience relationships with the fostering of audience-subject identification and subject-hypnotist identification via coentertainer status. The hypnotist was capable at times of capitalizing on what he apparently sensed were the needs and likely reactions of certain subjects in connection with some forms of post-hypnotic behavior. The quality of the performance was mixed from an amusement point of view. Errors in technique occurred to a surprising degree in view of the hypnotist's extensive experience. Some entertaining highlights supported the performance. The relationship between hypnotist-audience and hypnotist-subject interaction are of interest within the larger context of interpersonal relations involving small and large groups.

#### NOTES

1:

"Summary

1. 'Trance' involves a selective and relative inattention to internal and external stimulation.
2. Hypnosis involves one type of 'trance' behavior but hypnosis differs from other types of 'trance' in that it is an interpersonal relationship in which one person, the operator, restructures the 'perceptions' and conceptions of the other person, the subject.
3. The operator can restructure the thoughts and 'perceptions' of the 'good' hypnotic subject because (a) the subject is relatively detached and inattentive to his self and his surroundings and (b) the subject is 'set' -- he is ready and willing -- to accept the operator's words as true statements and to 'literally think as the operator wants him to think.'
4. 'Perceptual-cognitive restructuring' and not 'suggestion' is the essential element in hypnosis.
5. We can begin to understand hypnosis and the phenomena of hypnosis by one general principle: the hypnotic subject behaves differently because he 'perceives' and conceives differently. The behavior of the hypnotic subject is in strict accordance with his altered conceptions of his self and his surroundings" (p. 162).

Solovey, Galina; Milechnin, Anatol (1957). Concerning the induction of the hypnotic state. Journal of Clinical and Experimental Hypnosis, 5 (2), 82-98.

#### NOTES

1:

The hypnotic state has four attributes: "an effect of emotional stabilization, a retrogression to an

infantile psychological functioning, suggestibility, and transmissibility of the hypnotic relationship" (p. 82). "SUGGESTIBILITY is a special motivation to accept, incorporate within one's self, and execute direct or implicit propositions, which is equivalent to the motivation of a child to accept, assimilate and carry out the propositions of its parents" (p. 84). The authors propose that verbal and non-verbal suggestions are incorporated during the course of education, lasting years and thus becoming in effect post-hypnotic suggestions. "The person will have in the future a special responsiveness, that may be more or less pronounced according to the circumstances, for those data (coming from books, movies, conversations, etc.) which agree with his emotionally-incorporated post-hypnotic suggestions" (p. 85). If while in an auto-hypnotic condition he comes in contact with someone "who appears to be the embodiment of the convictions or prejudices that on being stimulated started the process of emotional activation that led to the development of the hypnotic state, there may be a transformation of the auto-hypnotic condition into an interpersonal hypnotic relationship" (p. 86).

According to the authors, this theory can explain post-hypnotic (negative) sequellae. It also accomodates explanations of both Natural or Direct Orientation inductions and Indirect Orientation inductons, and explains phenomena such as patients entering hypnosis rather automatically while awaiting the appearance of Mesmer in his waiting room.

"To conclude, we will stress that the psychological mechanism of hypnotic induction is exactly the same in everyday life and in the experimental environment. The apparent differences like [sic] in the behavior of the subject in the hypnotic state, and are due to the motivation that arises from the circumstances and to the convictions, capacities, psychological maturity, and degree of retrogression of the individual" (p. 96).

Stillerman, Bernard (1957). The management in analytic hypnotherapy of the psychodynamic reaction to the induction of hypnosis. Journal of Clinical and Experimental Hypnosis, 5 (1), 3-11. (Abstracted in Psychological Abstracts, 58: 1715)

## NOTES

1:

The author suggests ways to diminish patient resistance that may emerge in the initial hypnotherapy sessions. "(1) Question him before the first trance regarding his reactions to observing or experiencing hypnosis. How does he feel about being hypnotized now? (2) Observe the patient's physical and emotional reactions in the trance -- any restlessness, jerky movements, moans or groans, sweating, crying, laughing, anger, etc. If any such reactions occur, ask him how he feels, what he is thinking about. (3) Immediately following the first trance, discuss with him his reactions to the trance (emotional reactions, thoughts, feelings, flashes, associations, fantasies or dreams): (a) as he went into the trance, (b) while in the trance, (c) coming out of the trance. (4) At the second hypnotic session, before induction, question him again regarding his reaction to the previous session. Also, inquire particularly about any dreams which occurred subsequent to the first hypnotic session. (5) In general and at all times, note his verbal and non-verbal productions and the dreams he spontaneously presents" (p. 4).

Seven case examples are provided.

## NOTES

1:

"In summary, in the actual hypnotic relationship, the attitudes of the operator may influence his behavior markedly and are probably even more important than those of the subject in carrying through a successful relationship. It has been indicated in another paper that the subject's impulse

handling is more important than his attitude toward hypnosis in actual hypnotizability. This view is a re-interpretation of that of Sarason and Rosenzweig (16) with regard to the same problem. The way the operator handles his own impulses seems in itself a most significant problem, and is expressed in his reactions to the induction and later the trance state of the subject. It is indicated that to some workers, the hypnotic response of the subject offers a rare feeling of power which may have psychosexual implications of a heterosexual or homosexual kind depending on the sex of the patient and the emotional needs of the operator. Child-parent relationship attitudes may also be elicited as well as conflicts about dominance-submission related to earlier experience of the worker.\*\* As suggested by Bruno-Bettelheim (1) for children who cannot participate in relations with others as a result of a fear of their own hostility, it appears that some persons might find the hypnotic situation difficult because of a similar factor. Thus some therapists or research workers might be impelled to reject the use of this measure or to fail in using it, because of a non-verbalized fear of their own impulses toward a 'helpless' subject in their power. This same situational response may be a problem that arises in the psychotherapeutic or even ordinary medical relationship. Its effect may be to limit full exploration and exploitation of therapeutic possibilities, and to hamper treatment of numerous disorders.

"It is perhaps appropriate to point out in conclusion that Freud left hypnosis, it would seem, because of some unresolved problems. Wolstein (23) says because he could not hypnotize all his patients and because of the magical connotations of hypnosis. The hypnosis in transference is still an open field. Are the two phenomena over-lapping or on a continuum? Are the problems of the therapist really the same in both areas? Is transference an aspect of hypnosis" (pp. 66-67).

"\*\* Data on male-female differences in success as hypnotists with members of the opposite sex might be very illuminating" (p. 66).

Meares, Ainslie (1956). The hysteroid aspects of hypnosis. American Journal of Psychiatry, 113, 916-918. (Abstracted in Psychological Abstracts, 57: 3514)

#### NOTES

1:

Article discusses hypnotic behavior as ego defense.

Solovey, Galina; Milechnin, Anatol (1956). Concerning a theory of hypnosis. Journal of Clinical and Experimental Hypnosis, 4, 37-45.

#### NOTES

1:

"The essential attributes of the hypnotic condition may be understood to derive from three sources:

- 1) The hypnotic emotional state per se
- 2) The resultant motivation of the 'subject' to comply with the desires of the 'operator' (reinstating a child-like responsiveness).
- 3) The RETROGRESSION to an earlier form of psychological functioning that takes place under a hypnotic state of growing intensity" (p. 43).

"Although the retrogressive process is a general response to emotions and probably exists in some toxic states as well, it has a remarkable feature in the hypnotic state: THE COALESCENCE OF MOTIVATION AND RETROGRESSION, which exists in hypnotized people, permits a peculiar manipulation of the retrogressed condition. The peculiar responsiveness of the subject may be tested and molded by means of propositions which act as suggestions. In this manner, the so-called HYPNOTIC PHENOMENA are elicited" (p. 44).

Wagner, Frederik F. (1956). A dynamic approach to the problem of hypnotic induction. Journal of Clinical and Experimental Hypnosis, 4, 93-98.

## NOTES

1:

The author discusses inductions in a broadly psychoanalytic framework. "In keeping with the terminology, hypnotic induction can be defined as a deliberate attempt to disturb the psychic [sic] equilibrium leading to a reorganization on a regressed level. This process takes place in a structured, goal directed interpersonal relationship to which the subject attempts to adjust himself. The outcome of this potential conflict determines whether or not the subject can be hypnotized. Hypnotizability can consequently be formulated as the degree of motivation to regress in this transference-like relationships with the hypnotist" (p. 95). He suggests that the thoughts and fantasies about the hypnotist are very important, as well as the kind of physical setting the subject would prefer, to assure adequate induction.

"With such information at hand the hypnotist would probably, to a greater extent, be able to phrase his suggestions in the patient's lingo and assume a proper attitude according to the patient's needs. By avoiding suggestions which stir up fearful fantasies about hypnosis he will try to keep anxiety at a minimum. By assuming a protective parental role he may stimulate infantile needs and give the patient a maximum of security; anxiety, and consequently, defenses may thereby be minimized. He may even assume an authoritarian role, deliberately stirring up anxiety, if he expects the subject will respond with regression" (p. 97).

## NOTES

1:

"Summary. Freud's rejection of hypnosis in the development of psychoanalytic psychology becomes upon closer examination a two fold process. It involves on the part of Freud the conventional recognition that suggestion plays a basic role in the primitive emotional energy that binds people together and influences the acting out of primary libidinal drives. From an ontogenetic (and presumably phylogenetic) point of view, Freud viewed suggestibility as a repressive element in the organization of behavior and one which in effect had to be dealt with indirectly. To deal with it directly was to create a state within which powerful emotions of an unpredictable nature could emerge. Hypnosis to Freud was a 'condition' which led to general heightened suggestibility and was identical with it. To make use of this condition was in essence an attempt to make use of an individual's energies in a dependent and essentially uninhibited manner. It seemed to Freud that having produced the hypnotic 'condition,' one actually had achieved a state of suspension or ablation of certain critical ego functions and this could lead to an intense and perhaps unmanageable interpersonal relationship. It was almost an 'ethical' rather than a scientific view as Freud discussed it in his thinking and theorizing about a general psychology.

"To a great extent the basic concepts of psychoanalysis were developed as the result of Freud's awareness of the existence of hypnotic phenomena and his need to circumvent and indirectly deal with the ego manifestations of this 'condition.' Thus Freud never really rejected hypnosis as a mechanism of human behavior. His comment of the psychosocial development of man (from which psychoanalytic psychology is influenced) was heavily weighted by his awareness of 'suggestibility' and the 'condition' descriptively called hypnosis.

"The simple equation of hypnosis with suggestibility is now scientifically outmoded and incorrect. The role of suggestion and its psychosomatic equations has taken on a drastically changed perspective in social psychology, particularly with regard to the early concepts of Le Bon, Freud and McDougall (5). For these reasons alone, Freud's circumvention of hypnosis becomes increasingly unsound scientifically and adherence to such a perception of hypnosis serves only to obscure theoretical

research in psychology and to maintain a rigidity born essentially of emotional ties and ethics alien to the nature of scientific inquiry" (pp 128-129).

Leuba, Clarence (1955). Conditioning during hypnosis. Journal of Clinical and Experimental Hypnosis, 3 (4), 256-259.

#### NOTES

1:

The author is responding to an article that concludes that conditioning during hypnosis leads to effects better accounted for by the research subjects' attempts to conform or please the Experimenter (Fisher, Seymour. An investigation of alleged conditioning phenomena under hypnosis. *J. clin. exp. hypnosis*, 1955, 3, 71-103).

"Informal attempts have been made to eliminate the personal subjective influence of the hypnotist when testing for the effects of 'alleged' conditioning under hypnosis. The conditioned stimulus has been administered post-hypnotically by other persons than the hypnotist, or when S was occupied, offguard, and presumably not set to please the hypnotist. The results have been equivocal. Usually, the conditioned responses occurred when the conditioned stimulus was administered by others than the hypnotist and in a variety of situations; when caught offguard, however, the S may not respond, at least not overtly; he may, for instance, only feel a tendency to cough when touched. This might be, of course, because coughing is often inhibited in social circumstances and the tendency, therefore, does not become overt. Sometimes when told by the hypnotist post-hypnotically that the experiments were over, the alleged conditioning disappeared; sometimes, on the other hand, when the hypnotist emphatically stated post-hypnotically that there was no odor present and that it had been just hallucinated, the S nevertheless smelled it when the cue was again present" (p. 258).

Rosen, Harold (1955). Regression hypnotherapeutically induced as an emergency measure in a suicidally depressed patient. Journal of Clinical and Experimental Hypnosis, 3 (1), 58-70.

#### NOTES

1:

After cautioning that regressive techniques are only to be undertaken by very experienced therapists, the author states in conclusion, "However, if the therapist have a thorough grounding in dynamic psychiatry, he may as an emergency measure, through the adjunctive use of hypnotic techniques of the type described in this article even induce regressive phenomena in the potentially homicidal or suicidal psychotic patient, in order that they may be integrated and utilized in the service of the ego, at first by blotting out ego-boundaries between patient and therapist, so that later on during the course of the therapeutic process these self-same ego-boundaries may be re-defined and re-constituted on a more mature emotional level and with much healthier personality functioning.

Schneck, Jerome M. (1955). Hypnotic interviews with the therapist in fantasy. Journal of Clinical and Experimental Hypnosis, 3 (2), 109-116. (Abstracted in *Psychological Abstracts*, 56: 1126)

" Summary. This report furnishes illustrations from two patients of the technique consisting of hypnosis interviews conducted by the patients with the therapist in fantasy. This method emerged from previous work with visual imagery in the form of scene visualization and some of its derivatives. The writer believes that further work with the technique presented now may prove to be beneficial in psychotherapy. At the same time it offers an opportunity for further study of personality functioning in general and certain aspects of psychodynamics. The patients manipulate the session in a way which furthers a duality in their functioning as a result of which they attempt to probe and contend with contradictory tensions in their unconscious. The image of the therapist undergoes certain distortions demonstrating dynamisms such as projection and identification as utilized by the patient. The

therapist is in a position to view all of this and to discern elements in his relationship with the patient which may otherwise have escaped him. Countertransference issues may be clarified in this way. The technique may assist at points where the therapist seems to be functioning too blindly and where the patient may more pointedly show the way by guiding the therapist while relating to a mental image of him. There is a possibility that some aspects of this approach in treatment may prove of value in psychotherapy which does not incorporate hypnosis. This may be of assistance to workers who have not been trained in hypnotherapy" (pp. 115-116).

Schneck, Jerome M. (1955). Transference and hypnotic behavior. Journal of Clinical and Experimental Hypnosis, 3 (3), 132-135.

"Summary. This report describes an extreme posture in hypnosis, spontaneously assumed by a male patient, when the patient, seated in a chair, curved his head, neck, and upper body far forward so that his face finally was turned inward toward his body at the level of lower abdomen or pubis. This spontaneous motor phenomenon, aside from serving as an addition to spontaneous sensory and motor phenomena described previously, continued throughout a series of sessions and reflected symbolically a combination of broad rather than limited interest in treatment and its implications were accepted and used as a base in determining the direction and management of therapy. The constellation of events furnished an additional example of incorporation of hypnotic technique into psychotherapy" (p. 135).

Stokvis, Berthold (1955). Hypnosis and psychoanalytic method. Journal of Clinical and Experimental Hypnosis, 3, 253-255. (Abstracted in Psychological Abstracts, 57: 1157)

#### NOTES

1:

The author distinguishes between hypnosis/psychoanalysis and 'hypno-analysis' which Hadfield previously described as a combination of hypnotic catharsis and re-educative suggestions.

At the Leyden Clinic the author uses one of several methods to "apply hypnosis together with the utilization of psychoanalytic principles. ... [It] consists in a cathartic-analytic treatment of the patient in the waking state, while endeavouring to re-enact repressed psycho-traumatic events of the past, in the hypnotic state. The experiences in question are subsequently discussed with the patient and elucidated" (p. 253).

1954

Meares, Ainslie (1954). History-taking and physical examination in relation to subsequent hypnosis. Journal of Clinical and Experimental Hypnosis, 2 (4), 291-295.

#### NOTES

1:

"Summary. The history-taking and physical examination of the initial interview can be so structured as to facilitate the subsequent induction of hypnosis. Rapport is established, and negative transference feelings are not allowed to develop. There must be no holding back or hiding of the real complaint with screen symptoms. Physical examination is a symbolic surrender and paves the way for the real surrender of passive hypnosis. If induction by an active method is anticipated, authoritative attitudes are introduced into the history-taking and physical examination" (p. 295).

Watkins, John G. (1954). Trance and transference. Journal of Clinical and Experimental Hypnosis, 2 (4), 284-290.

## NOTES

1:

The author proposes that [hypnotic] trance and transference are essentially the same phenomena. "Yet while the hypnotherapist is often unaware he is dealing with transference, the psychoanalyst is often equally oblivious to the fact that he is interacting with his patient in a light trance ego state. ... Perhaps a re-examination of the entire problem of ego states and hypnotic trance is due" (p. 290).

1953

Kline, Milton V. (1953). Toward a theoretical understanding of the nature of resistance to the induction of hypnosis and depth hypnosis. Journal of Clinical and Experimental Hypnosis, 2, 32-41.

## NOTES

1:

In this theoretical paper, the author makes the following theoretical deductions:

"1. Resistance to hypnosis appears to be a fundamental characteristic of hypnosis.

2. The nature and pattern of such resistance is highly variable and may be expressed consciously or unconsciously, ideationally or affectively, psychologically or somatically, actively or passively and in combinations of the above characteristics.

3. Hypnosis is often perceived as a threat to the individual's equilibrium or homeostatic adjustment and the reactions or resistance to this threat depend upon both the severity of the threat and the strength and nature of the subject's defenses.

4. The pattern and structure of resistance to hypnosis may be initially determined by the first stimulus the subject perceives as a threat:

(a) The stimulus could be the psychophysiological correlates of hypnosis per se, the vaso-motor and related phenomena and their influence on ego function. Even very light hypnotic states have been demonstrated to produce alterations in ego functioning (5, 21).

(b) The stimulus could be the threat of, or the activation of, a transference relationship which is quickly crystallized and synthesized in the patient's receptor perceptuality, because of alterations in receptor function which can accompany the induction of hypnosis.

(c) The stimulus could be a \_conditioned\_ response, either to the transference or to elements of the hypnotic procedure related to it.

(d) The stimulus could be an \_associated\_ response, either to the transference situation or to elements of the hypnotic procedure related to it.

(e) The stimulus could be a configuration of all the aforementioned components, stemming directly from association to the words of the hypnotist. Such a Gestalt-like response to hypnosis might involve transference threat, increased transference-impulse drives, neuro-psychological changes in ego function resulting from hypnosis per se and conditioned response patterns and associated imagery activity.

(f) Secondary and higher order stimuli may be come incorporated into hypnotic resistance or reaction patterns through a feeding back of stimulation through either physiological activity or associated cortical activity" (pp. 34-35).

Williams, Griffith W. (1953). Difficulty in dehypnotizing. Journal of Clinical and Experimental Hypnosis, 1, 3-12.

## NOTES

1:

The author collected "instances of difficult dehypnotization from the experience of experimenters and therapists and then [discussed] them with reference to three aspects: a) their behavioral characteristics, b) their dynamics so far as these could be ascertained, and c) the methods used to deal with them" (p. 3).

## RELIGION

2003

Holroyd, Jean (2003). The science of meditation and the state of hypnosis. American Journal of Clinical Hypnosis, 46 (2), 109-128.

Two aspects of Buddhist meditation -- concentration and mindfulness -- are discussed in relationship to hypnosis. Mindfulness training facilitates the investigation of subjective responses to hypnosis. Concentration practice leads to altered states similar to those in hypnosis, both phenomenologically and neurologically. The similarities and differences between hypnosis and meditation are used to shed light on perennial questions: (1) Does hypnosis involve an altered state of consciousness? (2) Does a hypnotic induction increase suggestibility? It is concluded that a model for hypnosis should include altered states as well as capacity for imaginative involvement and expectations.

1998

Court, John (1998). Not the state, but the territory. Australian Journal of Clinical and Experimental Hypnosis, 26 (2), 104-112.

With the current growth of interest in spirituality, the interface between hypnosis and religious practices takes on new significance. Cautions have traditionally been expressed about the hypnotic state, with fears about control and willpower. While developments in the ethical use of hypnosis make such concerns less pressing, there remain significant paradigm issues which are being explored in the literature. These include pursuit of the age-old question, "Who are the legitimate healers in a society?" The territory of the church and the territory of the clinic are not entirely separate, so issues arise regarding the relative authority of practitioners to intervene in people's lives, and what such interventions should look like. Many Christians who might benefit from hypnosis have been warned to be totally against it. Evidence will be brought forward to challenge this and make it safer to look to therapeutic hypnosis without compromising beliefs.

1998-1999

Easterlin, Barbara L.; Cardena, Etzel (1998-99). Cognitive and emotional differences between short- and long-term Vipassana meditators. Imagination, Cognition and Personality, 18 (1), 69-81.

This study compared perceived stress and cognitive and emotional differences between two groups of Buddhist mindfulness [Vipassana] meditators. Nineteen beginning and twenty-four advanced meditators carried electronic pagers for five days and responded to daily random signals by completing an Experience Sampling form (ESF) containing items related to the dependent variables. As compared with beginners, advanced practitioners reported greater self-awareness, positive mood, and acceptance. Greater stress lowered mood and self-acceptance in both groups, but the deleterious effect of stress on acceptance was more marked for the beginners. These findings validate in a naturalistic setting some of the effects described in traditional Buddhist texts on mindfulness.

## NOTES

1:

"Meditation can be defined as the deliberate deployment of mental attention to obtain a particular patterning of consciousness. The aim of such control may be the stabilization of the stream of thought, greater relaxation, the attainment of an altered state, or the development of insights into the nature of mind [12]. Mindfulness meditation has sometimes been contrasted with concentration meditation as one of two main forms of meditation practice [13, 14]. The usual distinction is that mindfulness involves opening awareness to all contents and processes of mind, whereas concentrative forms of meditation involve shutting out all stimuli extraneous to a single object of attention" (p. 70). Long-

term meditators averaged 103 months and 85 days of retreat training. They did not differ from short-term meditators on measures of absorption, neuroticism, trait anxiety, or cognitive style; however they evidenced greater self-awareness and acceptance. The short-term meditators actually had more than a year of meditation experience so that differences between groups are not likely to be due to self-selection. The authors conclude that "meditation brings about sustainable changes in people's lives, above and beyond relaxation. ... [and] that greater conscious awareness through mindfulness techniques such as Vipassana meditation, increases acceptance, positive mood, and the ability to dispassionately observe one's mental states. These results have implications for clinical issues such as pain management and psychotherapy, in which acceptance and awareness are necessary ingredients for therapeutic change" (p. 78). JH

1997

Court, John (1997). Hypnosis, healing and the Christian. Carlisle United Kingdom: Paternoster Press.

Seeks to explore the interface between hypnotic phenomena and religious experiences. On the basis of clinical examples, and historical review, argues that the constraints expressed by some churches against hypnosis cannot be justified. Rather that there is a good deal of support for seeing religious experiences and clinical phenomena as similar. Challenges the use of the Old Testament to discount hypnosis in favor of more positive evaluations from the New Testament.

1996

Rosenbaum, Robert & Dyckman, John (1996). No self? No problem! Actualizing empty self in psychotherapy . In Hoyt , Michael F. (Ed.), Constructive therapies (2, pp. 238-274). New York NY: Guilford.

NOTES

1:

In this book chapter, Rosenbaum and Dyckman (1996) argue that self has no permanently fixed, defining, thing-like characteristics (p. 270). They thus dispute the classical notion--commensurate with the position of philosophical realism --that the self is a substance, with fixed qualities and measurable qualities. The authors refer to this classical self as a full self, contained inside the skin and delimited by its participation in linear time. Instead, they propose an empty self, not to be construed as a void, but as a fluid, connected, relational self that overflows the traditional boundaries of the skin and is open to greater possibilities for change. To support their view of an empty self, the authors include several case examples of working with hypnosis and strategic/narrative therapy with clients experiencing a variety of psychological and physical symptoms. The authors further contend that self is not unitary, but the product of multiple drafts (p. 248)[Editor note: See Dennett, 1991, in this database]. In the narrative-constructivist tradition, they argue, if we speak in terms of multiple contextual selves for us all...[then, people diagnosed with MPD/DID] are not so different from the rest of us (p. 249). The chapter draws from western & Buddhist philosophy, strategic/systemic and narrative therapies, Ericksonian hypnosis, and, cognitive science theories regarding memory, consciousness, embodiment, and language, to support their alternative view of, and treatment for, the self.

Csoli, Karen; Ramsay, Jason T.; Spanos, Nicholas P. (1994, August). Psychological correlates of the out-of-body experiences--a reexamination. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

## NOTES

1:

12% of population reports an out-of-body experience (OBE) sometime in their lives. They leave their body and can see self from the outside. Awareness is confined to the new point of view, not fragmented; there is unimpaired intellectual ability; feelings of detachment, completeness, well being, and profound relaxation. Can occur under stress or deep relaxation; not while driving a car.

Psychological correlates aren't known. Studies are inconclusive with respect to belief systems (religious, death anxiety, etc.); measures of absorption, hypnosis, imaginative ability, imagery controls. Recent Carlton study with 87 Ss (33 had OBE) got results we didn't expect. They completed questionnaires, were tested for hypnotizability, had an interview re OBE experience.

This study found the OBE-experiencing people had higher levels of anxiety, psychosomatic symptoms, and panic attacks. They were also higher on magical thinking, perceptual aberration, and Schizophrenia scores. They didn't differ on mysticism, levels of drug or alcohol use, or level of self esteem

Epstein, Seymour (1994). Integration of the cognitive and the psychodynamic unconscious. American Psychologist, 49 (8), 709-724.

Cognitive-experiential self-theory integrates the cognitive and the psychodynamic unconscious by assuming the existence of two parallel, interacting modes of information processing: a rational system and an emotionally driven experiential system. Support for the theory is provided by the convergence of a wide variety of theoretical positions on two similar processing modes; by real-life phenomena--such as conflicts between the heart and the head; the appeal of concrete, imagistic, and narrative representations; superstitious thinking; and the ubiquity of religion throughout recorded history--and by laboratory research, including the prediction of new phenomena in heuristic reasoning.

1994

Walsh, Roger (1994, August). Transpersonal psychology--the state of the art. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

## NOTES

1:

Twenty-five years ago a group formed that was called transpersonal psychology, following after humanistic psychology (e.g. Maslow). Some of the humanistic psychologists came into transpersonal psychology. Maslow was interested in healthy people, and in peak experiences that were transpersonal in nature--experiences encompassing wider aspects of life, including mystical experiences.

Peak experiences were thought to be positive, but also overwhelming. When psychologists looked Eastward, they found that there were whole families of these types of experiences, and that they could be induced by will and could be stabilized into not only peak but plateau experiences. There was a reservoir of wisdom in the world's religions that could be drawn upon. This wisdom is being integrated with Western science to create the discipline of transpersonal psychology.

There is a broad spectrum of altered states of consciousness. Traditionally, altered states of consciousness were thought to be few in number, and usually pathological. Our society has been resistant toward studying them. For example, Esdaile's use of hypnosis in surgery was not welcomed, even though he was lowering morbidity and mortality because he controlled shock. His paper was turned down for publication. He amputated a leg in front of colleagues in Britain, who commented that he "must have hired a very hard rogue" to have his leg cut off under hypnosis.

Our culture is monophasic, deriving its world view almost exclusively from the waking state; other cultures are polyphasic and also draw their world view from dreams, meditative, or yogic contemplative states, etc. Recently we can apply more sophisticated analyses, to compare states of consciousness and map these out, phenomenologically. There are several key dimensions of experience

for mapping the states: 1. Control 2. Awareness of Environment 3. Concentration 4. Mental Energy/Arousal 5. Emotion 6. Identity or Self Sense 7. Out-of-Body Experience 8. Content of Experience

Using these dimensions, we could compare shamanic, yogic, and Buddhist practices.

A Nepalese shaman drums himself into a trance state, demonstrating: 1. Ability to enter and leave an altered state of consciousness and partly control experience 2. Decreased awareness of his environment 3. Increased concentration, fluid attention 4. Increased mental energy/arousal 5. Either pleasurable or not [pleasurable] emotion 6. Separate self sense: may be experienced as a non-physical "spirit" or "soul" 7. Controlled ecstasy (Out of Body experience)

Buddhist meditation is training awareness to examine experience as minutely as possible, in effect a heightened awareness (Vipassana).

A yogic practitioner engages in concentration, focusing on a fixed stimulus and holding it unwaveringly, till it dissolves a sense of separation into a unity with the object, ultimately with the Self. [Author showed a slide comparing the three.] All three approaches have increased control and concentration. (The Yogi's is unshakable.) An awareness of the environment is increased for the Buddhist; the Yogi may lose awareness entirely. Others have ecstatic experience; the yogi has enstatic experience. Identity for the shaman is separate (a soul); for the Buddhist awareness is so precise that what was "I" is deconstructed into evanescent flux, into thoughts, images, emotions (like a movie with solitary frames); the yogi dissolves the self sense, but because of fixed concentration the separate self disappears and yogis feel like merging with larger Self.

So now for first time in history we can compare and map both similarities and differences. Now we have new possibilities for understanding and contrasting different practices. We can now differentiate the many states of consciousness that are available. But there are an awful lot of states. Can we find an over-arching framework? For the first time, we can say yes--due to the work of Ken Wilber. This is Developmental Structuralism (looking for common deep structures).

For example, you can identify millions of different faces, and they are surface structures; but they all have a common deep structure. Likewise, if we see that a Hindu creates images of [devas] and a Christian sees saints, they are seeing archetypal images. Likewise, Buddhists experience nirvana in which all phenomena disappear, and so does another group. This [sense of all phenomena disappearing] is common to both, but different from those who see archetypal images. We may be able to come up with a typology of altered states.

Wilber also says that these deep structures and corresponding states may develop in a developmental sequence, with common stages. Three transpersonal stages are subtle, causal, and non-dual. In meditation, first you learn how out of control the mind is, then gradually it quiets and you discover subtle experiences that you usually overlooked. Going further, all thoughts cease to arise, and there is only pure consciousness. Beyond that, images re-arise but are now recognized as projections of consciousness.

Subtle images may be formless (as in pure light, pure sound). The person may pay attention to more and more subtle sounds. Or the images may have form (as in shamanic power animals).

At the casual stage, the person may be aware of consciousness itself, only consciousness, with no objects: pure consciousness, void, the Atman of Vedanta, abyss of gnosticism.

At the non-dual stage, objects arise again: everything is recognized as expressions of consciousness--e.g., Zen's "one mind." Consciousness now has awoken and sees itself in all things, unbounded by space and time and limits because consciousness is what creates space, time, and limits. This is Moksha, Enlightenment, etc.

This is not the final task, because the final task is bringing the awakening to the world (Plato's re-entering the cave, to educate others; Zen oxherder entering the marketplace with help-bestowing hands; Christianity's "fruitfulness of the soul"). For Joseph Campbell, this was the hero's return.

Toynbee observed that each great contributor had withdrawn and then returned to the world to offer what they had found.

[It is a process of] transforming a peak into plateau experience; an altered state into a trait; stabilized into enduring understanding, and then bringing it back into the world.

Is there evidence for enlightenment? There now is analogical and laboratory support for this. Analogical support is lucid dreaming. Until 20 years ago, Western psychology thought lucid dreaming was impossible, but now LaBerge at Stanford University has shown physiological evidence. We know from every night's experience that we can create worlds and bodies on which our lives seem to depend. The claim of spiritual traditions is that there is a state of consciousness that bears a relationship to the ordinary [waking] state as lucid dreaming has to nonlucid dreaming. The Dalai Lama said they train yogis to be aware during dreams, not to lose awareness 24 hours a day; then to be aware of dreaming while in a waking period. A Tibetan dream yoga aim is the "great realization," that everything in existence is like a dream.

Laboratory studies have been done on enlightened people. The EEG data obtained while they are sleeping is consistent with lucidity during their dreams and between dreams. Rorschach tests have been done on advanced Buddhist meditators; at the penultimate of enlightenment, they show no evidence of conflicts around sexuality and aggression. The 2000 year old Buddhist texts say that at this stage these issues are resolved.

The implications for our usual state are that normality is not the peak of human development; normality is arrested development. The link between apes and civilization is us! We experience a consensus trance, a collective psychosis, society's hypnosis. We live in the biggest cult of all: CULTURE. The answer is, "Wake up."

A most important question is, if it is true that our conventional state of development is suboptimal, how do we develop other states? The classic answer is: take up a discipline, a practice (e.g., meditation, service, being in nature). One problem is that spiritual traditions are usually couched in archaic language, and have accumulated nonsense around them over the years. It is desirable to abstract out the essential elements. That is a recent thrust of transpersonal research.

There are six common elements: 1. Ethics: the moment you sit down to meditate, what emerges is all the unethical stuff you've done and what was done to you. Ethical behavior (not conventional morality) is a tool for mind training. 2. Attentional training: ordinarily we cannot sustain attention. (William James said the maximum is 3 seconds.) The aim is to be able to maintain attention on what one wants. It leads to the stabilization of mind, calming. 3. Emotional training: destroying negative emotions (well developed in Western psychology, maybe better than in the Eastern traditions, because we recognize the problem with repression); cultivating positive emotions (where contemplative practices do well, because they offer tools for unwavering, unconditional, and all-encompassing [positive regard]; what is known as agape in Christianity). 4. Redirection of motivation: changing what you want, etc. 5. Perceptual refinement: we mistake shadows for realities; according to St. Paul we "see through a glass darkly." This enhances sensitivity, accuracy, and subtlety of perception. 6. Wisdom: actually the first element, playing a role all through the path. Initial motivation sees suffering of the world; provides motivation for realizing that there must be another way of living, culminates with deep insight into nature of the world, mind, consciousness, reality (prajna; Christian's gnosis). When the mind is trained, stabilized, and clarified, the mind has a heightened capacity for understanding.

So for the first time we can recognize the common elements in religions; we can see that the contemplative core contain practices and road maps. This approach recognizes multi-state psychologies and philosophies.

APPLICATION. Many areas of research are developing in transpersonal psychology. These studies have implications for the state of the world. It is only 25 years since the founding of transpersonal psychology. The world's population has developed to the extent that every four months we are losing as many people from malnutrition as from a Holocaust. Our problems are still solvable. The best

population explosion control is to make education available to women in the Third World. The transpersonal vision gives a frame to recognize that we are all connected.

For a fuller account of transpersonal psychology, see R. Walsh & F. Vaughan (Eds). (1993) *Paths Beyond Ego: The Transpersonal Vision.* \_ New York: Tarcher/Putnam.

1993

Kokoszka, Andrzej (1993). Occurrence of altered states of consciousness among students: Profoundly and superficially altered states in wakefulness. *Imagination, Cognition and Personality*, 12, 231-247.

In a questionnaire survey waking altered states of consciousness (ASC) are found to be common among 174 Polish students. The experience of Superficially Altered States of Consciousness (SACS) was reported by 96 percent of subjects and more than half of them had such experiences often. Whereas an experience of Profoundly Altered States of Consciousness (PASC) was confirmed by 75 percent and about one-third of them had them often. The comparison of the experiences accompanying the ASC indicates that SASC are characterized by disturbances in experiencing the reality and oneself combined with positive, pleasant feelings and with quietness. On the other hand, PASC are accompanied by experiences related to an absolute, universal, eternal, and existential or religious matters. PASC are accompanied by extremely strong positive emotions of happiness, total love, etc. and are experienced as more rational than SASC, and with significantly less feelings of cognitive disturbances than in SASC. The comparison of circumstances of the ASC occurrence indicates that SASC occur in usual and common states and situation of everyday life, whereas PASC mainly in the context of religion and nature. The congruence of these findings with an integrated model of the main states of consciousness suggests a natural tendency for a cyclical occurrence of ASC, or more precisely, the differentiated waking states of consciousness.

1991-1992

Nelson, Peter L. (1991-92). Personality attributes as discriminating factors in distinguishing religio-mystical from paranormal experients. *Imagination, Cognition and Personality*, 11, 389-406.

In the first section of this article, an operationalized notion of preternatural experience is described which includes two general classes of experience: religio-mystical (Ontic) and paranormal (Perceptual). The exploratory study which follows uses the personality measures of the complete Tellegen Differential Personality Questionnaire taken from 120 subjects who reported having had spontaneous religio- mystical and/or paranormal experiences at some time in the past. The scores on all eleven primary dimensions, three higher order affect factors, and two validity scales were used individually, in univariate ANOVAs, and together, in a Direct Discriminant Function Analysis, to successfully separate two classes of preternatural experients from non- experients and from each other.

Zika, William (1991, January). *Hidden observer in psychotherapy.* [Lecture] Seminar in the UCLA Department of Psychiatry and Biobehavioral Sciences.

NOTES

1:

Author has explored use of a "hidden observer" metaphor in psychotherapy. He distinguishes between two types of dissociation--that resulting from involvement in fantasy and imagery (separation from the Generalized Reality Orientation described by R. Shor) and that between the "I" and the Observer. He calls the latter nonattachment instead of dissociation, aligning it with meditation concepts. The observer, in the hypnotized patient, is objective and even more in touch with reality than the patient in the waking state. He likens the Observer to Erickson's Inner Self, noting that just as patients learn to

allow the therapist to care for them, they can come to allow the Observer to care for them. During inductions he speaks of the Hidden Observer (H.O.) that always knows what is going on, giving a suggestion that the H.O. can be helpful. (This concept seemingly relates also to the observer in Multiple Personality Disorder, and to John Kihlstrom's discussion of William James and the self, as well as to amnesia/duality in age regression or duality (HO) in pain control.)

1988

Tobacyk, Jerome; Milford, Gary; Springer, Thomas; Tobacyk, Zofia (1988). Paranormal beliefs and the Barnum effect. Journal of Personality Assessment, 52 (4), 737-739.

Examined in 128 college students the hypothesis that paranormal beliefs emphasizing divinatory procedures that produce personalized feedback are associated with greater susceptibility to the Barnum effect, which is acceptance of bogus personality feedback consisting of relatively trivial statements with a high base rate. 76% of the Ss rated the accuracy of their personality descriptions favorably, showing a robust Barnum effect.

Spanos, Nicholas P.; Cross, Wendi P.; Lepage, Mark; Coristine, Marjorie (1986). Glossolalia as learned behavior: An experimental demonstration. Journal of Abnormal Psychology, 95, 21-23.

60 Ss listened to a 60-s sample of glossolalia (defined to them as pseudolanguage) and then attempted to produce glossolalia on a 30-s baseline trial. Afterward, half of the Ss received two training sessions that included audio- and videotaped samples of glossolalia interspersed with opportunities to practice glossolalia. Also, live modeling of glossolalia, direct instruction, and encouragement were provided by an experimenter. Both the trained subjects and untreated controls attempted to produce glossolalia on a 30-s posttest trial. About 20% of subjects exhibited fluent glossolalia on the baseline trial, and training significantly enhanced fluency. Seventy percent of trained subjects spoke fluent glossolalia on the posttest. Our findings are more consistent with social learning than with altered state conceptions of glossolalia.

Burnham, John C. (1984, October/1986). The fragmenting of the soul: Intellectual prerequisites for ideas of dissociation in the United States. In Quen, Jacques M. (Ed.), Split minds/split brains (pp. 63-84). New York: New York University Press. (Based on symposium in Bear Mt., N.Y., by Section on the History of Psychiatry of Cornell University Medical Center)

NOTES

1:

"Reductionism was a relentless pursuit of the idea that knowledge of components led to knowledge of causes. In this context, I propose to show how, in the psychological-medical realm, the initial concept was the soul, and the final intellectual product was dissociative phenomena" p. 64.

Wilson, Ian (1984). Jesus--The evidence. London England: Weidenfeld and Nicolson.

## NOTES

1:

Miracles of Jesus are attributed to hypnosis, in a culture that had already experienced faith healers. Many of those healed had diseases that today might fall into the 'hysteria' or 'psychosomatic' categories (paralysis, lameness, fever, catalepsy, haemorrhage, skin disease, mental disorder), which diseases are frequently responsive to hypnosis. Further, Jesus' reputation preceded him, and the fact that his cure rate was low in his home town is evidence of both the veridicality of the written record (Mark 6: 1-6) and the expectancy factor. "The significance of this episode is that Jesus failed precisely where as a hypnotist we would most expect him to fail, among those who knew him best, those who had seen him grow up as an ordinary child. Largely responsible for any hypnotist's success are the awe and mystery with which he surrounds himself, and these essential factors would have been entirely lacking in Jesus' home town" (pp. 111-112). The author also assigns other miracles (his transfiguration into dazzling light before three disciples; turning water into wine) to hypnosis [which other writers might ascribe to suggestion].

1982

Larbig, W.; Elbert, T.; Lutzenberger W.; Rockstroh, B.; Schnerr, G.; Birbaumer, N. (1982). EEG and slow brain potentials during anticipation and control of painful stimulation. Electroencephalography and Clinical Neurophysiology, 53, 298-309.

Cerebral responses in anticipation of painful stimulation and while coping with it were investigated in a 'fakir' and 12 male volunteers. Experiment 1 consisted of 3 periods of 40 trials each. During period 1, subjects heard one of two acoustic warning stimuli of 6 sec duration signaling that either an aversive noise or a neutral tone would be presented at S1 offset. During period 2, subjects were asked to use any technique for coping with pain that they had ever found to be successful. During period 3, the neutral S2 was presented simultaneously with a weak electric shock and the aversive noise was presented simultaneously with a strong, painful shock, again under pain coping instructions. EEG activity within the theta band increased in anticipation of aversive events. Theta peak was most prominent in the fakir's EEG. A negative slow potential shift during the S1-S2 interval was generally more pronounced in anticipation of the aversive events than the neutral ones, even though no overt motor response was required. Negativity tended to increase across the three periods, opposite to the usually observed diminution. In Experiment 2, all subjects self-administered 21 strong shock-noise presentations. The fakir again showed more theta power and more pronounced EEG negativity after stimulus delivery compared with control subjects. Contrary to the controls, self-administration of shocks evoked a larger skin conductance response in the fakir than warned external application.

## NOTES

1:

A published case study by Pelletier (1977) reported EEG theta enhancement during pain control states, which were maintained by EEG feedback of alpha and theta bands. That author concluded that EEG theta was necessary for the control of pain psychologically.

The authors of this article measured slow brain potentials (SBPs) and vertical eye movements (VEMs). Principal components analysis of the EEG wave forms found three components: theta (4-5.6 c/sec), alpha band (9-10 c/sec) and high frequencies (above 14.4 c/sec) plus harmonics loading in frequencies of 3.2-4.5 c/sec, 7.5-9, and above 15 c/sec.

Alpha "decreased over periods in the parietal record and was virtually absent in the fakir's EEG during period 3" (p. 301). The fakir had a lot of non-sinusoidal, especially square wave, activity.

"Very pronounced negativity was recorded preceding the aversive S2, greater than under neutral stimulus conditions ... This difference was most pronounced at the vertex ... The late negativity

increased over periods in control subjects ... especially in anticipation of the aversive S2 ... . This contrasts with the usually observed decrease of SBP components over trials. As is shown in Figure 2, the PCA [principal components analysis] yielded two components for the 2.0 sec S2 interval, a positive deflection, which can be assigned to the P300 complex (here not reported), and a negative deflection, labeled post- imperative negative variation. ... This negative component increased over periods, being more pronounced in response to the aversive stimulation ... with increasing differentiation over period ..." (p. 302-303).

The fakir undertook an elaborate self hypnosis or trance induction to achieve analgesia that he had previously demonstrated in the laboratory (thrusting 4 unsterilized metal spikes into his abdomen, tongue, and neck without bleeding). This included "long- continued fixation on a point above the eye-brows. Blank facial expression, staring eyes, and a very low rate of eye-blinks indicated a trance-like state (periods without eye-blinks more than 30 min)" (p. 299). During the experiment itself, the fakir showed few ocular movements during the second and third periods. He also demonstrated large skin conductance responses, recorded from the second phalanges of the index and middle fingers of the left hand, to the aversive S1.

Experiment 2 was designed to emulate the self-administered aversive stimulation that the fakir routinely undertook, by having the volunteer Ss hold a switch that they pressed twice/minute, giving themselves a mild shock and an aversive noise. (These were the same aversive stimuli as were used in Experiment 1.) There were 21 self-paced button presses.

Three additional measures were taken: 1. Bereitschaftspotential (BP) - the mean negative shift during the 0.3 sec interval prior to the motor response of pressing the switch 2. Postimperative component (PINV) - the mean negative shift 0.9 to 1.9 sec after stimulus onset, i.e. elicited by closing the microswitch 3. Skin conductance response (SCR) - maximum change in skin conductance level during five second interval after the motor response of pressing the switch.

The fakir, but not the control Ss, showed a pronounced precentral PINV on each single trial of Experiment 2. He also showed pronounced SCRs (indicating autonomic arousal), which was even greater than the SCRs of control Ss. His subjective pain rating was 1 in Experiment 1 (compared with 6.4 for controls) but 8 during Experiment 2 (compared with 5.7 for controls), on a scale of 1 to 10 maximum. Thus the fakir's pain increased from Experiment 1 to 2, while for many volunteer Ss it decreased 2 or 3 points. When interviewed, he said that "intention and motor commands prevented the fakir from getting into 'trance' satisfactorily. Consequently, he reported to have experienced the aversive stimuli as more painful than in experiment 1. Thus it might be that the observed PINV indicates the noncontingency between the demand for coping and the failure to cope or the discrepancy between expected control and presently experienced control" (p. 307).

In their Discussion, the authors speculate that control of pain such as can be achieved by the fakir may involve dissociation of higher (possibly thalamic and cortical) and lower (reticular formation) arousal structures. Their observation of slow brain potentials (theta) recorded in anticipation of painful or aversive stimuli is in agreement with earlier published studies. However their observation of increasing negativity in anticipation of aversive stimuli is in contrast to previous research findings, in which diminution of negativity is generally observed.

Both the fakir and subjects showed a post-stimulus negative shift in response to the S2; this has been "observed in normal subjects under conditions of change from controllable to uncontrollable aversive stimuli... and/or from obvious response- consequence contingencies to unpredictable control over the S2... PINVs were associated with an unexpected change in contingency or the inability to resolve ambiguity. Since a relationship was found between PINV amplitude and subjective ratings or experienced aversiveness of the painful stimulation, it may be speculated that obvious failure in coping with pain (i.e. more experienced pain) together with the requirement to cope (induced by instructions and experimental setting, giving rise to increased expectancy for control), produced a PINV (and probably feelings of uncontrollability together with a state of reactance and frustration) in the present

experiments. In accordance with this point of view, it is of particular interest that only the fakir showed a more pronounced PINV in experiment 2, in which subjects delivered the painful stimuli to themselves. A postexperimental interview revealed that intention and motor commands prevented the fakir from getting into 'trance' satisfactorily" (p. 307).

Prince, Raymond (1980). Variations in psychotherapeutic procedures. In Triandis, Harry C.; Draguns, Juris G. (Ed.), Psychopathology (6, pp. 291-349). Boston: Allyn & Bacon.

NOTES

1:

Prince points out that indigenous practitioners often capitalize on the organism's endogenous healing mechanisms which develop spontaneously when the individual is distressed. "healers around the world have learned to manipulate and build upon these endogenous mechanisms in a variety of ways to bring about resolution of life's problems and alleviation of suffering" (p. 292). Prince is referring here to altered states of consciousness such as dreams, trance states, dissociations, and mystical experiences of various sorts which are cultivated and elaborated by indigenous healers for therapeutic purposes. In general, Western type practitioners have denigrated these procedures...." (from Ann. Rev. of Psychol., 1982, pp 243-244).

Sacerdote, Paul (1977). Application of hypnotically elicited mystical states to the treatment of physical and emotional pain. International Journal of Clinical and Experimental Hypnosis, 25, 309-324.

Mystical states by-pass usual sensory perception and logical thinking. They often represent the ultimate goal of long apprenticeships in Eastern or Western monastic practices which stress self-discipline and meditation; or they correlate with sudden religious conversions. While interest has also been revived in mystical experiences stimulated by hallucinogens within the appropriate physical, intellectual, and emotional environment, less attention has been paid to those mystical experiences which appear spontaneously during hypnosis and Transcendental Meditation. The present author facilitates the unleashing of mystical experiences by using hypnotic approaches specifically aimed at altering space and time perceptions. Case presentations illustrate the methodologies for guiding receptive subjects to mystical states with the aim of relieving or correcting organic and functional painful syndromes unresponsive to other interventions. The probable biopsychological processes are discussed.

1965

Pedersen, Darhl M.; Cooper, Leslie M. (1965). Some personality correlates of hypnotic susceptibility. International Journal of Clinical and Experimental Hypnosis, 13 (3), 193-203.

The present research was directed principally toward determining the relationship of a number of personality variables to hypnotic susceptibility. The personality variables utilized were selected to cover the personality domain as broadly as possible. Hypnotic susceptibility was measured by the Stanford Hypnotic Susceptibility Scale, Form A. A correlational analysis was completed for 30 Ss. This included (a) the correlations between each of the personality variables and hypnotic susceptibility and (b) the intercorrelations among all of the personality measures. It was found that the following variables correlated with hypnotic susceptibility at the 5% level of confidence: age (-.37), year in college (-.36), and missionary service (.37). Social class rating of father's occupation correlated significantly at the 1% level of confidence (.54). (29 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

NOTES

1:

Notes by Milton Erickson. "This large paper-covered volume is a collection of reprints and original studies making available in Portuguese some 45 articles by South American, North American, Mexican, and British authors reporting upon the use of hypnosis in the various fields of medicine and surgery, dentistry, psychology, and related fields. In addition there are included reports on the subject of hypnosis by Brazilian, North American, and British medical groups and two pronouncements by Pope Pius XII concerning the use of hypnosis and applied psychology.

1959

Bowers, Margaretta K. (1959). Friend or traitor? Hypnosis in the service of religion. International Journal of Clinical and Experimental Hypnosis, 7 (4), 205-215.

NOTES

1:

Hypnosis may potentiate religious experiences like prayer and worship, where hypnosis meets the world of inner reality. In the first to fourth centuries, Jewish mystics alluded to depth of mind in religious experience, but the idea of oneness with God "cannot be accepted as a healthy psychological concept" (p. 207).

"We have the possibility of understanding prayer and worship as an intrapsychic phenomenon, as a communication with one's total being. Once the premise of the indwellingness of God can be accepted as a psychological [sic] entity, then we can understand prayer as being a total response of the psychic life of the individual in order that he can understand the feelings of wholeness, self-confidence, and self-esteem in himself, and further, how this can be aided by hypnotic techniques" (p. 207).

The author interprets the 13th Century mystic's words, 'the divine will, dresses or cloaks itself in the will of the devout,' as similar to hypnosis, in which a state "may occur where the patient loses his awareness of the separateness of himself and the hypnotist so that the hypnotist's voice may be felt as his own voice" (p. 208). This is all right as long as awareness of separateness is re-established when the person comes out of the hypnotic or religious experience.

The religious mystic also may use autohypnosis "to achieve a greater experiencing of God and a heightened religious experience. Such a state likewise produces an ecstasy. Such ecstasy is sometimes present in religious conversion experiences as well. This ecstasy is healthy if the separateness and integrity of God and Man are kept separate" (p. 209). The author describes a phenomenon in which a priest who leads a deeply devotional religious service may feel a loss of a sense of self afterward, complaining of great fatigue and inability or unwillingness to relate to people. The same post-devotional emptiness and depression sometimes occurs among parishioners.

A psychoanalytically oriented case study of misdirected religious belief, amplified by religious service induced trance, is presented.

1958

Bowers, Margaretta K.; Glasner, Samuel (1958). Auto-hypnotic aspects of the Jewish cabbalistic concept of Kavanah. Journal of Clinical and Experimental Hypnosis, 6 (1), 50-70.

NOTES

1:

The authors present material quoted from numerous Jewish mystics to support the position that many

achieved self hypnosis or trance states in the course of their spiritual, especially prayer, practices. "Kavanah" means concentration in the Talmud; "the entire hope of efficacy of ritual or of prayer is wholly dependent on the person's achieving a proper state of concentration and devotion, which is Kavanah" (p. 51). Ecstasy is one aspect of Kavanah and was induced in one way through "concentration upon the magical and mystical properties of the Hebrew letters, arranging and rearranging the letters" (p. 51) in such manner as to produce a trance. Sometimes dissociation occurred ("suddenly I saw the shape of my self standing before me and myself disengaged from me and I was forced to stop writing!" [p. 64]).

Sometimes a particular way of breathing, a particular position of the body, or fasting were used to promote trance development. Imagery and fantasy were also used, in a way resembling the work of Erickson, Kline, and Young; imagery of light and light sources was especially prevalent, reminding one of the candle flame induction technique.

"... it would appear that one of the ambitious purposes of the ecstatic Kavanah was to produce prophets" (p. 61). Some medieval prophets would describe a person's past and predict his future like the modern Edgar Cayce. "The auto-hypnotic state of ecstasy represented by Kavanah was also used for the deliberate induction of states of hysterical dissociation so that the 'prophet' would be able to see his self on the opposite side of the room" (p. 63). But the practice of the mystic ecstatic Kavanah was "generally discouraged or reserved for the elite at best" (p. 65).

"... however, in the medieval Christian world ignorance of the unconscious mental processes was so profound that it made it extremely difficult for wise and prudent religious leaders to cope with the religious excitement and delusory revelations which broke out periodically. That the Jews were not entirely immune from such excesses at this time is shown by Dr. Scholem's [Major Trends in Jewish Mysticism, 1941] report that:

'In the writings of Eleazar of Worms .... one also finds the oldest extant recipes for creating the Golem -- a mixture of letter magic and practices obviously aimed at producing ecstatic states of consciousness. It would appear as though in the original conception the Golem came to life only while the ecstasy of his creator lasted. The creation of the Golem was, as it were, a particularly sublime experience felt by the mystic who became absorbed in the mysteries of the alphabetic combinations described in the "Book of Creation." It was only later that the popular legend attributed to the Golem an existence outside the ecstatic consciousness, and in later centuries a whole group of legends sprang up around such Golem figures and their creators'" (pp. 64-65).

Concentration was apparently used to avoid pain during torture of martyrdom and death. According to Scholem, the mystic Abraham ben Eliezer Halevi of Jerusalem recommended "to concentrate, in the hour of their last ordeal, on the Great Name of God; to imagine its radiant letters between their eyes and to fix all their attention on it. Whoever will do that, will not feel the burning flames or the tortures to which he will be subjected" (p. 66).

"We have demonstrated, therefore, that the Jewish mystics of former times, from the Biblical period through the Rabbinic period, on through the Middle Ages and almost up to the present day, used autohypnosis as a deliberate technique for the production of religious ecstasy and as a means for obtaining deeper religious insights or revelations. Both the methods by which they induced the autohypnotic trance, or Kavanah, and the ways in which they utilized it parallel some of the modern methods of hypnotic induction and of the utilization of the hypnotic trance" (p. 67-68).

"... hypnosis might well prove itself an important tool for an organized program of research into religious phenomena. Thus, for instance, hypnotic research could possibly provide us with an operational understanding of prayer and its effects. This might further lead to the development of more sophisticated and more effective techniques of prayer for use by scientifically-minded religionists. And it might even lead to the type of direct religious experience reported by religious geniuses of former days, but unfortunately lost to modern man" (p. 68).

Note: The second author is a rabbi.

1955

Glasner, Samuel (1955). A note on allusions to hypnosis in the Bible and Talmud. Journal of Clinical and Experimental Hypnosis, 3 (1), 34-39.

#### NOTES

1:

Author states, "To summarize: Although it is impossible to state with any definiteness that hypnosis is referred to in the Bible (Old and New Testaments) and in the Talmud, there would seem to be considerable evidence that the authors of these works were indeed familiar with phenomena which we today should call hypnotic or which we should explain in terms of suggestion" (p. 39). He refers to induced sleep states (e.g. when God took Adam's rib in creating Eve); "prophesying" (e.g. in the Book of I Samual) being "some sort of frenzied behavior induced by mass hypnosis" (p. 35); suggested blindness (e.g. Elisha's story in II Kings); mystic visions in which eyes appear (e.g. Ezekiel's visions of spiral wheels); miraculous cures in the New Testament, which could be due to suggestion; cures by Rabbis in early Christian centuries (known as 'sorcery'); and creation of illusions by rabbis, reported in the Talmud.

#### REPRESSION

1995

Bowers, Kenneth S. (1995, November). Revisiting a Century-Old Freudian Slip -- from Suggestion Disavowed to the Truth Repressed. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

#### NOTES

1:

Cites J. Herman, Mason, and Miller who accused Freud of retreating from trauma theory to save his theory. Feminists view the Oedipal theory as a coverup for the denial of child sexual abuse. This moral position fuels trauma theory and practice. It is the moral dimension of this debate that gives so many problems for the investigation of traumatic memory.

The intellectual origins of repressed trauma are examined here. Freud's early trauma theory, his later conflict theory.

Etiology of Hysteria (1896) presents Freud's argument, based on 18 patients: child is passive victim of experience imposed on them; memory is repressed and hysterical symptoms are derivatives of these repressed memories; when memories return as pictures the task of therapy is easier than if returning as thoughts. Bartlett's memory research showed visual image is followed by sense of confidence that surpasses what should be there.

The fact that patients had to be compelled to remember was offered by Freud as evidence against the idea that the memories were suggested. The patients initially would deny the reality of their memories, which Freud used in saying that we should not think that patients would falsely accuse themselves. In letter to Fleiss, he presented the conflict theory, which he presented in 1905 in Three Essays on Sexuality and later in My Views...on Etiology of Neurosis.

In 1905 Freud indicated he was unable to distinguish fantasy from true reports (and did not deny the existence of the latter). Freud often reconstructed the "memories" from dreams, transference, signs, symptoms, fantasies, etc. They were not produced as conscious memories, and it was Freud who inferred the sexual abuse. From signs of distress he took evidence of proof.

Freud presented his theory to his patients and then sought confirmation.

Freud asks us to abandon historical for narrative truth. The problems with Freud's first theory became worse with his second theory. In Introductory Lectures Freud states that opponents say his treatment talks patients into confirming his theories. He relies on the patient's inner reality confirming

the theoretical ideas given to him. Success depends on overcoming internal resistance, however. The danger in leading a patient astray by suggestion has been exaggerated, because the analyst would have had to not allow the patient to "have his say." Freud denied strongly ever having done this.

Incorrect interpretations would not be accepted by the patients, and if believed would be suggestion. Brunbaum, another writer, said that this doesn't mean acceptance of a faulty idea won't occur. Both Milton Erickson and especially Pierre Janet reported cases in which suggestions were used to give benign memories to replace malignant ones.

Freud also viewed patient resistance to his interpretations as evidence that the interpretations were correct. Thus both resistance and acquiescence were thought to be validating. Popper's critiques using philosophy of science note that this makes his theory untestable.

Freud could not distinguish between the patient's reluctant acceptance of the truth and reluctant acceptance of a suggestion.

Contemporary theorists struggle less than Freud did with the problem of suggestion and suggestibility (and Freud did not have available the research on those areas!) Emotional upheaval that accompanies "insight" is readily taken to be validating. It may be true that bad memories are repressed, but that doesn't mean that all bad memories are true.

Treatment groups focus on recalling memories and sharing memories with others in the group, not on current relationships. Hermann states that the group provides powerful stimulus for remembering. The group, of course, is reinforced by others remembering. Repeatedly considering the possibility of abuse can increase the sense of familiarity.

Current views expressed by some clinicians that certain symptoms and syndromes (eating disorders, etc.) indicate early sexual trauma are similar to Freud's theory of hysteria. In these proposals, the inability to recall abuse becomes evidence that it occurred; and it tallies with the patient not having a sense of remembering.

Because some believe it is necessary to bring memory to light for cure to occur, there is a tendency to believe the reports of early childhood abuse.

Recognizing that some "memories" may have been a product of a therapist's suggestion helps prevent untoward effects. Modern therapists recapitulate Freud's "slip" when they do not acknowledge the role of suggestion.

Endorsing repression does not commit us to a belief that recovered memories must be accurate in all particulars. A memory that is repressed does not escape the usual kinds of degradation of memory.

And just because the material comes from unconscious sources, or has emotional accompaniments, it doesn't mean it is true. (Bowers gave an example of his dream that Israel and Venezuela shared a common border, which was rectified by his waking awareness of the Atlantic Ocean and the Mediterranean. He noted that nothing like the Atlantic can be called upon if the dream is that one's parent molested oneself at the age of six.)

Ian Hacking, in *Rewriting the Soul*, labels a more fundamental indeterminacy (for the historical past itself). Bathing rituals in childhood can be redescribed as abuse, which determines the historical past rather than describing it. It is thus easier to justify abuse if the event is something that can be reinterpreted. For example, the conflicts of adolescents with their parents, may be reinterpreted later if personality problems continue. If in adulthood one concludes that abuse occurred, then bathing rituals can be reinterpreted as if it were earlier abuse, as if the abuse has continued for years.

Sarbin, Theodore R. (1995). On the belief that one body may be host to two or more personalities. *International Journal of Clinical and Experimental Hypnosis*, 43 (2), 163-183.

The belief in the validity of the multiple personality concept is discussed in this article. Two scaffolding constructions are analyzed: dissociation and repression. As generally employed, these constructions grant no agency to the multiple personality patient. The claim is made that the conduct of interest arises in discourse, usually with the therapist as the discourse partner. In reviewing the history of

multiple personality and the writings of current advocates, it becomes clear that contemporary users of the multiple personality disorder diagnosis participate in a subculture with its own set of myths, one of which is the autonomous actions of mental faculties. Of special significance is the readiness to transfigure imaginings into remembering of child abuse, leading ultimately to the manufacture of persons. The implications for both therapy and theory of regarding the patient as agent in place of the belief that the contranormative conduct is under the control of mentalistic faculties are discussed.

Taylor, D. R. (1995). The validity of repressed memories and the accuracy of their recall through hypnosis: A case study from the courtroom. American Journal of Clinical Hypnosis, 37 (3), 25-31.

NOTES

1:

This case was one of a defendant who lived in California and who was accused of his wife's murder. Due to amnesia for the events at the time of the wife's death, he was not considered competent to aid in his own defense. "Conclusion. This case demonstrates that extremely emotional events, interpreted as life threatening on some level, can be actively repressed from conscious memory and that these memories can later be accurately recalled under hypnosis. This conclusion provides justification for using hypnosis in some legal cases" (p. 31). The fact that the accused committed suicide six months after acquittal supports the "premise behind repressed memories ... that they provide protection against a psychologically life-threatening event. At the time of the investigation, Mr. Bains had no waking memory of his suicide attempt; therefore, it could be hypothesized that had the amnesia continued, his suicide could have been prevented" (p. 31).

1994

Frankel, Fred H. (1994, October). On patients remembering abuse when it in fact may not have occurred. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

NOTES

1:

The concept of hidden memories has supported the profession of psychotherapy for a century. This process can only occur if there is a mechanism to support it. Bowers says, if memory is not reliably accurate, it is not reliably inaccurate either.

"Ideas passing as descriptions lead us to equate the tentative with [the factual.]" - Gould.

Three studies purporting to establish repression: 1. Briere & Comte sampled 450 adults who reported abuse. They asked, "Was there ever a time when you couldn't remember the forced experience?" How does respondent understand the question? Clients were all in therapy. 2. Herman and Schatzow (1989) "verification of abuse" study. 53 Ss in a survivor's group. Reports percentages who had no or little recall. Authors don't acknowledge that the group discussion and the attitude of therapist may have shaped the response. It is also not clear how many Ss who claimed to have "verified" their accounts were among those who had severe amnesia for the event. They could be Ss who had never lost the memory in the first place. 3. Williams interviewed women who earlier were in Emergency Rooms because of abuse being suspected. 38% did not report childhood abuse when questioned, and author concluded it was due to repression. Significant numbers of adults cannot remember things even past the age of 5.

Problem with wording of questions. Some of the women interviewed might have preferred not to report the event. This was not investigated in the study.

1994

Freyd, Jennifer J. (1994). Betrayal-trauma: Traumatic amnesia as an adaptive response to childhood abuse. Ethics and Behavior, 4.

Betrayal-trauma theory suggests that psychogenic amnesia is an adaptive response to childhood abuse. When a parent or other powerful figure violates a fundamental ethic of human relationships, victims may need to remain unaware of the trauma not to reduce suffering but rather to promote survival. Amnesia enables the child to maintain an attachment with a figure vital to survival, development, and thriving. Analysis of evolutionary pressures, mental modules, social cognitions, and developmental needs suggests that the degree to which the most fundamental human ethics are violated can influence the nature, form, processes, and responses to trauma.

## NOTES

1:

"A logical extension of this research direction, based on a strategy that has been very effective in cognitive neuroscience, would be to look for neuroanatomical underpinnings of the cognitive mechanisms implicated in dissociation. ... For instance, the ability to dissociate current experience may depend partly on representational structures that support spontaneous perceptual transformations of incoming events. One possible perceptual transformation that is amenable to scientific investigation, would be the creation of spatial representations in which the mental 'observer' is spatially distinct from the real body of that observer. Such a representation would fit patient descriptions of 'leaving their body' during a traumatic episode and viewing the scene as if from afar. Additionally one could investigate the role of mental recoding and restructuring during memory 'recovery' and psychotherapy" (pp. 19-20).

Loftus, Elizabeth; Polonsky, Sara; Fullilove, Mindy Thompson (1994). Memories of childhood sexual abuse: Remembering and repressing. Psychology of Women Quarterly, 18, 67-84.

Women involved in out-patient treatment for substance abuse were interviewed to examine their recollections of childhood sexual abuse. Overall, 54% of the 105 women reported a history of childhood sexual abuse. Of these, the majority (81%) remembered all or part of the abuse their whole lives; 19% reported they forgot the abuse for a period of time, and later the memory returned. Women who remembered the abuse their whole lives reported a clearer memory, with a more detailed picture. They also reported greater intensity of feelings at the time the abuse happened. Women who remembered the abuse their whole lives did not differ from others in terms of the violence of the abuse or whether the violence was incestuous. These data bear on current discussions concerning the extent to which repression is a common way of coping with childhood sexual abuse trauma, and also bear on some widely held beliefs about the correlates of repression.

NOTES: In previous research, it was reported that violent or incestuous abuse is particularly susceptible to repression. This study differs from previous investigations in the definition of violence. In the present study, 'violence' is defined as any act involving vaginal, oral, or anal sex. Earlier research defined 'violence' as involving sexual assault with physical injury or fear of death.

Depending on the definition of repression, a sizeable minority (31% or almost 1/5) of this sample forgot their earlier abuse for a period of time. The authors state that this suggests there is little 'robust repression' in this sample. They cannot rule out the possibility that some women who were abused still, to this day, do not recall the experience; or that some who continue to have memory loss based on organic causes, including blackouts.

The authors suggest that future research in this area use more specific questions, including assessing whether Subjects respond to statements like: "There was a time when I would not have been able to remember the abuse, even if I had been directly asked about it," or "There was a time when I would not have been able to report the abuse because I had no idea that it had even happened to me." Also, when Subjects report that a memory had emerged after a period in which they had no recall, the Experimenter should enquire about how and when the recovered memory occurred.

The authors conclude that remembering abuse is more common than forgetting it.

Nash, Michael R. (1994, October). Reports of early sexual trauma: The problem of false negatives and false positives. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

The problem of false positives and problem of false negatives are distinct and should be treated differently. The question involves pseudomemories vs repression.

Evidence for false positives: 1. Memory research 2. Developmental psychopathology 3. Contemporary psychoanalytic theory 4. Clinical field studies

No laboratory researcher has produced false memories that are as vivid, or as emotionally loaded as early abuse.

Evidence for repression: 1. "Repressor Personality" research (Weinberger & Schwartz, who view it as a trait rather than a state). 2. Implicit memory research 3. Hypnosis research on memory (see Nash chapter in Fromm & Nash book on research in hypnosis) 4. Clinical field studies

Ofshe, Richard; Singer, Margaret T. (1994). Recovered memory and robust repression: Influence and pseudomemory. International Journal of Clinical and Experimental Hypnosis, 42, 391-410.

A subset of the psychotherapists practicing trauma-focused therapy predicate their treatment on the existence of a newly claimed, powerful form of repression that differs from repression as used in the psychoanalytic tradition and from amnesia in any of its recognized forms. Recovered-memory specialists assist patients to supposedly retrieve vast quantities of information (e.g., utterly new dramatic life histories) that were allegedly unavailable to consciousness for years or decades. We refer to the hypothesized mental mechanism as 'robust repression' and call attention to the absence of evidence documenting its validity and to the differences between it and other mental mechanisms and memory features. No recovered-memory practitioner has ever published a full specification of the attributes of this mechanism. That is, the properties it would have to have for the narratives developed during therapy to be historically accurate to any significant degree. This article reports a specification of the properties of the robust repression mechanism based on interviews with current and former patients, practitioners' writings, and reports to researchers and clinicians. The spread of reliance on the robust repression mechanism over the past 20 years through portions of the clinical community is traced. While involved in therapy, patients of recovered-memory practitioners come to believe that they have either instantly repressed large numbers of discrete events or simultaneously repressed all information about abuse they may have endured for as long as a decade. Patients' therapy-derived accounts are thought by some social influence, memory, and clinical specialists to be inadvertently created iatrogenic effects: inaccurate pseudomemories and confabulations produced due to patient-therapist interaction, the use of leading, (sic) suggestions, hypnosis, and the mismanagement of the dependent relation of the patient on the therapist. Three cases are reported which illustrate how new life accounts predicated by robust repression can develop during therapy with a recovered-memory practitioner.

Spiegel, David; Schefflin, Alan W. (1994). Dissociated or fabricated? Psychiatric aspects of repressed memory in criminal and civil cases. International Journal of Clinical and Experimental Hypnosis, 42 (4), 411-432.

During the last decade, clinicians, courts, and researchers have been faced with exceedingly difficult questions involving the crossroads where memory, traumatic memory, dissociation, repression,

childhood sexual abuse, and suggestion all meet. In one criminal case, repressed memories served as the basis for a conviction of murder. In approximately 50 civil cases, courts have ruled on the issue of whether repressed memory for childhood sexual abuse may form the basis of a suit against the alleged perpetrators. Rulings that have upheld such use underscore the importance of the reliability of memory retrieval techniques. Hypnosis and other methodologies employed in psychotherapy may be beneficial in working through memories of trauma, but they may also distort memories or alter a subject's evaluation of their veracity. Because of the reconstructive nature of memory, caution must be taken to treat each case on its own merits and avoid global statements essentially proclaiming either that repressed memory is always right or that it is always wrong.

Spiegel, David (1994, October). On patients not remembering abuse when it in fact may have occurred. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

## NOTES

False memories and false non-memories may be two sides of the same coin. What is the evidence for repression?

If people are abducted by extraterrestrials, why don't they just keep them? [Joke!] It seems counter-intuitive that people would forget important, arousing things that happen.

The three main components of hypnosis (suggestibility, absorption, and dissociation) are also aspects of memory: 1. Absorption relates to encoding (narrowing attention); also happens during traumatic events (Loftus' "gun memory" which is so clear, while they don't encode what gunman's face looks like). 2. Dissociation relates to memory storage (compartmentalization of information). Traumatized people have symptoms of dissociation, depersonalization. If you are in an unusual mental state, you may watch the event; the memory is stored without the usual network of associations. 3. Suggestibility relates to retrieval. The way questions are asked influences one's response. But hypnosis is not an infinite influencer; the main damage to memory contributed by hypnosis is "confident errors" (McConkey).

We did research one week after the Loma Prieta earthquake, and found significant cognitive alterations, memory alterations, etc. In our sample, 1/4 of the people felt detached from their body or from the ground right after the earthquake.

Memory alterations were compared with data from other studies after other traumas. Difficulties with memory occurred in 29% of our sample.

The disorganization of memory can follow even just witnessing trauma (e.g. the recent slaying of 8 people in the law office in San Francisco) And people who witnessed the execution of Harris. They were in no danger themselves, yet the level of dissociative symptoms were as high in the former.

The Briere & Cone and Herman & Shatzow studies are based on self report of earlier trauma, and that is a problem in research. But Williams' study does have the age of people when they were abused as children; see her article in Journal of Consulting and Clinical Psychology.

## COMMENTS FROM THE AUDIENCE

Dabney Ewin: Sex abuse trauma differs from earthquakes because the abuser says, "If you tell anybody I'll kill you." This is like a post hypnotic suggestion, which is carried out compulsively when given to the victim during fear.

Dale: How do we account for the vigor in the attempts of each side to convince the other. The people who have been real victims of sexual abuse need to be able to talk with the people who are victims of False Memory Syndrome. The impact on a family is just as traumatic as the sexual abuse itself.

Response by D. Spiegel: I wouldn't recommend that combination, but the point you make about damage to the falsely accused is relevant. Their lives are shattered but remember the damage done throughout life by sexual abuse.

1993

Watkins, Helen H. (1993). Ego-State therapy: An overview. American Journal of Clinical Hypnosis, 35, 232-240

Ego-state therapy is a psychodynamic approach in which techniques of group and family therapy are employed to resolve conflicts between the various "ego states" that constitute a "family of self" within a single individual. Although covert ego states do not normally become overt except in true multiple personality, they are hypnotically activated and made accessible for contact and communication with the therapist. Any of the behavioral, cognitive, analytic, or humanistic techniques may then be employed in a kind of internal diplomacy. Some 20 years experience with this approach has demonstrated that complex psychodynamic problems can often be resolved in a relatively short time compared to more traditional analytic therapies.

Wickramasekera, Ian (1993, August). Some psychophysiological and clinical implications of the coincidence of hypnotic ability and neuroticism during threat perception. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.

The electrodermal response to cognitive threat (mental arithmetic) of un hypnotized female patients with somatic symptoms, high on hypnotic ability and high on neuroticism (high-high) was found to be significantly higher ( $p .01$ ) than that of a matched group of female patients moderate on hypnotic ability and low on neuroticism (moderate-low). On verbal report or a subjective units of distress scale (SUDs), the high-high and moderate-low groups did not differ, but they were significantly different on a measure of self-deception or repression. The above findings are consistent with predictions from the High Risk Model of threat perception. (ABSTRACT from the Bulletin of Division 30, Psychological Hypnosis, Fall, 1993, Vol. 2, No. 3.)

1992

Christianson, S-A (1992). Emotional stress and eyewitness memory: A critical review. Psychological Bulletin, 112, 284-309.

Although not addressing hypnosis specifically, this is a comprehensive review of literature on memory for negative emotional events relevant to issues of hypnosis and memory. The final conclusion is that emotional events are indeed remembered differently than neutral or ordinary events and are well retained with respect to the event itself and concerning central, critical detail (not peripheral detail). Such memories seem less susceptible to forgetting. There is evidence for dissociation between memory for emotional information and memory for specific event information. There is also evidence of amnesia or memory impairment effects after high-arousal events, with memory increasing as more time passes after the event. The functional amnesia effects are probably due to an interaction between altered encoding operations and the specific retrieval circumstances aiding consciously and unconsciously controlled reconstructive processes. There is little evidence to support Loftus' contentions that emotional stress is bad for memory.

Gravitz, Melvin A. (1992, October). Historical and legal issues. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

## NOTES

1:

The 1976 Chowchilla kidnaping case in California stimulated interest in using hypnosis for forensic investigation; in the same year, it was used in a case of airline hijacking in the Mediterranean to Uganda. Hypnosis is used for obtaining "leads" and doesn't claim to develop "the truth."

Other uses include: lifting amnesia of witnesses and victims of trauma—including but not limited to crime; obtaining additional information in nonamnesic Ss; evaluation of a subject's mental condition (e.g. multiple personality disorder vs malingering, as in the Bianchi case). In each use, hypnosis is not infallible, is not complete. But no procedure is. Motivation, resistance, transference are all critical.

Historic questions: 1. whether coercion is entailed 2. impact of hypnosis on memory 3. possible harm to subject, physically and mentally

The coercion issue dates to Mesmer, whose procedures led to accusations of immoral suggestions. In the 1880s Charcot said no one could be forced to do anything while the Nancy school (Liebeault) said they could. Since then we have seen laboratory studies using student volunteers, fake "poison," rubber daggers, etc., as well as recent "real life" studies where Ss were induced to violate their morals (see Watkins). Review articles include those by Jacob Conn of Baltimore and the 1985 JAMA article written by a panel headed by Martin Orne.

For impact of hypnosis on memory, see the Orne report which did not fully support using hypnosis for memory enhancement.

Regarding possible harm to a hypnotic subject in the 19th century, a young man's death was attributed to nervousness and exhaustion and diabetes due to repeated hypnosis. Other studies of death (of chickens, of a frog) due to repeated hypnotization were published. Now the consensus is that hypnosis is not dangerous (but incompetence using hypnosis may be dangerous).

## LEGAL PRECEDENTS.

In 1897 a California court refused to accept testimony of a Subject who had been hypnotized. *People vs Eubanks*.

The 1950's Cornell case established that a person can be hypnotized for their own defense.

In 1963 the California supreme court ruled that a lower court made a mistake in not admitting testimony from someone who had been hypnotized.

In *Harding* (a Maryland case), the trauma victim, amnesic, was hypnotized one month later. The testimony was accepted. A 1983 Maryland appeals court overturned it, influenced by the California *Shirley* case.

In 1983 *Hurd* case, a victim, hypnotized, identified her husband as attacker. Lower court didn't permit the testimony; then a higher court reversed it. The court issued what are known as the Hurd rules, governing testimony that is acceptable: 1. hypnotist is licensed psychologist or psychiatrist with training in hypnosis 2. hypnotist must be independent of both the prosecution and defense 3. all information given to the hypnotist about the case must be written 4. hypnotist must obtain a nonhypnotic account of the memory before hypnosis is used. 5. must have taped record of the hypnosis sessions (preferably videotaped) 6. only hypnotist and subject should be present in the room

Soon after, California had the *Shirley* case. The California court ruled hypnosis per se is unreliable because it produces confabulation. This decision had a chilling effect throughout the country for several years.

In 1987 we had *Rock vs Arkansas*, the first and only case involving hypnosis to come before the U. S. Supreme Court. Vicky Rock shot her husband. Under hypnosis, she remembered she did not have her finger on the trigger, and her husband grabbed her and shook her. Lower court wouldn't admit the testimony of the gun expert, who testified the trigger was sensitive to jarring. Supreme Court ruled defendants (not necessarily others) could use hypnosis in their own defense.

## NOTES

1:

Opinions are provided by Nancy Hornstein, Putnam, and Ganaway.

Lohr, Jeffrey M.; Kleinknecht, Ronald A.; Conley, Althea T.; Dal Cerro, Steven; Schmidt, Joel; Sonntag, Michael E. (1992). A methodological critique of the current status of eye movement desensitization (EMD). Journal of Behavior Therapy and Experimental Psychiatry.

Eye Movement Desensitization (EMD) has been recently advocated as a rapid treatment for the elimination of traumatic memories responsible for the maintenance of a number of anxiety disorders and their clinical correlates. Despite a limited conceptual framework, EMD has attracted considerable interest among clinicians and researchers. The popularity and interest generated by EMD will likely result in wide usage. We present a methodological critique of it with reference to assessment, treatment outcome, and treatment process. We also provide guidelines for judging the methodological adequacy of research on EMD and suggest intensive research to assess effectiveness, treatment components, and comparisons with other procedures.

Putnam, Frank W. (1992). Using hypnosis for therapeutic ab reactions. Psychiatric Medicine, 10, 51-65.

Abreaction, the dramatic reliving of traumatic events under hypnosis, is a powerful therapeutic intervention useful in the treatment of victims of trauma. First systematically applied in World War I, abreaction coupled with psychotherapeutic processing of the recovered material is increasingly being used with victims of child abuse and chronic PTSD. Abreactions are helpful in recovering dissociated or repressed traumatic material, reconnecting missing affect with recalled material and for transforming traumatic memories. Although abreactions can be induced with medications, hypnosis is the method of choice except in acute situations where it is not possible to establish rapport. A variety of hypnotic techniques for the induction and management of abreaction are discussed, together with the indications and contraindications for their use.

Somerville, Wayne R.; Jupp, James J. (1992). Experimental evaluation of a brief 'ideodynamic' hypnotherapy applied to phobias. Contemporary Hypnosis, 9, 85-96.

This study used a test-retest design to investigate the effectiveness of a brief 'ideodynamic' hypnotherapy which notionally located and reformulated memories in the treatment of simple phobia disorder. Subjects were 19 phobics randomly assigned to treatment (n = 10) and waiting control groups (n = 9). Rapid, significant, and sustained relief from phobic fear and avoidance was reported by 50% of treatment subjects. A number of symptoms and therapy process variables were correlated with treatment outcome. These included a negative association with hypnotizability and a positive association with hypnotic depth estimates. The ramifications of these and other associations are discussed and it is concluded that the 'ideodynamic approach' investigated may have contributed a therapeutic effect beyond the operation of treatment non-specific factors.

## NOTES

1:

Treatment consisted of: 1. Hypnotic induction. 2. Establishment of ideomotor signals described to clients as a means of communicating with the 'inner unconscious mind'. 3. Beyond the first therapy session, a review of work done in previous sessions. 4. Gaining signaled permission from clients to work on their problem and for the 'inner mind' to review relevant memories. 5. Location of the

'earliest critical event' by the 'inner mind'. 6. Review of the located memory by the 'inner mind'. 7. Establishing age at the occurrence of the 'critical' event. 8. Ideomotor signaling indicating suitability of a visual imagoic processing of the event.

If visual processing was chosen, the dissociated viewing procedure (step 9A) was used next, otherwise the ego-state procedure (step 9B) was employed.

The authors describe each treatment step in detail. Each subject received at least two sessions of therapy, or a maximum of three sessions if signaling indicated the presence of further unresolved memories after two sessions.

They present a case illustrating that the approach is possible with minimally hypnotizable subjects, in the apparent absence of imagoic experience, 'desensitization', catharsis, unpleasant affect, talking through or 'insight'.

"There was a positive correlation between changes in phobic fear and capacity for mental imagery which suggests that this may be one relevant variable in predicting response to memory reformulating therapy.

"There was a negative correlation between changes in fear and hypnotic responsiveness. So, successful therapeutic outcome was obviously not limited to highly hypnotizable subjects. Hypnotizability was assessed in a careful and standardized manner but testing was conducted 10 weeks following therapy. This meant that subjects had a substantial experience in hypnotherapy at assessment. Furthermore, at the time of assessment subjects were aware of the outcome of therapy and of the kinds of memories located during therapy. It has been suggested that an association between level of hypnotizedness achieved during treatment and outcome rather than an association between degree of hypnotizability possible during therapy and outcome, taps an hypnotic effect (Spiegel & Spiegel, 1978).

"All therapy sessions were of equal duration and, as the inductions were standardized, all subjects had an approximately equal opportunity to engage in memory reformulation. However, there were individual differences in the number of memories located and a strong significant association was found between reduced fear and the number of these critical memories that were dealt with. This result suggests that the therapeutic effect may have derived either from factors specific to the therapy cycle or from differing levels of motivation among subjects to undertake the necessary 'work'.

"Maximum discomfort experienced during session two of treatment was negatively correlated with relief from phobic fears. This relationship may again reflect the influence of unresolved problematic memories on subjects who had not achieved relief by that time. It is clearly consistent with relief not being associated with painful abreaction.

"The therapy permitted a pervading privacy through the options of non-imaginative processing of recalled material (which was used by a substantial minority of subjects) and conscious withholding of the content of memories from the therapist (which was employed to a large extent by all subjects). Their reports indicated that this 'privacy' was seen as attractive by both successfully and unsuccessfully treated subjects. Taken with other results mentioned above these process findings suggest that the treatment studied stood up quite well against other brief but highly stressful exposure treatments for phobia currently in use (e.g. Ost, 1989).

"Further research needs to address the complex question as to what are the necessary and sufficient features of this procedure in producing therapeutic change. Unsolicited comments by subjects about their experience during treatment suggested that some of them were surprised by the 'involuntary' nature of their ideomotor signaling while others said that signaling was under their voluntary control. Some expressed surprise at the nature of the memories that came to them 'suddenly' during therapy. Some memories were of traumatic childhood experiences that were unexpected and considered to have 'nothing to do with my phobia'" (pp 93-94).

**Terr, Lenore C. (1991). Childhood traumas: An outline and overview. American Journal of Psychiatry, 148, 10-20.**

Suggests 4 characteristics common to most cases of childhood trauma: visualized or otherwise repeatedly perceived memories of the traumatic event; repetitive behaviors; trauma-specific fears; and changed attitudes about people, life, and the future. Childhood trauma is divided into 2 basic types. Type I trauma includes full, detailed memories, "omens," and misperceptions while Type II trauma includes denial and numbing, self-hypnosis and dissociation, and rage. Characteristics of both types of childhood trauma can exist side by side. Such crossover Type I - Type II traumatic conditions of childhood are characterized by perceptual mourning and depression and childhood disfigurement, disability, and pain. Case examples are provided.

**Van Der Kolk, Bessel; Van Der Hart, O. (1991). The intrusive past: The flexibility of memory and the engraving of trauma. American Imago, 48, 425-454.**

Describes the work of Janet concerning narrative versus traumatic memory, dissociation, and subconscious fixed ideas. Janet (1904) believed PTSD patients suffer from a phobia for the traumatic memory. Repression and dissociation are distinguished. Contemporary concepts of memory processing and the concept of schemas are then reviewed. Finally, a model is presented about how the mind freezes some memories. Evidence for the involvement of autonomic hyperarousal, triggering, and state dependent learning in PTSD is reviewed. They conclude that helplessness and the inability of the PTSD victim to take action (psychological and physical immobilization) facilitates dissociation. Includes practical ideas for the working through of trauma.

"Traumatic memories are triggered by autonomic arousal ... and are thought to be mediated via hyper-potentiated noradrenergic pathways originating in the locus coeruleus of the brain... The locus coeruleus is the 'alarm bell' of the central nervous system, which properly goes off only under situations of threat, but which, in traumatized people, is liable to respond to any number of triggering conditions akin to the saliva in Pavlov's dogs. When the locus coeruleus alarm gets activated, it secretes noradrenaline, and, if rung repeatedly, endogenous opioids. These, in turn, dampen perception of pain, physical as well as psychological (van der Kolk et al. 1989). These neurotransmitters which are activated by alarm affect the hippocampus, the amygdala and the frontal lobes, where stress-induced neurochemical alterations affect the interpretation of incoming stimuli further in the direction of 'emergency' and fight/flight responses" (p. 443).

1990

**Bonnano, George A. (1990). Remembering and psychotherapy. Psychotherapy, 27, 175-186.**

Reviews some of the empirical literature demonstrating the reconstructive nature of memory. The notion that the memory trace can consist of different forms of information is integrated with J. S. Bruner's (see PA, Vol 38:6801) tripartite model of representation, using the concepts of narrative and memory schemata. A case illustration demonstrates the pervasive organizing quality of the nuclear script and how, through such a structure, childhood events can hold a lasting impact on adult behavior. It is concluded that conceptual understanding can be translated into schematic terminology provided it is adequately modified to account for the reconstructive nature of memory.

**Frankel, Fred H. (1990). Hypnotizability and dissociation. American Journal of Psychiatry, 147, 823-829.**

Describes the multidimensionality of hypnosis and hypnotizability. He also points to the lack of clarity regarding the concept of dissociation and the extent to which its roots lie in the clinical experience of hypnosis. The concept of dissociation increasingly preempts repression and other defense mechanisms in current nosological thinking. The author cautions against equating hypnosis scores with dissociative capacity and advocates a clearer elaboration of the term "dissociation." Meanwhile, restraint in the use of the term "dissociation" is recommended.

Kunzendorf, Robert G.; Jesses, Michael; Dupille, Leonard; Butler, William (1990-91). Subliminal activation of intrapsychic conflicts: Subconscious realms of mind vs subconscious processes of mentation. Imagination, Cognition and Personality, 10, 117-128.

Cognitive-state monitoring theory asserts that people perceive subliminal stimulation without self-consciously monitoring its external innervation (as opposed to central innervation). Thus monitoring theory predicts that subconsciously perceived discord, in the absence of any 'external location' cues, should be misinterpreted as centrally generated discord and should disrupt self-generated behavior. Consistent with this prediction, mathematical problem-solving in the current experiment was disrupted after mathematically competitive males repeatedly heard the subliminal message IT'S WRONG TO CRUSH DADDY stereophonically localized in the middle of their heads--but not after they repeatedly heard this subliminal 'Oedipal' message binaurally localized on one side of their heads. A subliminal message binaurally localized on one side of the self should not interfere with problem-solving behavior \_because, even though the message's external innervation is not self-consciously 'monitored,' its external location is inferable from subconscious cues.\_

Monitoring theory asserts that subliminal [perceptions] of 'unmonitored' messages are unaccompanied by any self-consciousness that one is perceiving them (rather than imaging them), and that subliminal or 'unmonitored' messages of distress are mistaken for self-generated distress.

Disruption by the 'internal' subliminal word WRONG seems to us consistent with the fact that disruption was limited to mathematically competent males.

Indeed, 'repression' itself is a mode of processing fearful information: a mode in which subjects suspend their self-awareness that they are perceiving fearful stimulation, as research by Kunzendorf and McLaughlin has demonstrated. This selective suspension of monitoring provides immediate relief from fearful stimuli, Freudian or otherwise, but it does so at the risk of turning self-conscious fear into subconscious anxiety (into consciously lingering fear without a self consciously perceived source). No subconscious realm full of lurking fears is implicated in this 'unmonitored' mode of self-protection. All that is implicated is an unconscious storehouse of potentially fearful memories--potentially fearful but sensationless memories, which can be 'suppressed' from conscious sensory representation or 'constructed' into conscious memory images or 'subconsciously represented' as unself-consciously imaged sensations

Spiegel, David; Cardena, Etzel (1990, October). New uses of hypnosis in the treatment of posttraumatic stress disorder. Journal of Clinical Psychiatry (Supplement), 51, 39-43.

Vietnam veterans with PTSD and those abused as children have above average hypnotizability. Hypnosis provides controlled access to memories that may otherwise be kept out of consciousness. New uses of hypnosis with PTSD victims involve coupling access to the dissociated traumatic memories with positive restructuring of those memories. Hypnosis can be used to help patients face and bear a traumatic experience by embedding it in a new context, acknowledging helplessness during the event, and yet linking that experience with remoralizing memories, such as efforts at self-protection, shared affection with friends who were killed, or the ability to control the environment at other times. In this way, hypnosis can be used to provide controlled access to memories that are then placed into a broader

perspective. Patients can be taught self-hypnosis techniques that allow them to work through and thereby reduce spontaneous, unbidden, intrusive recollections.

1989

Eisen, Marlene R. (1989). Return of the repressed: Hypnoanalysis of a case of total amnesia. International Journal of Clinical and Experimental Hypnosis, 37 (2), 107-119.

A case study is presented of a woman suffering from global amnesia so profound that she had lost all sense of personal identity. Hypnotherapy was used to establish, through imagery, a solid inner core on which to rebuild a sense of self. From the image of a strong column on which rested a book with a golden lock (her history), to reading about other lives, books and stories were utilized to establish a safe external environment in which the reawakening of repressed memories was not longer perceived as dangerous. A discussion of relevant literature on the subjects of global amnesia, loss of personal identity, and post-traumatic stress is offered as a basis for discussing the present case.

Van der Kolk, Bessel A.; Van der Hart, O. (1989). Pierre Janet and the breakdown of adaptation in psychological trauma. American Journal of Psychiatry, 146, 1530-1540.

Reviews Janet's investigations into mental processes that transform traumatic experiences into psychopathology. He was the first to systematically study dissociation as the crucial psychological process with which the organism reacts to overwhelming experiences and show that traumatic memories may be expressed as sensory perceptions, affect states, and behavioral reenactments. Janet provided a broad framework that unifies into a larger perspective the various approaches to psychological functioning which have developed along independent lines in this century. Today his integrated approach may help clarify the interrelationships among such diverse topics as memory processes, state-dependent learning, dissociative reactions, and posttraumatic psychopathology.

1988

Pettinati, Helen M. (1988). Hypnosis and memory. New York and London: Guilford Press.

NOTES

1:

From a review in British Journal of Experimental and Clinical Hypnosis, 7, 175- 178, by Vernon H. Gregg]:

Book has 5 sections: 1. method, theory 2. mechanisms of memory enhancement 3. hypnotic and other forms of reversible amnesia 4. clinical uses of hypnosis for increasing accessibility of memories and fantasies 5. Summary

The chapter by Martin Orne et al presents a comprehensive review. Perry, Lawrence, d'Eon and Tallant contribute a lively assessment of age regression procedures in the elicitation of inaccessible memories. They provide a description of procedures, a brief historical review, and discuss problems of confabulation and creation of pseudomemories. Their account is illustrated by clinical and forensic examples and gives an interesting account of belief in reincarnation in terms of source amnesia.

Section 3 has Hollander's chapter on hysteria and memory, which illustrates the concept of reversibility of amnesia with two types of hysterical conditions: one of these types, the dissociative disorders, has the potential for amnesia to be reversed but the other, histrionic personality disorders, is characterized by no reversibility.

In the section on clinical studies of memory enhancement Frankel and Kolb both accept that uncovering repressed memories and fantasies is therapeutically beneficial and that the faithfulness of recovered memories is often not important for therapeutic success. Frankel illustrates the usefulness of hypnosis with several case studies. But he thinks that clinical issues are dealt with too briefly in this

book. In her summary chapter Pettinati points to the dearth of systematic research into the effectiveness of hypnosis in clinical settings.

Terr, Lenore C. (1988). What happens to early memories of trauma? A study of twenty children under age five at the time of documented traumatic events. Journal of the American Academy of Child and Adolescent Psychiatry, 27, 96-104.

The verbal and behavioral remembrances of 20 children who suffered psychic trauma before age 5 were compared with documentations of the same events. Ages 28 to 36 months, at the time of the trauma, serves as an approximate cutoff point separating those children who can fully verbalize their past experiences from those who can do so in part or not at all. Girls appear better able than boys to verbalize parts of traumas from before ages 28 to 36 months. Short, single traumas are more likely to be remembered in words. At any age, however, behavioral memories of trauma remain quite accurate and true to the events that stimulated them.

## NOTES

This article is relevant to those working with PTSD and in age regression.

1985-1986

Kunzendorf, Robert G.; Benoit, Michelle (1985-86). Spontaneous post-hypnotic amnesia and spontaneous rehypnotic recovery in repressors. Imagination, Cognition and Personality, 5 (4), 303-310.

The Salpetriere school of hypnosis posited that true hypnotic effects occur spontaneously in people with repressive tendencies. Consistent with this early position, the current study indicates that both spontaneous amnesia after hypnosis and spontaneous recovery during rehypnosis are statistically associated with repression (but not with hypnotic suggestibility). In contrast, both suggested forgetting and suggested recovery are statistically associated with hypnotic suggestibility (but not with repression). Whereas the latter effects of suggestibility are attributable to the demand characteristics of hypnotic suggestions, the spontaneous effects of hypnosis on repressors' memories are not reducible to social psychological principles.

1985

Nichols, Michael P.; Efran, Jay S. (1985). Catharsis in psychotherapy: A new perspective. Psychotherapy, 22 (1), 46-58.

Contemporary thinking about catharsis in psychotherapy is still dominated by Breuer and Freud's work with the cathartic method. Psychoanalysts take the fact that Freud abandoned catharsis as evidence of its ineffectiveness, while the emotive therapies developed in the 1960s returned to Freud's earliest view that neurosis results from repressed affect and can be cured by cathartic uncovering. Emotional memories continue to be thought of as foreign bodies lodged in the human psyche and requiring purgation. Unfortunately, this view divorces people from responsibility for their conduct and encourages a fractionation of human experience into feeling, thought, and action. In the current presentation, emotion is construed instead as a class of blocked or partially blocked actions, and in terms of a two-stage adaptational process. Implications of this view for psychotherapeutic practice are proposed, emphasizing richer self-expression and fuller appreciation of the consequences of responsible vs. disclaimed actions.

1984

Perry, Campbell (1984). Dissociative phenomena of hypnosis. Australian Journal of Clinical and Experimental Hypnosis, 12, 71-84.

Janet's concept of dissociation, Freud's notion of the Censor and Hilgard's multiple controls of consciousness are considered in relation to the hidden observer (HO) phenomenon. A review of reports of recent research, including that of the author and co-workers, indicates that the hidden observer effect occurs only in 40-50% of high susceptible subjects. It is speculated that subjects who show Hidden observer have maintained some contact with reality whilst those high susceptibles who do not show hidden observer are more deeply involved in hypnosis.

## NOTES

Author describes a series of experiments in their laboratory. Ss are double screened to select highly hypnotizable people, and accepted into the research only if they pass the amnesia item of SHSS:C and most of the other 11 items of that scale. Ss are told that hypnosis is a procedure which permits subjects to exercise various skills or abilities such as relaxation, imagination, imagery, absorption and selective attention--that everyone has some of these skills to varying degrees, and that hypnosis is one of many techniques (including yoga, etc.) for bringing out these skills and abilities. All sessions are videotaped for the Experiential Analysis Technique (EAT). The Hidden Observer (HO) procedure was modified so that E touched the S's shoulder lightly at the start of the item, and a second time to terminate the item. Whereas Hilgard used cold pressor pain, they used a mildly unpleasant shock provided by a Take-Me-Along electric stimulator.

1980

Replying to Spanos and Hewitt (1980) in which data was interpreted as implying that the HO is an artifact of demand characteristics, "It struck me then, and still does, that people like Hilgard and ourselves, who believe that the HO is a phenomenon of hypnosis and not just some laboratory artifact, can only get it 40-50% of the time, whereas the investigators like Spanos and Hewitt, who believe it is all laboratory artifact, get the phenomenon almost 100% of the time. Usually it is the other way around, so it seems to me that if the HO is an artifact, it is unique in the history of psychology" (p. 77). They found that all highs with the HO also reported subjective experiences similar to HO experience when they were not hypnotized. "For instance, one female subject who has the HO, insists that she is not hypnotized, despite compelling evidence to the contrary, because she feels the same way when she is not hypnotized. By contrast, another subject who is interested in creative writing reports HO type experiences when she is on a creativity binge and also when she is stoned" (p. 79).

They observed several consistent findings in their research: "(1) contrary to the belief that subjects who report HO's are more susceptible than those who do not, our findings are the reverse" (p. 79). The differences are not large enough to be significant, but that may be due to a ceiling effect on the scales since the subjects are already selected to be high hypnotizables. "(2) A second repeated observation is that when all the Ss were administered the HO instructions, they were given a second electric shock to the still analgesic hand, and asked to report the degree of pain they felt on a 1-10 scale where 1 = no pain and 10 = extreme pain. ... the HOs report having the HO experience and their pain reports on the 1-10 scale increase, in the manner described by Hilgard using cold pressor pain. The no HOS report no subjective difference, and their degree of analgesia actually increases" (p. 79).

The author describes further studies in which they obtained results in the opposite direction from what they had expected, based on the supposition that people who do not have the HO appear to set aside critical judgement more and to be more imaginatively involved. "So the finding of greater recall after reversal of amnesia for the no HOs both on number of items and on bits was a surprise" (p. 81). When they extended this research into the area of pseudo-memories, they found that "of the 8 subjects who had the HO, 7 of them believed the pseudo-memory was real. Of the 19 subjects who did not have the

HO, only 6 of them accepted the pseudo-memory as real ... The effect was even stronger for duality in age regression. Of 12 subjects reporting duality, 10 reported the hallucinated noises as real; of the 15 with no duality, 3 accepted the reality of the pseudo-memory as actually having happened" (p. 81).

1980

Stam, Henderikus J.; Radtke-Bodorik, Lorraine; Spanos, Nicholas P. (1980). Repression and hypnotic amnesia: A failure to replicate and an alternative formulation. Journal of Abnormal Psychology, 89 (4), 551-559.

In an attempt to replicate and extend a study by S. R. Clemes, 2 groups of 10 undergraduate hypnotic Ss learned a list of 18 words and were given an amnesia suggestion telling them they would be able to remember only 10 of these words. Half of the list words were critical (i.e., considered to be related to repressed conflictual material) and half were neutral (unrelated to conflictual material) as determined by Ss' responses to a word association test. Experimental Ss received their own critical and neutral words and yoked control Ss received the critical and neutral words of experimental Ss. Neither the experimental nor the yoked control group exhibited selective amnesia in favor of critical words, thus constituting a failure to replicate Clemes's result. However, variables affecting the degree to which words were initially learned (e.g., imagery value, serial position) predicted their resistance to amnesia. These findings are inconsistent with a repression hypothesis but congruent with an inattention hypothesis of suggested amnesia. (41 ref).

1979

Kleinhauz, Moris; Dreyfuss, Daniel A.; Beran, Barbara; Goldberg, Tova; Azikri, David (1979). Some after-effects of stage hypnosis: A case study of psychopathological manifestations. International Journal of Clinical and Experimental Hypnosis, 27, 219-226.

Some deleterious effects of stage hypnosis are described through a case report. A middle-aged respected member of a kibbutz who became the subject of an evening's entertainment by a stage hypnotist suffered a posttraumatic neurosis. The stage hypnotist, unaware of her traumatic childhood during World War II when she and her sister were hidden by Gentiles, requested her to regress to that age. This reactivated a former successfully repressed trauma and acted as a precipitating factor to the development of a traumatic neurosis which was left untreated. She was self-referred for adequate psychiatric treatment 11 years later. This treatment successfully restored her to an adequate level of functioning.

1978

Shiple, R. H.; Butt, J. H.; Horowitz, B.; Farbr, J. E. (1978). Preparation for a stressful medical procedure: Effect of amount of stimulus preexposure and coping style. Journal of Consulting and Clinical Psychology, 46, 499-507.

Anxiety during the stressful medical procedure of endoscopy was studied as a function of the number of prior viewings of an explicit preparation videotape and of repression-sensitization coping style. Sixty naive patients viewed a videotaped endoscopy either zero, one, or three times. Dependent measures included heart rate, behavioral ratings, tranquilizer required, and self-report. On each dependent measure, three viewings generally resulted in the least distress; one, more distress; and zero, the most distress. Most comparisons reached statistical significance. These results are interpreted as resulting from extinction and/or habituation of anxiety. The repression-sensitization factor interacted with heart rate change. Sensitizers showed a monotonic decrease in heart rate as a function of number of tape exposures. Repressors showed an inverted-U-shaped function, with one viewing producing the highest

heart rate; this is interpreted as resulting from a disruption of repressing defenses by one tape exposure followed by extinction of fear by three exposures.

1974

**Galín, David (1974). Implications for psychiatry of left and right cerebral specialization: A neurophysiological context for unconscious processes. Archives of General Psychiatry, 31 (4), 572-583.**

A brief review is presented of hemispheric specialization for different cognitive modes, and of the symptoms that follow disconnection of the two hemispheres by commissurotomy. Our present knowledge of the hemispheres' cognitive specialization and potential for independent functioning provides a framework for thinking about the interaction of cognitive structures, defensive maneuvers, and variations in awareness. Parallels are noted between some aspects of the mental processes of the disconnected right hemisphere and some aspects of primary process thinking and repression. The hypothesis is proposed that in normal intact people mental events in the right hemisphere can become disconnected functionally from the left hemisphere (by inhibition of neuronal transmission across the cerebral commissures), and can continue a life of their own. This hypothesis suggests a neurophysiological mechanisms for at least some instances of repression and an anatomical locus for the unconscious mental contents.

1972

**Cedercreutz, C. (1972). The big mistakes: A note. International Journal of Clinical and Experimental Hypnosis, 20, 15-16.**

: In his book, *A System of Medical Hypnosis*, Ainslie Meares writes, "Most books on hypnosis, from Bernheim to the present time, devote a great deal of space to the description of successful and dramatic cures. These accounts may be of prestige value to the author, and may do something to inform the profession of the potential value of hypnosis in medicine, but these success stories are really of little help to those who would learn the technique of hypnotherapy because the emphasis is always on the success of the treatment rather than on analysis of the psychodynamic mechanisms which brought it about. As in everything else, we learn most from a study of our failures [p. 3]." These comments remain as true today as they were ten years ago. With the notable exception of Meares, few colleagues have been willing to share their errors, allowing us to profit from their experience. Thus, when Dr. Cedercreutz sent along a note describing his experience with one of his patients, I was struck by his generosity, and it seemed most appropriate for all of us to share his experience by way of the Journal. Hopefully, this may encourage other colleagues to share their failures as well as their successes so that all of us may learn to be more effective therapists and better scientists. M.T.O. [Martin Orne]

NOTES

The case reported involves a patient who had migraine headache removed with hypnosis, but later developed gastrointestinal symptoms that were operated surgically with absence of positive (physical) pathology noted. Subsequent investigation of the psychological component of the problem with hypnosis revealed an early trauma (seeing a soldier killed with a bayonette) that led to migraine-like pain in the head and vomiting

1970

**Fromm, Erika (1970). Age regression with unexpected reappearance of a repressed childhood language. International Journal of Clinical and Experimental Hypnosis, 18, 79-88.**

Describes the case of a 26-yr-old, 3rd-generation Japanese-American who thought he knew no Japanese. When hypnotically age-regressed to levels below age 4, he spontaneously and unexpectedly spoke Japanese, while only English was spoken at the adult and age-regression levels above 4 yr. The psychodynamics of the S's repression of the childhood language and questions pertaining to the nature and theory of age regression are discussed. (Spanish & German summaries) (16 ref.) 1969

Raginsky, Bernard B. (1969). Hypnotic recall of air crash cause. International Journal of Clinical and Experimental Hypnosis, 17, 1-19.

Discusses the use of hypnotic techniques to help a 33-yr-old male recall suppressed material which implicated him in an air crash. The cause was found after 2 short hypnotic sessions, where other methods used over 2 years had failed. The method can be used in all cases of amnesia. The S was made to hallucinate a threatening situation, and his hallucination gave a clue to the basic problem. He was then made to hallucinate a pleasant scene, which gave an indication of the method he used to escape from the problem. This was repeated at the 2nd session for confirmation. If the patient did not bring up the required material by free association under hypnosis, a dissociation of the personality induced in which the observing ego watched what the experiencing ego was doing to cause the accident. The results demonstrated that hypnotic techniques were more successful than sodium amytal interviews, free association, psychiatric interviews, physical and emotional isolation, pressure by authorities, and kindness of friends. Reference was made to the problems involved when the interests of the S were in conflict with public safety. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1966

O'Connell, D. N. (1966). Selective recall of hypnotic susceptibility items: Evidence for repression or enhancement?. International Journal of Clinical and Experimental Hypnosis, 2, 150-161.

5 samples of Ss given initial standardized tests of hypnotic susceptibility were analyzed for posthypnotic item recall. All samples showed evidence of selective recall favoring passed items compared to failed items. 4 samples however, showed greater selectivity among the low-scoring Ss, contrary to previous report. This evidence is interpreted as favoring an interpretation of selective recall in terms of an enhancement rather than a repression model. Intersample differences in pattern of recall are stressed. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Stross, L. (1966). Impulse-defense implications in a case of amnesia. International Journal of Clinical and Experimental Hypnosis, 2, 89-103.

An 18-yr-old girl with a delinquent history leading to several suicide attempts and a fugue is described as she was observed during shifting phases of her amnesic syndrome. Using the case study as a research tool, it is suggested that alteration of ego state might be an archaic, primitive means of defense against relatively unneutralized, intense drives. More speculative are the propositions, generated from this case, that the ego could employ different defensive means with regard to libidinal and aggressive drives and that alteration of ego state might be a specific defense against aggression. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1965

**Halpern, Seymore (1965). Body-image symbols of repression. International Journal of Clinical and Experimental Hypnosis, 13 (2), 83-91.**

Hypnointrospection, a method of hypnoanalysis which emphasizes self-perception during voluntary immobilization, is of demonstrable value in the elucidation of the problem of body-image. Hypnointrospective fragments of a case history showing the reorganization of the body-image during therapy are presented. The sequence of body-image phenomena is interpreted as an expression of attitudinal compromises among conflicting wishes implemented through neuromuscular channels. The continuous reorganization of the physical self as perceived by the patient during hypnointrospective analysis appears to be of significance for a general theory of body-image. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

**1963**

**LeCron, Leslie M. (1963). Uncovering early memories by ideomotor responses to questioning. International Journal of Clinical and Experimental Hypnosis, 11, 137-142.**

The author argues for the veridicality of birth and prenatal memories elicited by hypnosis, and in any event states they are therapeutically useful fantasies. He also advocates use of ideomotor signalling as a means of access to unconscious material. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

**1960**

**Dorcus, Roy M. (1960). Recall under hypnosis of amnesic events. International Journal of Clinical and Experimental Hypnosis, 8 (1), 57-61.**

**NOTES**

**1:**

The author reported on hypnosis work with eight cases, four dealing with attempts to recall misplaced or lost articles and four dealing with recall of information related to the commission of crimes. He concluded "that recall is not greatly improved under hypnosis. However, when strong emotional elements surround the events to be recalled some additional information may be secured" (p. 60).

**1955**

**Erickson, Milton H. (1955). Self-exploration in the hypnotic state. Journal of Clinical and Experimental Hypnosis, 3 (1), 49-57.**

**NOTES**

**1:**

A medical student who was interested in psychiatry and specifically in the question of whether one could in hypnosis remember something from earlier life that had been forgotten participated in an experiment. In hypnosis he was given instructions that amounted to permissive suggestions that he would be able to complete that task. Following about 30 minutes of silence he reported feeling fear, appeared as if he would vomit, went through a series of extreme negative emotions (reporting that he still did not have the significant memory), and requested that he be awakened. After resting 10 minutes he spontaneously returned to the somnambulistic level and then again went through extreme emotions, reporting that he had the memory but feared forgetting it again when he awoke. The author indicated that after awakening he would know whether or not he wanted to recall the memory. In the waking state, with support and indirect suggestions, the student gradually recalled a traumatic memory of childhood aggression and its consequences. Following that disclosure, some ideosyncratic problems in medical school (e.g. difficulty with dermatology) more or less disappeared.

1954

LeCron, Leslie M. (1954). A hypnotic technique for uncovering unconscious material. Journal of Clinical and Experimental Hypnosis, 2, 76-79. (Abstracted in Psychological Abstracts, 54: 7497)

"Summary. A technique is given whereby unconscious material and information may be learned under hypnosis through automatic movements of the fingers, or of Chevreul's pendulum. The movements are controlled by the unconscious mind of the patient. Questions are asked which can be answered either 'yes' or 'no.' With most people the movements of the pendulum can even be elicited in the waking state. Essentially, the method is a variation of automatic writing with movements substituted for writing. A brief case history is given wherein knowledge was gained in this way as to the causes for severe menstrual pains" (p. 79).

## RESEARCH METHOD

1995

Barabasz, Arreed F.; Barabasz, Marianne (1995, November). What we can do about it: Combining the expertise of clinicians and experimentalists. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

Bowers' study in which post hypnotic suggestion to touch ear, given by the secretary outside the laboratory, was followed by the high hypnotizables and not the lows was described.

Hypnosis research owes its development to clinical methods. However proto- studies fail publication and/or efficacy criteria.

We know nothing about the specificity of hypnosis in terms of its effects unless we measure hypnotizability. It's important that, even though lows may respond due to placebo etc., we not fool ourselves about what contributes to success.

Proto-studies lack literature survey, e.g. not citing prior research.

Case study research is helpful as a first step in furthering our knowledge. Key is careful observation and description. Fromm, 1981, wrote, "The purpose of a clinical manuscript must be to communicate to other clinicians new hypotheses, observations and findings which expand the professional horizon; or to present in detail new or modified techniques. It is important to state in clear cut, concrete form what was actually done so others can replicate, test, or apply the procedure to their own patients."

Barnier, Amanda J.; McConkey, Kevin M. (1995, November). Posthypnotic suggestion: Knowing when to stop helps to keep it going. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

1:  
Posthypnotic suggestion sometimes leads to compulsive and involuntary responding, but we have little information about the parameters of such a response. In some research in our laboratory, we found that subjects who were given a posthypnotic suggestion that encouraged them to experience a desire to respond, showed a different pattern of response from those simply told to make a specific behavioral response. In another study, we gave subjects a posthypnotic suggestion to mail a postcard every day to the experimenter; some subjects were told to respond until they saw the hypnotist again (termination), others were given no specific information about how long they should respond (no termination). Those expecting a termination to the suggestion showed a different pattern of response across 16 weeks of

testing. Thus, the information included in the suggestion about how or when to respond influences posthypnotic responding.

**Present Experiment:** Laboratory test of including specific information in the posthypnotic suggestion about how long to respond - cancellation cue vs. no cancellation cue. Responding indexed on four different tests: formal, embedded, informal, postexperimental. Also used real/simulating methodology. We expected that responding would decline across the four tests, but that the decline would be slowest for those expecting a cancellation cue.

**Methodology:** High hypnotizable subjects scored 8-10 on SHSS:C, lows scored 0- 3 on SHSS:C. Given real/simulating instructions (Orne, 1959). Formal test was given immediately after deinduction; embedded test was given during an inquiry question; informal test was given as the hypnotist appeared to terminate the experiment and leave the room; postexperimental test was given by another experimenter during a postexperimental inquiry. The suggestion was to cough when Ss heard a particular response cue.

**Results:** On the formal test, there was no difference between reals or simulators in either the cue or no cue condition, although simulators in the cue condition tended to overplay their response. Across the tests, responding declined. In particular, the majority of reals and simulators in the no cue condition stopped responding after the formal test. In the cue condition, reals and simulators responded similarly on the embedded test, but differently on the informal test; more reals than simulators continued to respond across the tests. Few subjects responded on the postexperimental test. Subjects' postexperimental comments indicated that reals and simulators in the no cue condition believed that one response was sufficient; simulators in the cue condition were confused about whether to keep responding, and reals in the cue condition responded compulsively across the test.

**Conclusions:**

The inclusion of a cancellation cue in a posthypnotic suggestions maintains responding for a longer period. Responding posthypnotically is not explained solely by demand characteristics. Rather, individuals respond on the basis of their interpretation of the implied intent of the hypnotist's message (c.f., Sheehan, 1971). Responding changes across test types. These findings contribute to a model of posthypnotic responding. They point to the active responding of hypnotized individuals (c.f., Kihlstrom: experimental subjects try to make sense of the message of the suggestions and instructions they receive).

[Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

**NOTES:**

As clinicians we need to embrace what researchers provide, but they need to pay attention to what clinicians provide, which is not myth and not fantasy.

Eastwood, John D.; Gaskaski, Peter; Bowers, Kenneth S. (1995, November). Frequency of pain reporting and analgesia: Exploration of a possible interaction. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

**NOTES**

1:

Two theories of pain control by hypnosis currently exist: 1. Socio-cognitive model - patient actively copes with noxious stimulus. Hypnotic analgesia should be like cognitive techniques like stress inoculation training. It requires deliberate effort. 2. Dissociative control model - pain reduction requires little cognitive effort.

These 2 theories have different predictions. He explains "ironic effects" theory, in which person must identify pain to reduce pain. Wagner's reflexivity constraint: any process of mental control must be consistent with state we are trying to create.

This investigation involved 25 Highs and 24 Lows who reported pain, produced by strain gauge. Taught either hypnotic analgesia or stress inoculation. Reported every 5 sec (high load) or 45 sec (low load). Subtracted report from baseline to make pain reduction scores. Highs in hypnosis had no difference in pain reduction under high or low mental load. For the other 3 groups (Highs under stress inoculation; Lows under either hypnosis or stress inoculation) the results were different. That is, for Highs in hypnosis the mean of pain reduction scores was the same even when challenged by frequent reports of how much pain was being experienced.

Results are congruent with Miller and Bowers' dissociative control model.

Wagner's ironic process theory is useful. Frequency of pain reporting moderates Ss reports of pain in analgesia. These results challenge the cognitive social model of hypnotic analgesia and support a dissociative control model. Unlike stress inoculation, hypnotic analgesia does not require cognitive effort for high hypnotizable subjects.

1994

Kiernan, Brian; Dane, Joseph R. (1994, October). Hypnoanalgesia reduces new physiologic index of pain, the R-III Index, but the role of hypnotic susceptibility remains unclear. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

NOTES

1:

Stimulated by work of Basil Finer, and following upon the Neodissociation theory of Hilgard; pain is registered by the body but dissociation that produces analgesia is a function of higher brain centers.

Could hypnotic analgesia be mediated lower, at the level of the spinal cord? Gate at dorsal horn could be open or shut; subject to descending modulation. Is hypnosis involved in descending modulation of activity in the dorsal horn?

Hypothesis: reduced pain intensity would be associated with reduced activity at dorsal horn. From Price & Barber, we wanted to look at affect and intensity aspects of pain. Polysynaptic reflex, R-III, latency consistent with conduction velocity (when hand touches a hot stove); even with severed spinal cord injury we still demonstrate the reflex. The magnitude of reflex is linearly related to the pain sensation. The stronger the electrical pulse, the greater the magnitude of the reflex. Magnitude of reflex is linearly related to subjective pain. It is an index of nociceptive activity.

Procedure: Evoke reflex with electrical stimulus at ankle; measure signal at muscle with EMG. We anticipated that at dorsal horn, descending modulation would dampen signal.

15 healthy volunteers. Sural nerve was stimulated. R III reflex measured via EMG response. Used the visual analogue scale (VAS) to assess pain.

1993

Council, James R.; Grant, Debora L. (1993, October). Context effects: They're not just for hypnosis anymore. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

NOTES

Context effects in Absorption research are found in correlations, not in mean differences. Original paper has been replicated and yet results are not always significant. Now we are trying to generalize the effect to other areas: an individually administered measure will influence other measures made in the same session.

Other tests that correlate with hypnosis are studied with 2 x 2 design, enabling order effects and same vs separate contexts to be studied. Or two tests are administered at two points in time, with "bridges" between the two sessions (e.g. same experimenter, same consent forms, etc.) As one adds more and more bridging cues, the correlation of Absorption with other Tellegen MPQ subscales increases.

Same context assessment increases correlation between hypnotizability and 6-8 other scales; with childhood trauma scale when trauma scale is administered first; with beliefs in paranormal phenomena when the measure is related to an adjustment scale. The same inflation of correlations was found in Beck Depression scale research.

These results are of concern because we may have to re-do a lot of personality research that suggested correlation between personality test variables, as the correlations may be inflated by the effects of testing in the same context.

Farvolden, Peter; Bowers, Kenneth S.; Woody, Erik Z. (1993, October). Hypnotic amnesia: Avoiding the 'Intentional Loop'. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL

#### NOTES

1:

The social cognitive view is that Ss actively try to forget and fool themselves, making an attributional error. Davidson & Bowers say (in neo-dissociation theory) the information is temporarily unconscious-like forgetting a friend's name at a cocktail party. Executive initiative, effort, and control are bypassed.

We used heart rate as indicator of cognitive effort. For highs there should be little increase in heart rate. 20 lows and 20 highs who passed amnesia item on Waterloo-C were used. Post-experimentally we asked them what they were doing following the suggestion of amnesia, and had judges evaluate the degree of effort.

Frischholz, Edward J. (1993, October). The many roles of context in clinical and experimental hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

1:

There are two potential sources of dissociation: 1. Person Effect - genetic factors, personality types 2. Situation Effect - situations like environmental causes, contextually dependent

Person Effects and Hypnotizability. Morgan (1973 Journal of Abnormal Psychology) Intraclass correlation determines heritability index: 62% of score is accounted for by genetic factors (though the twins were not reared apart, so family influences also were present). Piccione's research demonstrated long-term stability for hypnotizability scores; 25 years' test-retest  $r = .71$ ,  $N = 50$

Situational Effects and Hypnotizability. Norman Katz (1979) varied context before giving the Stanford Form C for a second time (sleep/trance induction, social learning induction, social learning relaxation induction). The latter two inductions showed significant gains of 3.33 and 2.87 on the scale, compared to .80.

Context effects must always be placed in perspective. When reanalyzing Katz with ANOVA, according to the recommendation of Cronbach for change score analysis, situation accounts for 17% of effect while person effect accounts for 49% (See Spiegel & Frischholz, 1992.)

Dixon, Michael; Laurence, Jean-Roch (1992). Two hundred years of hypnosis research: Questions resolved? Questions unanswered!. In Fromm,

Erika; Nash, Michael R. (Ed.), Contemporary hypnosis research (pp. 34-66). New York: Guilford Press.

## NOTES

These notes summarize only that part of the chapter concerning nonvoluntary behavior (pp 38-39; 58-61).

The concept of 'nonvolition' has been and continues to be an important issue in hypnosis research. The concept pertains to the "subjective report that the hypnotic suggestion is enacted without the subject's conscious and willful participation" (p. 38). When hypnosis was attributed to a magnetic fluid, in the days of Mesmer, the issue did not arise (because of course a person would not have control over something that happened to them physically). However, when hypnosis came to be considered a psychological phenomenon, the issue of how a behavior could be the result of motivated action and yet not perceived as being under conscious influence became important. In 1819 Faria wrote that the nonvolition paradox is due to the hypnotized subject's tendency to misattribute the source or reason for one's behaviors; he noted that successful suggestions depended upon the subject falsely attributing to the hypnotist the power to influence them. From that point forward, circular reasoning was used to state that one is hypnotized if one experiences their behavior as nonvolitional, and nonvolitional behavior signifies that a person is hypnotized.

"The observation of the seemingly complete automaticity of response in the highly hypnotizable subject led Liebeault in his 1866 book (followed later on by Bernheim and Liegeois) to describe these subjects as 'puppets' in the hands of the hypnotist. This was a quite unfortunate statement, since it would lead to one of the fiercest legal debates surrounding the use of hypnosis in the last 20 years of the 19th century (Laurence & Perry, 1988). ...

"The most prominent author (if not the only one) who attempted to tackle this difficult question was Pierre Janet, who would make the investigation of automatism the basis of his theory of hypnosis, rather than suggestion or suggestibility. This theoretical orientation is best exemplified by his concept of *desagregation psychologique* seen in some psychopathologies, or the carrying out of a posthypnotic suggestion in the normal individual (Janet, 1889; see also Ellenberger, 1970; Perry & Laurence, 1984; Prevost, 1973). Nonetheless, until the end of the 19th century, and for a good part of the 20th century, these reports of nonvolition were thought to be the end result of some neurological changes happening during hypnosis--an idea that has not been substantiated by contemporary research." (pp 38-39)

Reports of nonvolition are explained as due to dissociation by Hilgard, or as the results of misattributing the origins of behaviors and experiences by Spanos and by Lynn. Neodissociationists like Hilgard regard misattribution to be a cognitive alteration, mainly an internal triggering mechanism, while social psychologists like Spanos and Lynn regard the misattribution to be the results of situational demands and therefore an external triggering mechanism.

"Regardless of one's preferred metaphor, the issue of nonvolitional reports remains at the core of an integrated view of hypnosis and hypnotizability. The question remains as follows: By which mechanisms does this occur, and how can we predict a priori who will report involuntariness and under what circumstances? Whereas dissociationists have emphasized general cognitive mechanisms and de-emphasized situational factors, social-psychological theorists have emphasized situational variables and de-emphasized individual differences. Given the limitations of both approaches, emphasis will have to be placed not on their continued separation but on their integration, as more and more investigations demonstrate that they clearly interact with each other (see, e.g., Nadon, Laurence, & Perry, 1991)." (p. 60)

"At the height of the confrontation between the two French schools, hypnosis found its way into the legal arena. Following a series of criminal cases in which hypnosis had been allegedly involved, the two schools once again found themselves on opposite sides of the fence. For La Salpêtrière, only those who had a propensity toward criminality (and hystericals were prime candidates) could be the victims of hypnosis. For the Nancy school, in highly responsive individuals suggestions could lead to criminal behavior. Unfortunately for the Nancy school, it soon became evident that the concept of suggestion was not sufficient in explaining the questions raised by the courts, and Bernheim was forced to

recognize that in cases where suggestions had played a role, other dispositional and situational factors were probably more important in the genesis of the reprehensible behaviors. His espousing a too extreme position meant that the baby was thrown out with the bathwater. History may indicate that the same fate is now awaiting contemporary theoretical positions that adopt an extreme stance vis-a-vis the phenomenon of hypnosis" (p. 61).

## NOTES

A 1985 article by Balthazar & Woody in Psychological Bulletin is the best I have read on this topic, and on how factor analysis can be used fruitfully.

Many people using the same data sets have arrived at difference conclusions. My results are based on two data sets: Balthazar & Woody's, in which they created a unidimensional scale. (If you factor analyze a simplex matrix you obtain a 3 factor matrix; yet you knew it was unidimensional. They pointed out the 2nd factor correlated with item difficulty, and the 3rd factor had a U-shaped correlation with item difficulty.)

Factor analysis may not be best way to demonstrate unidimensionality.

I decided to use non metric multidimensional analysis to confirm unidimension. By this, Form A appears to be multidimensional. The same holds true for Stanford Form C scale.

Interpretability of the different dimensions? I agree with Dr. Stone: unidimensions are better for interpreting tests. But you should start out by constructing one in the first place.

I argue that Form C is unidimensional, because the items were selected by using item/full score correlations, hence a first component was built into it. But what does the scale measure? The only way to know is to correlate it with external measures, like Woody does. There are no studies using factor analysis showing that different factors on hypnotizability tests have different correlations with external measures (e.g. Factor 1 doesn't correlate differently with Absorption than Factor 3).

We might better start with a theory if we are going to construct new hypnotizability scales. Don't just use item total correlations. It would be better to find items representing different dimensions, scale the items, then correlate them with different external referents.

Then when we do collect data, make sure the items are unidimensional representations.

Third, we should appropriately validate these dimensions.

Garssen, Bert; de Ruiter, Corine; Van Dyck, Richard (1992). Breathing retraining: A rational placebo?. Clinical Psychology Review, 12, 141-153.

Breathing retraining of patients with Hyperventilation Syndrome (HVS) and/or panic disorder is discussed to evaluate its clinical effectiveness and to examine the mechanism that mediates its effect. In relation to this theoretical question, the validity of HVS as a scientific model is discussed and is deemed insufficient. It is concluded that breathing retraining and related procedures are therapeutically effective, but probably due to principles other than originally proposed, namely decreasing the tendency to hyperventilate. An alternative principle is the induction of a relaxation response, presenting a credible explanation for the threatening symptoms, giving a distracting task to practice when panic may occur, and promoting a feeling of control.

## NOTES

Goal of treatment is to (1) reduce respiratory rate, and (2) cognitive reattribution of physical symptoms to hyperventilation instead of other more catastrophic causes. Reviews a number of studies, mostly small sample, including panic disorder studies, and concludes that the majority point to a

therapeutic effect of breathing retraining and cognitive reattribution of physical symptoms to hyperventilation for patients suffering HVS and the closely related panic disorder with or without agoraphobia. However, the specificity of these techniques for HVS is questionable. Vlaender-van der Giessen (1986) found relaxation training just as effective as breathing retraining; and Hibbert & Chan (1989) found breathing retraining equally effective as a placebo treatment, and not more effective with patients who had recognized symptoms at a hyperventilation provocation test than with those who had not.

Hajek, P.; Jakoubek, B.; Kyhos, K.; Radio, T. (1992). Increase in cutaneous temperature induced by hypnotic suggestion of pain. Perceptual and Motor Skills, 74, 737-738.

Eight patients with atopic eczema and six healthy subjects were given hypnotic suggestion to feel pain in the upper part of the back and in one case on the palm. An average local increase in skin temperature of 0.6 degrees centigrade (detected by thermovision) occurred under this condition. For some patients cutaneous pain threshold was increased before the experiment by means of repetitive hypnotic suggestion of analgesia. These subjects reported feeling no pain subjectively, but the local change in skin temperature was equal in both cases. The results suggest a central mechanism induced by measuring changes in pain threshold in the skin, which changes are independent of local changes in blood flow. Local pain in the middle of the upper part of the back, and in one subject for comparative purposes in the region of the right palm, was induced during a single hypnotic session by specific suggestion which emphasized a subjective feeling of local pain lasting for 6 minutes. In four of the eczema patients long-lasting cutaneous analgesia was induced before this experiment by a different suggestion which stressed the impossibility of conducting pain from the skin to the brain and which was repeated in ten consecutive hypnotic sessions. The spatial thermal reaction of the skin surface was monitored, with consecutive recordings taken at 20-sec. intervals before and after finishing the hypnotic suggestion of pain. There was a gradual increase in temperature (1.08 degrees Fahrenheit). In the four eczema patients with long-lasting cutaneous analgesia treated equally, the thermal reaction of the skin was similar to that described above although no subjective feeling of pain was reported. These subjects reported feeling only that their skin was getting warmer at the specified place.

Holroyd, Jean (1992). Hypnosis as a methodology in psychological research. In Contemporary hypnosis research (pp. 201-226). New York: Guilford Press.

## NOTES

This chapter deals with how the changes brought about by hypnosis (in cognition, behavior, motivation, etc.) may be used in research in other areas of psychology. "The distinction between experimental effects attributable to a personality trait (i.e. hypnotizability), hypnosis context (i.e. an induction), and interaction between the two is particularly important in using hypnosis as a research strategy.

The author discusses suggestibility, imagery enhancement, and changes in the mind-body relationship (immunology, pain, cognitive neuropsychology, attention, learning and memory, and awareness) as they might be employed in social psychology or psychophysiology research. She reviews problems inherent in using hypnosis as part of the research methodology, while noting that hypnosis nevertheless offers new information when introduced into traditional content areas. "For example, in cognitive psychology it has re-introduced the importance of studying experiential aspects of cognition, i.e. I think, I remember, or self reference (Kihlstrom, 1987)" (p. 223).

She concludes, "Hypnosis as a research method will continue to benefit from contributions of radically different theoretical views of hypnotic phenomena. Social- cognitive psychologists have contributed significantly toward unifying the fields of hypnosis research and general experimental psychology. At

the same time, advances in neurophysiology and psychosomatic medicine employing hypnosis indicate that there is a role for hypnosis as a research strategy, solely because of its altered-state characteristics. If theoretical physics can reconcile both wave and particle theories of light, it is conceivable that psychology can accommodate both behavioral and state theories of hypnosis" (p. 224).

Isenberg, S. A.; Lehrer, P. M.; Hochron, S. (1992). The effects of suggestion on airways of asthmatic subjects breathing room air as a suggested bronchoconstrictor and bronchodilator. Journal of Psychosomatic Research, 36, 769-776.

Thirty-three asthmatic subjects were told they were receiving, alternately, an inhaled bronchoconstrictor and inhaled bronchodilator, although they actually were only breathing room air. No subjects showed suggestion-produced effects on FEV1, although two (of the 19 on whom FEF50 was measured) showed effects of greater than 20% on measures of maximal midexpiratory flow. The incidence of the effect is smaller than reported previously, possibly because some subjects in previous studies inhaled saline, a mild bronchoconstrictor, and reversal of effect was not required for classification as a reactor. Higher percentages of subjects in this study showed decreased MMEF in response to the "bronchoconstrictor", but this appeared to reflect fatigue rather than suggestion effects. However, the fact that the effect occurred in a relatively non-effort-dependent measure suggests that real changes occurred in bronchial caliber, not just in test effort. Suggestion had a significant effect on perception of bronchial changes, but the correlation between actual and perceived changes was minimal. There was an increase in FVC prior to administration of the "bronchoconstrictor", possibly reflecting a preparatory response to the expected drug. Correlations among self-report variables suggested the existence of three personality dimensions among our population related to suggestion and asthma: cognitive susceptibility to suggestion of bronchial change; feeling of physical vulnerability; and anxiety. However, there was no significant relationship between airway response to suggested changes and hypnotic susceptibility, as measured by the Harvard Group Scale of Hypnotic Susceptibility

Jacoby, Larry L.; Lindsay, D. Stephen; Toth, Jeffrey P. (1992). Unconscious influences revealed: Attention, awareness, and control. American Psychologist, 47, 802-809.

Recent findings of dissociations between direct and indirect tests of memory and perception have renewed enthusiasm for the study of unconscious processing. The authors argue that such findings are heir to the same problems of interpretation as are earlier evidence of unconscious influences--namely, one cannot eliminate the possibility that conscious processes contaminated the measure of unconscious processes. To solve this problem, the authors define unconscious influences in terms of lack of conscious control and then describe a process dissociation procedure that yields separate quantitative estimates of the concurrent contributions of unconscious and consciously controlled processing to task performance. This technique allows one to go beyond demonstrating the existence of unconscious processes to examine factors that determine their magnitude.

1991

Block, Robert I.; Ghoneim, M. M.; Sum Ping, S. T.; Ali, M. A. (1991). Efficacy of therapeutic suggestions for improved postoperative recovery during general anesthesia. Anesthesiology, 75, 746-755.

There have been claims that the postoperative course of patients may be improved by presentation during general anesthesia of therapeutic suggestions which predict a rapid and comfortable postoperative recovery. This study evaluated the effectiveness of such therapeutic suggestions under

double-blind and randomized conditions. A tape recording predicting a smooth recovery during a short postoperative stay without pain, nausea, or vomiting was played during anesthesia to about half the patients (N = 109), while the remaining, control patients were played a blank tape instead (N = 100). The patients were primarily undergoing operations on the fallopian tubes, total abdominal hysterectomy, vertical banding gastroplasty, cholecystectomy, and ovarian cystectomy or myomectomy. The anesthesia methods consisted of either isoflurane with 70% nitrous oxide in oxygen to produce end-tidal concentrations of 1.0, 1.3, or 1.5 MAC; or 70% nitrous oxide in oxygen combined with high or low doses of opioids. Assessments of the efficacy of the therapeutic suggestions in the recovery room and throughout the postoperative hospital stay included: the frequency of administration of analgesic and antiemetic drugs; opioid doses; the incidence of fever; nausea, retching, and vomiting; other gastrointestinal and urinary symptoms; ratings of pain; ratings of anxiety; global ratings of the patients' physical and psychological recoveries by the patients and their nurses; and length of postoperative hospital stay. There were no meaningful, significant differences in postoperative recovery of patients receiving therapeutic suggestions and controls. These negative results were not likely to be due to insensitivity of the assessments of recovery, as they showed meaningful interrelations among themselves and numerous differences in recovery following different types of surgery. Widespread utilization of therapeutic suggestions as a routine operating room procedure seems premature in the absence of adequate replication of previously published positive studies. (Key words: Anesthesia, depth: Awareness, Memory, Recall, Learning.)

## NOTES

Patients ages 19-55 were accepted into the study and they were paid for participation. (Older patients were excluded to guard against memory or hearing problems.) Other criteria for exclusion were: ASA physical status 4 or 5 indicating significant systemic disease, visual or hearing problems, middle ear disease (because it increases probability of nausea and vomiting), if their condition might require heavy sedation, if they were currently taking medication that interferes with memory (e.g. benzodiazepines, if there were intolerance to opioids, or if there were a likelihood of using postoperative pain treatment other than opioids.

The Spielberger State-Trait Anxiety Inventory was administered before surgery. Either suggestions (lasting 6 minutes) or a blank tape were played through headphones, starting 5 minutes after the surgical incision. The tape was played once for the first 59 patients, continuously for the remaining 150 patients. The first 139 patients received additional verbal materials on the tape, for memory tests to test possibility of learning under anesthesia. Operating room sounds were recorded by a tape recorder near the patient's head, throughout period of unconsciousness (except when tape was being played).

After the first 25% of cases, the team decided that lack of effect on therapeutic suggestions attributable to type of anesthesia did not warrant restriction to a single anesthetic method; also, multiple presentations of the suggestions on tape did not show an effect different from a single presentation.

After the patient regained consciousness and was reoriented, pain, nausea, retching, and vomiting were assessed every 30 minutes. Pain was rated orally on a scale from 1 to 10 in the recovery room, then on visual analogue scales every 2 hours on the day of surgery and the second day, and every 4 hours on subsequent hospital days during waking hours. Variables that were rated by staff every 24 hours included: opioids, other analgesics, antiemetics, nausea, vomiting, retching, presence or absence of nasogastric tube, passage of flatus, bowel movement, fluid intake, solids intake, urination. Temperature was recorded every 4 hours for the first 2 days after surgery, and after that less often. The anxiety measures were repeated on Day 3 postsurgery, as well as self ratings and nurse ratings on physical and psychological recovery. Staff recorded length of postoperative hospital stay and reasons for any delay of discharge. Separate analyses were performed for patients receiving opioids via patient-controlled analgesia (52%) vs traditional administration (48%), but no differences were found for effects of therapeutic suggestions except on postoperative Day 8.

"The inability to detect beneficial effects of therapeutic suggestions probably was not due to insensitivity of the measures of recovery. These measures were sensitive enough to show numerous significant differences in recovery after different types of surgery" (p. 751). The authors supported their contention that the measures were sufficiently sensitive by demonstrating meaningful correlations among the measures themselves; and by demonstrating adequate statistical power for detecting the effects of theoretical interest--at least 1 day in postoperative hospital stay or one half day in fever.

**Discussion:** The authors note that a recent investigation that found positive results in a double-blind, randomized design with 39 hysterectomy patients (Evans & Richardson, 1988. Improved recovery and reduced postoperative stay after therapeutic suggestions during general anaesthesia. *Lancet*, 2:491-493) may not have controlled for variables such as presence of malignancy, physical status of patients before surgery, or ethnicity. Authors note that Evans and Richardson observed shorter periods of pyrexia despite there being no relevant suggestions, but no differences in pain intensity, nausea, vomiting, or urinary difficulties despite there being suggestions relating to those symptoms. There also were no differences in mood and anxiety test scores postoperatively for the experimental and control groups.

The authors note that McLintock, Aitken, Downie, & Kenny (Postoperative analgesic requirements in patients exposed to positive intraoperative suggestions. *Br M J* 301:788-790. 1990) reported a 23% reduction in opioids by patients receiving suggestions, but no reduction in pain, nausea, or vomiting. They contrast the present study with these earlier studies that had obtained positive results.

"We studied patients who had more than one type of surgery to obtain a large sample size and to assess the possibility that beneficial effects of therapeutic suggestions would be restricted to certain types of operations. Had this been the case, interactions of therapeutic suggestions with type of surgery would have been significant in the overall analyses, and follow-up analyses would have indicated that they were attributable to beneficial effects of therapeutic suggestions for certain surgeries. This did not occur. The two types of surgeries involving the largest numbers of patients seemed particularly promising for demonstrating beneficial effects. It has been reported that therapeutic suggestions presented during anesthesia are likely to be less successful with major and extensive surgery. Certainly, surgery on the fallopian tubes and gastric stapling did not involve a great deal of tissue trauma and blood loss. Patients were motivated to have the surgery and to recover quickly; particularly motivated were those having operations on the fallopian tubes, who were very eager to become pregnant, and those having vertical banding gastroplasties, who wanted desperately to lose weight" (pp. 753-754).

"In practice, we observed no beneficial effects of therapeutic suggestions, and there was no hint that anesthesia methods influenced the efficacy of the therapeutic suggestions. Interestingly, anesthetic methods also did not influence learning under anesthesia in the implicit memory tests we have used previously. Patients anesthetized with nitrous oxide and opioids did not differ from those anesthetized only with inhalational agents. In general, implicit or unconscious memory occurs in patients regardless of anesthesia methods or dosages of drugs" (p. 754).

"The few significant effects of therapeutic suggestions in our study did not point toward a beneficial influence of these suggestions. We found, in fact, an increased frequency of retching (but not nausea or vomiting) in the experimental group. The multiple variables examined in this study increased the likelihood of significant differences arising by chance, such that the null hypothesis was rejected when it should have been accepted. This is the way we interpret the effect on retching---i.e., as a type I error. We used in our therapeutic suggestions one negative or exclusionary sentence, 'You won't feel nauseous or have to vomit', among several positive or affirmative statements, e.g., 'You will enjoy eating, drinking...You will swallow to clear your throat and everything will go one way, straight down. . . The food will taste good....Your stomach will feel fine.' We do not think that the negative sentence led to paradoxical results. Evans and Richardson (personal communication) used in their therapeutic

suggestions a negative sentence ('You will not feel sick'), which they repeated, yet the reported incidence of nausea and vomiting did not differ between the experimental and control groups" (p. 754).

Dennett, Daniel C. (1991). Consciousness explained. Boston: Little, Brown & Co..

## NOTES

Material in this book is relevant to discussions about 'nonvoluntary' behavior and (un)conscious experiencing. It combines information from cognitive neuroscience with the philosophy of mind. The author presents a view that consciousness (the 'mind') is the consequence of the brain's activities which give rise to illusions about their own properties. He presents the Multiple Drafts model of consciousness, which reformulates the concept of a 'stream of consciousness.' This provides a basis for consideration of concepts central to cognitive neuroscience and phenomena associated with hypnosis, e.g. experiential states and the nature of the self.

The author gives various examples of phenomenology and notes that although these examples are familiar to us, they are totally inaccessible to materialistic science; e.g. the way the sunset looks to someone. He treats people's descriptions of what they experience as a record of speech acts. Thus, observing and interpreting speech acts, inferring from them the speaker's inner states, is like a reader who is interpreting a work of fiction. He gives as examples of how one can scientifically study what does not 'exist' (a) literary theorists who describe fictional entities, (b) anthropologists who study cultural artifacts like gods and witches, and (c) physicists who study a center of gravity.

In Dennett's theory, multitrack processes of interpretation of sensory inputs and elaboration of those inputs amounts to a kind of 'editorial revision' by the brain. For example in the phi phenomenon a red dot is displayed, followed by a green dot in a different location; the first spot seems to begin moving and then change color in the middle of its illusory passage toward the second location. He points out that awareness of the change in color must occur after seeing the green spot, but one consciously experiences a single spot first red, then red-turning-to-green, finally green. In an example that relates directly to the words used for his theory, he cites contemporary publishing practices, in which several different drafts of an article are in circulation even while the author is revising it. Deciding on some specific moment of brain processing as the moment of consciousness is arbitrary, according to his Multiple Drafts model.

"Visual stimuli evoke trains of events in the cortex that gradually yield discriminations of greater and greater specificity. At different times and different places, various 'decisions' or 'judgments' are made; more literally, parts of the brain are caused to go into states that discriminate different features, e.g., first mere onset of stimulus, then location, then shape, later color (in a different pathway), later still (apparent) motion, and eventually object recognition. These localized discriminative states transmit effects to other places, contributing to further discriminations, and so forth. The natural but naive question to ask is: 'Where does it all come together'? The answer is: Nowhere. Some of these distributed contentful states soon die out, leaving no further traces. Others do leave traces, on subsequent verbal reports of experience and memory, on 'semantic readiness' and other varieties of perceptual set, on emotional state, behavioral proclivities, and so forth. Some of these effects--for instance, influences on subsequent verbal reports--are at least symptomatic of consciousness. But there is no one place in the brain through which all these causal trains must pass in order to deposit their content 'in consciousness'" (pp. 134-135).

The author describes the evolution of the brain, along Darwinian lines, and introduces the idea of culture as a repository and transmission medium for innovations (including innovations of consciousness) as a medium of evolution. Through learning, we humans evolve an American or a Japanese brain. Once we have evolved the 'entrance and exit pathways' for language, they become 'parasitized' by memes (entities that have evolved to thrive in such a niche).

Richard Dawkins coined the term memes to describe the smallest idea elements that replicate themselves reliably (e.g. wheel, alphabet, wearing clothes, right triangle). "The transformation of a human brain by infestations of memes is a major alteration in the competence of that organ" (p. 209). Dennett discusses the similarities and dissimilarities of brains and computers. He suggests that human minds are like serial virtual machines implemented on parallel processing hardware. The stream of consciousness results from our rehearsal of brief experiences, to commit them to memory; language then permits us to describe to ourselves the process of thinking which leads to judgement and action. The author's discussion of how a verbal expression evolves and becomes manifest is related to how so-called intentional action occurs. [This relates to discussions of nonvoluntary actions in hypnosis.] We assume that because our actions make sense, they are the product of serial reasoning. However, there are multiple channels "in which specialist circuits try, in parallel pandemoniums, to do their various things ... (pp. 253- 254). Bernard Baars has suggested "that consciousness is accomplished by a 'distributed society of specialists that is equipped with a working memory, called a global workspace, whose contents can be broadcast to the system as a whole (p. 42)'" (p. 257). Dennett states that there is no line dividing the events that are definitely in consciousness from those that are outside consciousness. He urges scientists to forgo the concept of the 'inner observer' implied by Cartesian materialism.

Examples of perception that is unaccompanied by consciousness include blindsight (in which the subject does better than chance on visual tests but denies consciousness, and the denials are given credence by neurological evidence of brain damage) and hysterical blindness, which is given less credence because subjects often use the visually provided information in ways blindsight Ss do not. Other behaviors not controlled by conscious thought include blinking when things approach the eye, walking without falling over, regulating our body temperature, adjusting our metabolism, etc. "If I am trying to see a bird that I hear, and stare at the spot but do not distinguish the bird from its background, can I say that it is present in the background of my (visual) consciousness or not?" (p. 336).

The author maintains that if an event doesn't linger and the person is unable to identify and reidentify the effect, it cannot be reported. But such reportability can be improved, as with training the palate of wine tasters. Often, however, we continue disregarding stimuli that impinge on us. There are minor oversights, such as our 'blind spots' or proof reading errors, and major oversights such as a brain-damaged patient's hemi-neglect. In the Multiple Drafts theory, the Observer is replaced by 'coalitions of specialists' that are distributed around in the brain, distributed in both time and space.

Though discrimination or discernment happens, there is no one Discerner doing the work. However, Dennett takes the middle ground on the question of whether a self exists: it is simply a creation like the nest of the Bower bird, or the organized colony of termite ants. "So wonderful is the organization of a termite colony that it seemed to some observers that each termite colony had to have a soul (Marais, 1937). We now understand that its organization is simply the result of a million semi-independent little agents, each itself an automaton, doing its thing. So wonderful is the organization of a human self that to many observers it has seemed that each human being had a soul, too: a benevolent Dictator ruling from Headquarters" (p. 416). The sense of self is a creation, like a physicist's center of gravity.

Thus, multiple personality disorder is viewed as a self that has gaps; and our sense of self might include different aspects from one year to the other. Hence, "selves are not independently existing soul-pearls, but artifacts of the social processes that create us, and, like other such artifacts, subject to sudden shifts in status. The only 'momentum' that accrues to the trajectory of a self, or a club, is the stability imparted to it by the web of beliefs that constitute it, and when those beliefs lapse, it lapses, either permanently or temporarily" (p. 423).

Finally, the author has an extensive discussion of the concepts of 'qualia' and of 'epiphenomena' and seems to have little use for either term in trying to understand Mind.

Hasher, L.; Stoltzfus, E. R.; Zacks, R. T.; Rypma, B. (1991). Age and inhibition. Journal of Experimental Psychology: Learning, Memory, and Cognition, 17 (1), 163-169.

Two experiments assess adult age differences in the extent of inhibition or negative priming generated in a selective-attention task. Younger adults consistently demonstrated negative priming effects; they were slower to name a letter on a current trial that had served as a distractor on the previous trial relative to one that had not occurred on the previous trial. Whether or not inhibition dissipated when the response to stimulus interval was lengthened from 500 ms in Experiment 1 to 1,200 ms in Experiment 2 depended upon whether young subjects were aware of the patterns across trial types. Older adults did not show inhibition at either interval. The age effects are interpreted within the Hasher-Zacks (1988) framework, which proposes inhibition as a central mechanism determining the contents of working memory and consequently influencing a wide array of cognitive functions.

Arendt-Nielsen, Lars; Zachariae, Robert; Bjerring, Peter (1990). Quantitative evaluation of hypnotically suggested hyperaesthesia and analgesia by painful laser stimulation. Pain, 42, 243-251.

## NOTES

Sensory and pain thresholds to laser stimulation were determined, and the laser-pain evoked brain potentials were measured for 8 highly hypnotizable (Harvard Scores 10-11) student volunteers in 3 conditions: (1) waking, (2) suggestion of hyperaesthesia during hypnosis, (3) suggestion of analgesia during hypnosis.

The investigators used a laser beam 3 mm in diameter, with a 200 msec stimulus duration; the same area (but different points within the area) was used for consecutive stimulations. Ss were otherwise maintained in low stimulus conditions so they would not have visual or auditory cues about laser beam onset; they wore goggles, had eyes shut, and had earphones on. Sensory threshold was defined as warmth; pain threshold was defined as a distinct sharp pin prick.

The laser intensity used for stimulation corresponded to strong pain. Interstimulus intervals averaged 15 sec (but were randomly varied between 10-20 sec). Sensory and pain thresholds as well as two evoked potential measurements were taken during waking, hypnotized hyperaesthesia, and hypnotized analgesia conditions in a single 1 1/2 hour session.

The evoked potential component of interest was the negative complex N1 with latency of 300 msec; amplitude (P1=N1-P2) and latency of this complex (N1) were measured. EEG epochs contaminated by eye movement were omitted from analysis.

The standardized induction and deepening of hypnosis required 15-20 minutes; then the suggestion was given that Ss could alter their perception of stimuli such as pain. Hyperaesthesia suggestions were to imagine the right hand was in very hot water, then taken out but still very red, hot, sensitive so that even the vaguest stimulus would be detectable and unpleasant. They were told that they would receive a series of painful but tolerable stimuli, and to raise the left index finger if they could just perceive a laser pulse (sensory threshold), and again if they felt pricking pain (pain threshold).

Suggestions for analgesia were to imagine that their right hand was placed on their chest, and that their 'former right hand' was no longer their own but was made of some heavy and completely insensitive material like wood or stone. Sensory and pain threshold measures were then taken. During the evoked potential measurement period they received continuous suggestions of analgesia. They also were told to relax and imagine they were in a pleasant place, ignoring everything except the pleasant, relaxed feelings and imagining pleasant sights, sounds, feelings and the imagined place. They were told that though they would receive stimuli, they probably would be able to ignore the stimuli completely.

Results were as follows.

1. In the hypnotic hyperaesthesia condition, sensory and pain thresholds decreased significantly by 47% and 48%, respectively. Three Ss reacted to laser intensities far below what normally can be

perceived in the waking state. [The authors ran a separate small control experiment to make sure that the Subjects were not using any other cues, but mention the possibility of light-sensitive skin reacting to the blue laser light, creating evoked potentials.]

2. In the hypnotic analgesia condition, sensory and pain thresholds increased by 316% and 190%, respectively. 7 of 8 Ss did not even respond to pain threshold when the laser intensity was increased to the noxious level of 3W, which is the level at which tissue damage can occur.

3. Pain-related evoked potentials. Amplitude of the first pain-related potential was increased significantly by 14% in the hyperaesthesia condition and reduced significantly by 31% in the analgesia condition. Changes in the evoked potentials were considered minor however compared to those observed for thresholds, which are subjective response measures. Even in Subjects who reported complete analgesia, the experimenters observed the laser pain evoked responses. There were no differences in latencies of the first pain-related potentials for the three conditions (indicating that peripheral and central afferent conduction velocities were the same).

Discussion. "There has been some dispute concerning the experimental design and the reliability of the data obtained in studies dealing with hypnotic suggested analgesia [Spanos & Chaves, 1970]. In our design 2 'opposite' conditions were induced, and the 2 inductions gave 'opposite' results.

"The experience of pain can be significantly altered by suggestions of analgesia, which is in accordance with a number of other studies (for review see [Barber & Adrian, 1982; Hilgard & Hilgard, 1975]). The finding that suggestions of hyperaesthesia can decrease the sensory and pain thresholds and increase the amplitude of the pain evoked potential is a new observation. Since synchronized auditory and visual stimuli from the laser were blocked, and the stimulus was given at random intervals, the changes might be induced by the hypnotic suggestions" (p. 247).

The authors discuss their results in terms of (1) four pain modulation systems (neural/opiate, hormonal/opiate, neural/non-opiate, and hormonal/non-opiate) and (2) focusing and defocusing attention. Because in their pilot study it was necessary to give suggestions continually in order to affect the laser evoked potentials, they conclude that endogenous substances or hormonal/non-opiates would play a minor role, if any, in hypnotic analgesia. (Price and Barber [25] had also found it important to give suggestions continuously.)

On the other hand, "event-related potentials [7, 26] and pain-related potentials have, previously, been shown to be sensitive to focused and de-focused attention. Recently, Miltner et al. [23] showed the influence of attention on the late pain-related component of potentials, evoked by painful intracutaneous electrical stimulation. The degree to which the subject paid attention to the painful stimulus had a powerful effect on the pain-related complex. When subjects ignored the pain, it was still possible to record the pain-related complex although all the subjects consistently reported less or no pain. In wakeful subjects where cutaneous pain was abolished by lignocaine infiltration, the pain-related evoked potentials were abolished [4]. In our study, we could also record evoked potentials although the subject subjectively did not feel pain. The reason might be that the S acted as if there was full analgesia to the stimuli, in order to satisfy the hypnotist. During suggested hyperaesthesia the thresholds declined below what normally could be perceived in the wakeful state. The volunteers could, therefore, not act hypersensitive, so something did happen.

"The discrepancy in subjective and objective responses might, however, be useful when investigating levels of the neuroaxis at which hypnosis might work" (pp. 248-249).

The authors note that this laser induced pain and the tooth pulp stimulation pain of Mayer & Barber both use the A-delta fibers. Barber & Mayer found it impossible to elicit pain within the output range of the stimulator (up to 150 microA) and reached maximal intensity for all volunteers during suggested analgesia. Using cutaneous laser stimulation the authors found that the skin damage level (3W) could be reached in 7 of 8 volunteers without any reaction of pain.

During the hyperaesthesia condition the sensory threshold was sometimes lower than can be detected in the waking state. Although some researchers have suggested that red light from a helium-neon laser

might activate cutaneous photosensitive receptors and thereby elicit brain potentials, the authors were unable to elicit potentials in waking Subjects using their blue and green argon laser light with below sensory threshold intensity.

The authors also note that previous attempts to use physiological correlates of pain such as heart rate, blood pressure, respiration, and galvanic skin response have yielded confusing results. The physiological indicators are present even when Subjects report analgesia, leading some investigators to conclude that the subjective reports are due to illusion [Sutcliffe, 1961], compliance [Wagstaff, 1986], or a placebo induced by the hypnosis context [Wagstaff, 1986]. "These confusing results lead to the conclusion that both the traditional methods used for induction of pain and the monitored physiological responses have been unsatisfactory. The present study has sought to eliminate some of the methodological difficulties by (1) using brief well-defined argon laser stimuli which in awake volunteers induce very stable perceptions between trials [Arendt-Nielsen & Bjerring, 1988], and (2) recording psychophysical thresholds and objective parameters quantitatively related to the intensity of the pain perceived (1, 3)" (p. 249).

1990

Bartis, Scott P.; Zamansky, Harold S. (1990). Cognitive strategies in hypnosis: Toward resolving the hypnotic conflict. International Journal of Clinical and Experimental Hypnosis, 38, 168-182.

Two experiments were carried out to assess the relative contributions of dissociation and absorption as cognitive strategies employed by high and low hypnotizability Ss in responding successfully to hypnotic suggestions. Of special interest was the manner in which Ss deal with conflicting information typically inherent in hypnotic suggestions. In the first experiment, Ss rated their attentional focus and the involuntariness of their experience after responding to a number of hypnotic suggestions administered in the usual manner. In the second experiment, the level of conflict was varied by instructing some Ss to imagine a circumstance that was congruent and other Ss to imagine a circumstance that was incongruent with the suggested behavioral response. The results of the 2 experiments were consistent in suggesting that, depending upon the nature of the hypnotic suggestion, high hypnotizability Ss are able to employ dissociation or absorption in order to respond successfully. Low hypnotizability Ss, on the other hand, seem to be relatively ineffective dissociators. When the structure of the hypnotic suggestion precludes the use of absorption, the performance of low hypnotizables deteriorates.

Edmonston, William E., Jr.; Moscovitz, Harry C. (1990). Hypnosis and lateralized brain functions. International Journal of Clinical and Experimental Hypnosis, 38, 70-84.

Bilateral EEG measures were obtained on 16 high hypnotizable Ss (scores of >8 on the Harvard Group Scale of Hypnotic Susceptibility, Form A, Shor & E. Orne, 1962), while performing hemisphere-specific tasks during hypnosis and a no-hypnosis control condition. Conditions and tasks were presented in counterbalanced order, and Ss served as their own controls. The data call into question the right hemisphere activation interpretation of lateralized brain function during hypnosis; rather, the data suggest a lack of task appropriate activity during hypnosis. The failure to attend to baseline activity measurements and the use of ratios to evaluate interhemispheric lateralization may contribute to potential misinterpretations of data. It is critical that activity changes of the separate hemispheres be taken into account in the interpretative process.

Hajek, P.; Jakoubek, B.; Radil, T. (1990). Gradual increase in cutaneous threshold induced by repeated hypnosis of healthy individuals and patients with atopic eczema. Perceptual and Motor Skills, 70, 549-550.

## NOTES

Cutaneous pain threshold was measured in "time in seconds from onset of heat source of defined size, distance from skin, and temperature, to subjective threshold percept of pain" (p. 549). Used two symmetrical locations on both forearms, at healthy areas of the skin. Ten hypnotic sessions were induced in each S three times weekly, each lasting one hour.

Suggestions were the following type: "The "conduction of switch to the brain is interrupted." Your "immunologic system will digest the damaged skin cells like a shark."

Subjects were 14 healthy subjects and 13 patients with atopic eczema treated for years with the usual medications, unsuccessfully or with complications.

There was gradual increase in cutaneous pain threshold across the 10 sessions, especially for the patient group. Control experiments with repeated threshold measurements in repeated sessions without hypnosis showed no changes.

"Time of increases in cutaneous pain threshold was associated with improvement of atopic eczema. Both effects correlated significantly ( $r = 0.8$ ) with hypnotizability as measured by the Stanford scale" (pp. 549-550).

"In 9 patients without further hypnotic sessions a slow spontaneous decay of the cutaneous pain threshold was observed during a 17-mo. period. Special experiments performed with six repeatedly hypnotized healthy subjects showing increased thresholds did prove, however, that the cumulative analgesic effect could be reduced to control values immediately by using the hypnotic suggestion that the 'skin sensitivity returns to normal values.'

"These results suggest a close association between hypnosis and activation and/or deactivation of endogenous analgesic systems (irrespective whether they are of opioid or nonopioid nature)" (p.550)

1989

Brentar, J.; Lynn, Steven J. (1989). 'Negative' effects and hypnosis: A critical examination. British Journal of Experimental and Clinical Hypnosis, 6, 75-84.

Reviews evidence concerning if hypnosis is responsible for unwanted or negative posthypnotic effects, concluding that support for this hypothesis is lacking. Many such investigations are either anecdotal reports or are marred by methodological flaws that render the interpretation of posthypnotic experiences problematical. Controlled research has not provided support for the hypothesis that hypnosis per se is responsible for certain subjective changes which accompany it, or that hypnosis is more stressful or anxiety provoking than other common experiences encountered by subjects. Although a small percentage of subjects appear to experience posthypnotic reactions, they are typically fleeting, and the link between hypnotic procedures and negative effects has not been adequately substantiated. Indeed, routine hypnosis is typically harmless and is perceived by many subjects as a pleasant, positive experience.

Buss, A. H. (1989). Personality as traits. American Psychologist, 44, 1378-1388.

Personality traits have been challenged as unimportant determinants of behavior, but evidence suggests that traits may carry as much variance as experimental manipulations. Asking whether traits or manipulations control more variance is useless because researchers can plan paradigms that favor one or the other. When traits and manipulations complement each other there are several major kinds of interaction. The trait-manipulation dichotomy is analogous to the person-environment dichotomy, and both are related to active versus passive models of behavior. Trait variance is increased by aggregating across responses, situations, and time. Underlying aggregation are the issues of units and classes of behavior. Individual responses are on a continuum of breadth that extends successively upward to response classes, personality traits, and higher order traits. Broad and narrow traits each

have advantages and disadvantages. Recent research has led to novel personality traits and to knowledge about the origin and maintenance of traits. If there is to be a specialty called personality, its unique and therefore defining characteristic is traits.

Friswell, Rena; McConkey, Kevin M. (1989). Hypnotically induced mood. Cognition and Emotion, 3 (1), 1-26.

This article addresses theoretical and methodological issues that are central to an understanding of hypnotically induced mood. Initially, the hypnotic procedures that are typically used to induce moods are examined. Then the empirical research that has employed hypnotic moods is reviewed; specifically, the impact of hypnotic moods on physiological responses, behavioural performance, perceptual and cognitive responses, and personality, and clinical processes is examined. Finally, major theoretical and methodological issues are highlighted, and the research directions that will lead to a greater understanding of hypnotic mood are specified.

1988

Van der Does, A. J.; Van Dyck, R.; Spijker, R. E. (1988). Hypnosis and pain in patients with severe burns: A pilot study. Burns Including Thermal Injuries, 14, 399-404.

Presents a pilot study on the effectiveness of hypnosis in the control of pain during dressing changes of burn patients. Eight patients were treated, and all evaluated the interventions as beneficial. The treatment of four patients was more closely analyzed by obtaining pain and anxiety ratings daily. Results show a 50%-64% decrease in reported pain level for three patients and a 52% increase of pain for one patient. The mean decrease for these four patients was 30% (for overall as well as worst pain during dressing changes). A 30% reduction of anxiety level and a modest reduction of medication use were achieved concurrently. It is concluded that hypnosis is of potential value during dressing changes of burn patients. Comparison of global evaluations and daily pain ratings shows that systematic research in some cases leads to conclusions opposite from clinical observations. Follow-up recommendations for future studies are given.

Houle, M.; McGrath, Patricia Anne; Moran, Greg; Garrett, Owen J. (1988). The efficacy of hypnosis- and relaxation-induced analgesia on two dimensions of pain for cold pressor and electrical tooth pulp stimulation. Pain, 33 (2), 241-251.

This study evaluated hypnosis- and relaxation-induced suggestions for analgesia for reducing strength and unpleasantness of pain (noxious tooth pulp stimulation; cold pressor stimulation). The Tellegen Absorption Questionnaire was used to assess hypnotic susceptibility for 28 subjects in order to match treatment groups according to sex and susceptibility scores. Tooth pulp stimulation consisted of a 1 sec train of 1 msec pulses at a frequency of 100 Hz, applied at 20 sec intervals to the central incisor. Six stimuli, selected between S's pain and tolerance thresholds, were presented 3 times each in random order. Cold pressor stimulation consisted of forearm immersion in a circulating water bath maintained at 0-1 degrees C. Subjects made threshold determinations of pain and tolerance and used Visual Analogue Scales to rate the strength and the unpleasantness of both noxious stimuli before and after receiving either hypnosis- or relaxation-induced analgesia.

There were no significant differences between hypnosis- and relaxation-induced interventions. However the percent reduction in both strength and unpleasantness varied as a function of type of pain. Both hypnosis and relaxation significantly reduced the strength and unpleasantness of tooth pulp stimulation, but only the unpleasantness of cold pressor pain. The pain reductions were not correlated with subjects' hypnotic susceptibility levels.

The results indicate that the extent and the quality of the analgesia produced by these cognitive-based therapies vary not only according to subjects' characteristics and the efficacy of the intervention, but also according to the nature of the noxious stimuli. Tooth pulp and cold pressor stimulation represent qualitatively different stimuli with respect to both the type of nerves activated and the mode of stimulus application. Discrete, randomly presented levels of noxious electrical stimulation to the teeth activate predominantly small fibers and produce brief pain sensations that vary unpredictably in intensity. In contrast, continuous cold stimulation to the forearm activates a variety of nociceptive and non-nociceptive fibers and produces progressive cold and pain sensations with a predictable increase in intensity from cold sensations to paresthesia and severe pain.

## NOTES

In this investigation, when the authors conclude that "pain reductions were not correlated with subjects' hypnotic susceptibility levels" (p. 241), it must be noted that hypnotizability was estimated from scores on the Tellegen Absorption scale, which is not actually a measure of hypnotic susceptibility level.

1985

Coe, William C.; Yashinski, Edward (1985). Volitional experiences associated with breaching posthypnotic amnesia. Journal of Personality and Social Psychology, 48 (3), 716-722.

Highly responsive hypnotic subjects classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia were compared during posthypnotic recall. Subjects reported their voluntariness after the experiment. Two contextual conditions were employed (2 x 2 design): a lie detector condition meant to create pressure to breach amnesia and a relax control condition. In contrast to earlier findings, the recall data showed that both voluntary and involuntary subjects breached under the lie detector condition compared with their counterparts in the relax condition; however, the degree of breaching was not great in any condition. The results are discussed as they relate to studies attempting to breach posthypnotic amnesia and characteristics of the voluntary-involuntary dimension.

1984

Bakker, Dirk J. (1984). The brain as a dependent variable. Journal of Clinical Neuropsychology, 6, 1-16.

The mainstream of neuropsychological research and practice has been devoted to the impact of the brain as an independent variable on behavior as a dependent variable. Evidence is currently available to make clear that the order of causation may be reversed: Behavioral changes can have a durable impact on the brain. The results of extensive research indicate that a large number of neuroanatomical, neurophysiological, neurochemical, and neuropsychological parameters of the animal brain can be modified through environmental manipulation, sensory experience, and systematic training. Some evidence is available to show that psychological stimulation has certain effects on the physiology of the human brain. For instance, hemisphere-specific stimulation through the presentation of words flashed in a visual hemifield appears to modify the electrophysiological activity of the contralateral hemisphere in dyslexic children and to affect their subsequent reading performance. Neuropsychology may profit from paying more attention to the ecology of the human brain.

## NOTES

An 18th Century anatomist in Italy, Malacarne, demonstrated increased cerebellar folds in the brains of trained (vs. untrained) dogs and birds. His approach to neuroanatomy was not continued because psychology has been more concerned with innate traits of the individual, and because of philosophical rationalism (citing Walsh, 1981). Until very recently, scientists have viewed the brain as "structurally insensitive to environmental experience" (p. 3).

Now we have evidence that animal brains are modifiable by experience, in gross morphology, fine (synapse) morphology, and neurochemicals. "Rich environments [for rats] ... produce heavier and thicker cerebral cortices and callosal connections (Walsh, 1981), larger cortex/subcortex weight ratios, larger cell bodies and nuclei (Walsh, 1981), and higher metabolic activity as suggested by increased RNA/DNA ratios (Rosenzweig, Bennett, & Diamond, 1972)" (p. 4). Enrichment leads to more extensive dendritic fields (occipital and temporal cortex, some hippocampal regions); this implies that each neuron has more synapses. Researchers have found large Purkinje-cell bodies and many dendrites in richly educated monkeys.

"Some evidence is available to show that 'preventive' and 'therapeutic' environments positively affect behavioral performances of brain-lesioned animals. However, knowledge about the brain mechanisms which underly these effects is, as yet, lacking" (p. 6). Rats that were handled during the first 21 days of life exhibited different brain lateralization from rats that were not (Denenberg, cited by Marx, 1983). Those stimulated early stored memories mainly in the right hemisphere.

The author also reviews evidence that human brains are psychologically modifiable. Children with astigmatism generate weakened cortical response to visual stimulation (Freeman & Thibos, 1973), because they experience difficulty in processing some visual-spatial patterns. People who have visual-field defects due to brain damage can improve in vision when forced to make eye movements toward lighted targets flashed in the blind areas (Zihl, 1981).

Bakker theorizes that hemispheric control of reading shifts from right to left during the learning-to-read process of normal readers; at least some aspects of reading are successively mediated by the right hemisphere at age 6 and by the left hemisphere at age 8, according to electrophysiological data in a longitudinal study (Licht, Bakker, Kok, & Bouma, 1983). He thinks P-type dyslexia results from continuing to rely on right- hemispheric strategies, leading to slow reading with fragmentation errors and repetitions. L-type dyslexia results from prematurely adopting a left-hemispheric strategy, i.e. at the very beginning of the learning process, making child insensitive to the perceptual features of script with consequent substantive errors such as omissions and additions. Thus, P- type dyslexics presumably show functional overdevelopment of the right hemisphere and L-types of the left hemisphere. Treatment would involve specific stimulation of the hemisphere that they are ignoring.

He presents data suggesting that "some electrophysiological parameters of the cerebral hemispheres can be modified in dyslexic children through hemisphere-specific stimulation and loading, and that these modifications may induce better reading" (p. 12).

**Brodsky, Annette M.; McNeil, Daniel W. (1984). Hypnotizability and volunteering for hypnosis experiments. American Journal of Clinical Hypnosis, 26, 206-211.**

A class of 145 college students was given Barber's Creative Imagination Scale (CIS) and Spiegel's Eye Roll Sign, and later given several opportunities to volunteer for research projects, some of which specified hypnosis was involved. Those S's who volunteered for the hypnosis experiments took the Harvard Group Scale of Hypnotizability (HGSHS). Hypnosis volunteers differed from the non-hypnosis volunteers by significantly higher grades and more total experimental volunteerism, but were no significantly different on the CIS or Eye Roll Sign. In general, nonwhites scored higher on the CIS. Among hypnosis volunteers, there was a low negative correlation between the Harvard Consciousness scale and volunteering for experiments other than hypnosis.

Critelli, Joseph W.; Neumann, Karl F. (1984). The placebo: Conceptual analysis of a construct in transition. American Psychologist, *39*, 32-39.

The placebo in psychotherapy has unfortunately retained the negative connotation of an inert "nuisance variable," a label that it originally incurred in the field of medicine. In addition, the transition toward more cognitive models of psychotherapy, particularly Bandura's theory of self-efficacy, has led to problems in defining the placebo within psychology. This transition has resulted in an awkward interface between certain preferred cognitive metaphors and the negative connotations of a presumably cognitive placebo construct. As a result, suggestions have recently been made to dismiss the placebo construct from psychology and to do away with the use of true placebo controls in outcome research. The present analysis maintains that (a) the placebo can be adequately defined within psychology, (b) the negative connotation of the placebo label is largely undeserved, (c) the placebo retains a continuing conceptual and empirical utility for evaluating psychotherapy, and (d) the therapeutic efficacy of current therapies is well established even though they have not generally been shown to be more effective than nonspecific treatment.

1983

Dillon, F. Richard; Spanos, Nicholas P. (1983). Proactive interference and the functional ablation hypothesis: More disconfirmatory data. International Journal of Clinical and Experimental Hypnosis, *31*, 47-56.

According to the functional ablation hypothesis, memories for which amnesia has been hypnotically suggested do not interact with other information in memory. This hypothesis was tested in 2 interrelated experiments. In Experiment 1, Ss high and low in hypnotic susceptibility were administered a hypnotic induction procedure and tested on a Brown-Peterson (e.g., Wickens & Gittis, 1974) memory task designed to induce proactive interference (PI). Ss were exposed to 10 blocks of successive 3-word lists. Within each block, all words were strongly related, and, therefore, lists presented early in a block interfered with the retention of lists presented later (PI "buildup"). Following the "buildup" of PI, Ss were administered either a cue to be amnesic for the previous words of a block or a cue to relax. Contrary to the functional ablation hypothesis, the amnesia suggestion did not produce a "release" from PI in high susceptible hypnotic Ss. In other words, the amnesia suggestion did not prevent previously learned material from interfering with newly presented material. Experiment 2 demonstrated that the amnesia cues employed in the Brown-Peterson task produced a reversible recall deficit even though they failed to produce PI "release." These findings are consistent with the results of studies of the functional ablation hypothesis using the retroactive interference paradigms.

Johnson, Lynn S.; Dawson, Steven L.; Clark, Janet Lee; Sikorsky, Catherine (1983). Self-hypnosis versus hetero-hypnosis: Order effects and sex differences in behavioral and experiential impact. International Journal of Clinical and Experimental Hypnosis, *31*, 139-154.

Recent studies (Fromm, Brown, Hurt, Oberlander, Boxer, & Pfeifer, 1981; Johnson, 1979, 1981; Johnson & Weight, 1976; Ruch, 1975) of self-hypnosis versus hetero-hypnosis are compared. A study is reported addressing unresolved questions about interactions between order of presentation and sex with the 2 types of hypnosis. 90 male and 149 female volunteer college students were proportionally assigned to 1 of 4 groups, each of which received 1 of the following hypnosis-order combinations on successive days: self hypnosis, then hetero-hypnosis; hetero-hypnosis, then self-hypnosis; self-hypnosis, then another self-hypnosis; or hetero-hypnosis, then another hetero-hypnosis. Half of each group of Ss had a male hypnotist; half had a female hypnotist. Analysis of variance of total scores for

behavioral and experiential impact showed: (a) a general order effect, a decrease from first to second experience; (b) initial self-hypnosis to facilitate either subsequent experience, mitigating the general decrement; (c) switching modes to also reduce the decrement; (d) a clarification of certain order and sex interactions from earlier studies; (e) self-hypnosis to be behaviorally superior to hetero-hypnosis on later presentations; and (f) crossed-sex training to be experientially facilitatory. Conclusions are drawn about unresolved issues in self hypnosis research, including the limits of comparability of self-hypnosis versus hetero-hypnosis, which depend on definitional assumptions of the self-hypnosis state and the allowance for order effects in the design.

## NOTES

In their Discussion, the authors note that self hypnosis and heterohypnosis yield similar results, and that although clinical hypnosis effects may increase with practice, such would probably not be true for hypnosis in the experimental setting. They speculate that "self-hypnosis triggers an 'active involvement' which provides more continuity in responsiveness across experiences, while hetero-hypnosis encourages a more passive mode which is more susceptible to external events (like order effects)" (p. 150).

1982

Farthing, G. William; Brown, Scott W.; Venturino, Michael (1982). Effects of hypnotizability and mental imagery on signal detection sensitivity and response bias. International Journal of Clinical and Experimental Hypnosis, 30, 289-305.

It was hypothesized that the ability to selectively concentrate attention on mental images would be greater among high hypnotizable Ss than among low hypnotizable Ss, as indicated by a greater interference with visual signal detection by concurrent visual mental imagery in response to specified nouns. This hypothesis was not supported in the overall results, though the finding of a significant interference effect among the high hypnotizable female Ss, but not among other subgroups, indicates that further research with a more refined procedure might be worthwhile. On the control trials without images, the high hypnotizable Ss made more false alarms than lows, and had a significantly different bias index indicating that high hypnotizable Ss were more likely than lows to respond "yes" when uncertain about whether the signal was present; false alarms can be interpreted as a nonhypnotic measure of suggestibility. The high and low hypnotizable Ss did not differ in their times to generate images in response to the specified nouns.

Friedman, Howard; Taub, Harvey A. (1982). Accessibility: A necessary control for studies of essential hypertension. International Journal of Clinical and Experimental Hypnosis, 30, 4-8.

A study which was planned to compare the relative effects of relaxation and hypnosis upon essential hypertension also offered the opportunity to replicate some of the findings of a previous investigation. A failure in such replication led to consideration of the effect of accessibility to the laboratory, a variable not typically controlled. A significant differential effect of easy versus hard access was observed.

Frischholz, Edward J.; Blumstein, Renee; Spiegel, David (1982). Comparative efficacy of hypnotic behavioral training and sleep/trance hypnotic induction: Comment on Katz. Journal of Consulting and Clinical Psychology, 50 (5), 766-769.

Examines the claim by N. W. Katz (see PA, vol 62:6454) that social- learning hypnotic inductions produce significant gains in hypnotizability relative to a traditional sleep/trance hypnotic induction.

His use of a "raw gain-score analysis" is criticized because it fails to identify the significant influences of pretreatment individual differences on posttreatment response. Reanalysis of Katz's data indicates a highly significant pretest effect more potent than the observed treatment effect. Inconsistencies between Katz's findings and those of 6 previous studies are examined.

1981

Fromm, Erika (1981). How to write a clinical paper: A brief communication. International Journal of Clinical and Experimental Hypnosis, 29, 5-9.

The standards for publishing clinical papers are in some ways the same and in some ways different from those applying to experimental articles. The present paper, written by the Clinical Editor of the International Journal of Clinical and Experimental Hypnosis, is meant to be a guide to clinicians on how to write publishable papers and to reviewers and readers on how to evaluate them.

NOTES

1:

"An outline could follow this sample:

- a) Statement of problem.
- b) Review of literature -- and not only the literature of the last 5 years.
- c) Clinical material -- number of patients, descriptions of cases.
- d) Description of method of treatment. If it is a new technique, give a verbatim account.
- 3) Results.
- f) Discussion. (Evaluate your own results and, if appropriate, compare them to those in the literature.)
- g) Conclusion.
- h) Tables and Figures (if appropriate).
- i) Footnotes.
- j) List of references.
- k) Abstract" (pp. 6-7).

"In closing, here is a short reviewers' and editors' guide -- a set of questions editors and referees ask. It might be helpful to be aware of these questions as you write a paper.

1. Is the article appropriate for our journal? Does it deal with hypnosis?
2. Has the hypothesis been made explicit?
3. Has the reason for or the origin of the hypothesis been made clear?
4. Does the paper describe something new or describe the approach to an old field in a new way?
5. Are references missing? Are all the citations correct and necessary? Or, is there padding?
6. Has the author been careful to cite prior reports dealing with the same topic? Prior theories about the same topic?
7. What was the "set" given to subjects? Was there control for experimenter influence and demand characteristics?
8. Were patients led to believe they were receiving treatment or not?
9. How was the diagnosis arrived at? Is it correct? Or, does the material given remain unclear as to the correctness or incorrectness of the diagnosis?
10. Was administration and scoring of tests and evaluation of the results done correctly?
11. If statistics were used, were they used correctly?
12. Are the figures, graphs, and tables used necessary and sufficient? Do they correspond logically to the textual argument of the article?
13. Is the discussion properly confined to the findings or is it digressive? Does it include new post-hoc speculations?
14. Has the author explicitly considered and discussed viable alternative explanations?" (p. 9).

Fromm, Erika; Brown, Daniel P.; Hurt, Stephen W.; Oberlander, Joab Z; Boxer, Andrew M.; Pfeifer, Gary (1981). The phenomena and characteristics of self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 189-247.

Self-hypnosis and hetero-hypnosis were compared, and self-hypnosis was studied longitudinally. Results indicated that absorption and the fading of the general reality orientation are characteristics of both hetero-hypnosis and self-hypnosis. The differentiating characteristics lie in the areas of attention and ego receptivity. Expansive, free-floating attention and ego receptivity to stimuli coming from within are state-specific for self-hypnosis, while concentrative attention and receptivity to stimuli coming from one outside source--the hypnotist on whom the subject concentrates his attention--are state-specific for laboratory defined hetero-hypnosis. Attempts to produce age regression and positive or negative hallucinations are markedly more successful in hetero-hypnosis. Imagery is much richer in self-hypnosis than in hetero-hypnosis. Self-hypnosis requires adaptation to the state: in the beginning of self-hypnosis there is a good deal of anxiety and self-doubt. As the subject feels more comfortable in the self-hypnotic state, he spends less time worrying about failures in self-suggestion, his ability to enter trance quickly and easily increases, as does the fading of the general reality orientation, trance depth, and absorption. An attempt was also made in the present study to find personality characteristics related to the ability to experience self-hypnosis.

1980

Case, David B.; Fogel, David H.; Pollack, Albert A. (1980). Intrahypnotic and long-term effects of self-hypnosis on blood pressure in mild hypertension. International Journal of Clinical and Experimental Hypnosis, 28, 27-38.

Self-hypnosis using the method of Spiegel (1974) was evaluated in 15 patients with labile or mild essential hypertension who were equally hypnotizable and adhered to a regimen of 6-10 daily exercises for a 4-month period. During the hypnotic state, there were consistent rises in both systolic and diastolic pressures in hypnotizable patients, but not in non-hypnotizable controls. Similar but smaller changes were also observed in normotensive subjects. Pressure rose immediately with hypnosis and subsided gradually over 15 minutes. However, the long-term effects of the daily practice of self-hypnosis were variable: ambulatory diastolic pressure fell in 5 patients, was unchanged in 7 patients, and rose in 3 patients. The changes in blood pressure could not be specifically attributed to the daily practice of self-hypnosis; however, all patients experienced improvement in well-being, mood, and behavior patterns during the 4-month period. The study indicates that self-hypnosis can produce changes in behavior and mood which may be beneficial to cardiovascular health, although paradoxically, the act of hypnosis by this technique is pressor. Aside from its therapeutic potential, self-hypnosis may provide useful information about central mechanisms of blood pressure regulation.

Ericsson, K. Anders; Simon, Herbert A. (1980). Verbal reports as data. Psychological Review, 87 (3), 215-251.

## NOTES

Proposes that verbal reports are data and that accounting for them, as well as for other kinds of data, requires explication of the mechanisms by which the reports are generated, and the ways in which they are sensitive to experimental factors (instructions, tasks, etc.). Within the theoretical framework of human information processing, different types of processes underlying verbalization are discussed, and a model is presented of how ss, in response to an instruction to think aloud, verbalize information that they are attending to in short-term memory (STM). Verbalizing information is shown to affect cognitive processes only if the instructions require verbalization of information that would not

otherwise be attended to. From an analysis of what would be in STM at the time of report, the model predicts what could be reliably reported. The inaccurate reports found by other research are shown to result from requesting information that was never directly heeded, thus forcing Ss to infer rather than remember their mental processes. Connors, J. R.; Sheehan, P. W. (1978). The influence of control comparison tasks and between-versus within-subjects effects in hypnotic responsivity. International Journal of Clinical and Experimental Hypnosis, 26, 104-122.

Type of experimental design (between- versus within-subjects) and type of control task were examined for their differential effects on the magnitude of objective and state report test scores associated with response to items on the Stanford Hypnotic Scale of Susceptibility, Form C (Weitzenhoffer & Hilgard, 1962). In an integrated program of work exploring design effects in hypnotic research, Ss in each of 7 comparison conditions that involved hypnosis and 4 separate comparison conditions that did not involve hypnosis were tested twice on successive occasions. Three of the control tasks used (waking, imagination, and imagination [alert] instruction) were counterbalanced with hypnosis to analyze possible order effects associated with hypnotic test conditions. Data indexed the patterns of between-versus within-subjects effects associated with standard control tasks and also highlighted the order effects that accompanied them. Imagination instructions, in particular, pose specific difficulties that require attention when Ss are tested as their own controls.

Hiscock, Merrill (1978). Imagery assessment through self-report: What do imagery questionnaires measure?. Journal of Consulting and Clinical Psychology, 46, 223-229.

Four studies examined imagery questionnaires and addressed issues of reliability, agreement among different questionnaires, social desirability, and construct validity. The Betts, Paivio, and Gordon scales were examined. In two studies the Betts and Paivio correlated .45-.50, but correlations involving the Gordon were inconsistent from one study to the next. Imagery measures generally were not influenced by social desirability. Factor analysis indicated that subjective and objective measures of visualization are independent. Concludes that imagery is not a unitary construct and that criteria other than visuospatial tests may be appropriate for validating imagery questionnaires.

Brown, Daniel P.; Fromm, Erika (1977). Selected bibliography of readings in altered states of consciousness (ASC) in normal individuals. International Journal of Clinical and Experimental Hypnosis, 25, 388-391.

The bibliography is divided into the following sections:

I. General Works

II. Reference material on personality in relation to altered states

III. Social and cultural determinants of altered states

IV. Cognition, information-processing, and ego-functioning

V. Methodology in the study of altered states

VI. Differentiation of hyperaroused states

VII. Shamanistic states

VIII. Possession-trance

IX. Psychedelic states

X. The meditative states

**XI. Personality differences and meditation**

**XII. Affective and cognitive change in meditation**

**XIII. Ordinary Buddhist meditation, concentration, and insight meditation**

**XIV. The variety of Buddhist meditation traditions**

**Crosson, B.; Meinz, R.; Laur, E.; Williams, D.; Andreychuk, T. (1977). EEG alpha training, hypnotic susceptibility, and baseline techniques. International Journal of Clinical and Experimental Hypnosis, 25, 348-360.**

3 alpha feedback sessions of 40 minutes were administered after a similar baseline period without feedback to 12 Ss high in hypnotic susceptibility and 12 Ss low in hypnotic susceptibility. Hypnotic susceptibility was not a significant dimension in alpha feedback training and previously reported relationship between alpha density and hypnotic susceptibility were not generally found. Evidence did support the efficacy of the current baseline procedure over others more commonly used. The possibility under certain conditions of there being a relationship between hypnotic susceptibility and alpha density and theoretical considerations in recording baseline are discussed.

#### **NOTES**

Be aware of underlying paradigm and how it influences every aspect of the research. Make assumptions more explicit. 2. Person who plans the study should be different from person who is responsible for data analysis. 3. Person who plans the study should not be person who serves as experimenter and collects the data. 4. Investigator should serve as "pilot" subject to gain insight into how the Ss view the experimental design, to tighten the design, and to change experimental instructions that are not clear to the Ss. 5. Use a tight experimental script or protocol that clearly specifies how the experimenter is to carry out each phase of the study, and that considers the various contingencies that may arise. 6. Give the experimenters sufficient supervised practice in implementing the protocol and in correctly and honestly recording the data. The experimenters should carry out pilot studies under supervision. 7. Understand the many kinds of data analyses that lead to misleading conclusions and the kinds of analyses that can be used appropriately with specified sets of data. 8. Judge the research on the validity of the design and procedures that are used to answer the questions that are posed rather than on the outcome or the results that are obtained. 9. Teachers should place much more emphasis on the value of carefully following the prescribed procedures and carefully and honestly recording the data. 10. Check often to see if the experimenters are faithfully implementing the experimental protocol and are carefully and honestly recording the data--e.g. by making tape recordings or video tapes, using one-way mirrors to observe, or by sending stooges, who give predetermined responses.

**Coe, William C. (1976). Effects of hypnotist susceptibility and sex on the administration of standard hypnotic susceptibility scales. International Journal of Clinical and Experimental Hypnosis, 24, 281-286.**

Hypnotists' susceptibility and sex were examined for their effects on the administration of the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & Hilgard, 1962). Neither resulted in different hypnotic responsiveness from Ss. Comparatively inexperienced hypnotists obtained data similar to the normative sample for the Stanford scale. The results suggest that inexperienced hypnotists are capable

of administering standardized scales validly, and that characteristics of the hypnotist are relatively ineffective in distorting Ss' responses to these scales.

**Kampman, R. (1976). Hypnotically induced multiple personality: An experimental study. International Journal of Clinical and Experimental Hypnosis, 24, 215-227.**

The purpose of the study was to clarify the frequency of appearance of a hypnotically induced secondary personality and to compare Ss who were able to create secondary personalities in hypnosis to control Ss who could enter a deep hypnotic trance but were unable to produce secondary personalities.

The sample of 1,200 pupils was made up of the 3 highest grades of the secondary schools in the city of Oulu, Finland. A total of 450 students volunteered to participate in the study. All those who could enter a deep hypnotic state, 78 in all, were selected for closer study. 32 Ss were able and 43 were unable to create multiple personalities in hypnosis.

Ss also underwent a psychiatric interview. In addition, the identity of Ss was measured.

Both the psychiatric interview and identity examination gave parallel results to the effect that Ss capable of producing secondary personalities were clinically healthier and more adaptive than the group without secondary personalities. This finding is at variance with results presented in previous studies.

#### NOTES

Procedure for induction of multiple personalities involved re-hypnotizing Ss, suggesting, "You go back to an age preceding your birth, you are somebody else, somewhere else," and repeating the suggestion many times. Other suggestions were given that everything was completely normal, nothing miraculous was happening. A multiple personality was counted if the S then said he was a human being, was able to give his name and where he lived, could describe the social environment and his own personality.

**Ahlberg, D.; Lansdell, H.; Gravitz, M. A.; Chen, T. C.; Ting, C. Y.; Bak, A. F.; Blessing, D. (1975). Acupuncture and hypnosis: Effects on induced pain. Experimental Neurology, 49, 272-280.**

The reactions of 14 volunteers to electrical stimulation near the supra-orbital nerve were studied under acupuncture, placebo-acupuncture, and hypnosis. As the intensity of stimulation increased, a minimum sensation, a minimum pain, and then a maximum or intolerable pain sensation were produced. Under hypnosis the average intensity of the stimulus for producing these sensations was higher than before the trance induction. Under acupuncture and placebo-acupuncture no clear increase in current intensity was observed. Acupuncture, as well as hypnosis, did not consistently change the blood, blood pressure, pulse rate, EKG, respiratory rate, or EEG.

**Brown, H. Alan (1973). Role of expectancy manipulation in systematic desensitization. Journal of Consulting and Clinical Psychology, 41 (3), 405-411.**

Expectancy, relaxation, and hierarchy content were manipulated in a 2X2 factorial design with two additional control groups. It was hypothesized that a major portion of therapeutic change following desensitization could be accounted for by the subjects' responses to positive feedback inherent in the paradigm. Spider-phobic subjects saw either photographs of spiders or blank slides that they believed to be tachistoscopically presented pictures of spiders. In the factorial part of the design, half of the subjects believed their progress through the hierarchy to be contingent on autonomic responses; the others believed rate of progress to be random. Findings did not support the hypothesis that expectancy

was the only factor in desensitization, but they did serve to clarify the role of expectancy vis-a-vis the counterconditioning elements typically discussed in the literature.

1968

Evans, Frederick J. (1968). Recent trends in experimental hypnosis. Behavioral Science, 13, 477-487. (Abstracted in American Journal of Clinical Hypnosis, 13, 143)

Research on hypnosis has been influenced by recent methodological contributions. Social psychological factors influence experimental results, and special control procedures have been developed to evaluate the essentially subjective nature of hypnosis. Several studies are reviewed covering posthypnotic suggestion and amnesia. These studies support a state oriented theory of hypnosis.

Graham, K. R.; Patton, Ann (1968). Retroactive inhibition, hypnosis, and hypnotic amnesia. International Journal of Clinical and Experimental Hypnosis, 16, 68-74.

THE RELATIONSHIP OF HYPNOSIS AND POSTHYPNOTIC AMNESIA TO RETROACTIVE INHIBITION. 4 GROUPS OF 10 STUDENTS EACH LEARNED LISTS OF ADJECTIVES IN A RETROACTIVE INHIBITION PARADIGM. 2 GROUPS LEARNED THE INTERVENING LIST WHILE THEY WERE HYPNOTIZED. SS OF 1 OF THESE WERE GIVEN INSTRUCTIONS FOR POSTHYPNOTIC AMNESIA, WHILE SS OF THE OTHER WERE TOLD TO RECALL WHAT THEY HAD LEARNED UNDER HYPNOSIS. THE SAVINGS AND RECALL SCORES OF BOTH GROUPS FOR ITEMS OF THE ORIGINAL LIST WERE NOT DIFFERENT FROM A 3RD GROUP WHICH HAD LEARNED ALL 3 LISTS IN THE WAKING STATE. ALL GROUPS

SHOWED SUBSTANTIAL RETROACTIVE INHIBITION WHEN COMPARED TO CONTROLS WHO HAD LEARNED NO INTERVENING LIST. (SPANISH + GERMAN ABSTRACTS) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1967

Bowers, Kenneth S. (1967). The effect for demands of honesty upon reports of visual and auditory hallucinations. International Journal of Clinical and Experimental Hypnosis, 15, 31-36.

SS, UNSELECTED FOR HYPNOTIC SUSCEPTIBILITY AND SIMPLY TOLD TO HALLUCINATE, MADE PRETEST RATINGS ON THE REALITY OF VISUAL AND AUDITORY HALLUCINATIONS. ALL SS WERE THEN TASK MOTIVATED TO HALLUCINATE. BEFORE THE RETEST RATINGS WERE MADE, 1/2 OF THE SS WERE CONFRONTED BY A 2ND E WITH DEMANDS FOR REPORT HONESTY. FOR BOTH SENSORY MODALITIES, THE MEAN CHANGE IN RATINGS FROM PRETEST TO RETEST WAS SIGNIFICANTLY GREATER FOR THE TASK-MOTIVATED THAN FOR THE HONESTY-REPORT CONDITION. RATINGS OF THE REALITY OF HALLUCINATIONS ARE EVIDENTLY HIGHLY SUSCEPTIBLE TO THE CONTEXT OF DEMANDS IN WHICH THE REPORT IS MADE. IT IS ARGUED THAT, IN THIS AND PREVIOUS EXPERIMENTS UTILIZING UNSELECTED SS, REPORTS OF HALLUCINATORY ACTIVITY ARE LESS APT TO REFLECT PERCEPTUAL ALTERATIONS THAN RESPONSE MODIFICATION IN ACCORDANCE WITH REGNANT EXPERIMENTAL DEMANDS. Evans, Frederick J. (1967). An experimental indirect technique for the induction of hypnosis without awareness. International Journal of Clinical and Experimental Hypnosis, 15, 72-85.

A procedure is described which has been used in an experimental setting as a method of indirectly inducing hypnosis without S's awareness. Ss are not told that hypnosis is involved in the procedure, but are told they will be taught how to relax. The aim of the indirect procedure is to create different expectations and preconceptions from those normally occurring in the special hypnotic relationship. Evidence from 3 studies (samples of 63, 63, 120) indicates that the procedure successfully induces hypnosis comparable in depth to other standard hypnotic procedures. About half of the Ss tested apparently do not recognize the procedure involves hypnosis. Approximately 30% of the Ss who receive the procedure, as well as 30% of the Ss in the control group who did not receive the procedure, but were tested with the same test suggestions, recognized that an attempt had been made to induce hypnosis. The perceptions about whether hypnosis was involved were unrelated to scores on typical hypnotic phenomena. It was concluded that the indirect induction technique successfully induces hypnosis and is a useful technique for manipulating S-expectations in an experimental context.

#### NOTES

"[The Subject] is told, 'A series of experiments are being conducted investigating the effects of relaxation on behavior. Because of confusing results in the literature, this study is designed to examine the relationship between relaxation and several other psychological phenomena, some of which might remind you of a variety of other phenomena which you may have heard or read about.' The S was told that a technique had been devised that would assist him to relax completely. His main task was to relax as completely as possible. This would be facilitated by lying comfortably on a couch, and by allowing his mind to become completely blank. To prevent himself from falling asleep, he should concentrate his attention on some object or idea. To help exclude other thoughts from his mind, E would continue to

talk in a monotonous voice saying little of importance, while the S stared at a spot on the wall. This shaping of the situation was continued with a considerable degree of apparent permissiveness.

"The S's attention was slowly directed to the rhythm of his own breathing as suggestions were given of eye fatigue. If S closed his eyes, he might find it convenient to concentrate on the rhythm of his own breathing. Perhaps this would be easy to think about if he visualized a pendulum swinging in time with his breathing. The E continued to talk and count in rhythm with S's breathing. Special words, such as 'breathing in and out; the pendulum swings back and forward,' were always spoken as S inhaled or exhaled. Counting was also timed to coincide with exhalation. Deeper relaxation was suggested as E counted slowly from 1 to 21, and later, from 1 to 31.

"Throughout the procedure, phrases and words (such as 'hypnosis,' 'trance,' 'drowsy') traditionally employed with hypnotic induction techniques were avoided. After approximately 30 minutes, a natural transition was made to the testing procedure. Suggestions of continued deep relaxation were intermingled between various tests administered. Termination was effected by suggesting that the relaxation would end as E counted from 'A' to 'H'" (p. 75).

Evans, Frederick J.; Schmeidler, D. (1966). Relationship between the Harvard Group Scale of Hypnotic Susceptibility and the Stanford Hypnotic Susceptibility Scale: Form C. International Journal of Clinical and Experimental Hypnosis, 14, 333-343.

3 SUBGROUPS OF 20 SS WITH HIGH, MEDIUM, OR LOW SCORES ON A SLIGHTLY MODIFIED, TAPE-RECORDED VERSION OF THE HARVARD GROUP SCALE OF HYPNOTIC SUSCEPTIBILITY, FORM A (HGSHS:A) WERE LATER ADMINISTERED THE STANFORD HYPNOTIC SUSCEPTIBILITY SCALE, FORM C (SHSS:C). THE 2 SCALES CORRELATED .59, WHICH IS LOWER THAN WOULD BE PREDICTED BY SCALE RELIABILITIES. THIS, TOGETHER WITH OTHER DATA BASED ON ITEM CHARACTERISTICS, INDICATES THAT THE 2 SCALES ARE NOT EQUIVALENT, BUT IN PART MEASURE DIFFERENT ASPECTS OF HYPNOTIC PERFORMANCE. SCORES ON HGSHS:A FOR LOW SS ARE PREDICTIVE OF SHSS:C SCORES, BUT THE STABILITY OF PERFORMANCE BETWEEN HGSHS:A AND SHSS:C IS NOT AS MARKED FOR MEDIUM AND HIGH SS ON HGSHS:A. THIS IS PARTLY A RESULT OF THE FAILURE OF PASSIVE MOTOR (PRIMARY) SUGGESTIBILITY TO DISCRIMINATE BETWEEN LEVELS OF SUSCEPTIBILITY, ALTHOUGH CHALLENGE ITEMS DO. THE 2 CLUSTERS OF ITEMS CORRELATE .23 AND .43 IN HGSHS:A AND SHSS:C, RESPECTIVELY. THE PASSIVE SUGGESTIBILITY ITEMS DETRACT FROM THE VALIDITY OF THE 2 SCALES. (SPANISH + FRENCH SUMMARIES) (20 REF.) Evans, Frederick J.; Thorn, Wendy A. (1966). Two types of posthypnotic amnesia: Recall amnesia and source amnesia. International Journal of Clinical and Experimental Hypnosis, 14 (2), 162-179.

Posthypnotic recall amnesia refers to S's inability to recall, when challenged posthypnotically, the events which occurred during hypnosis. Posthypnotic source amnesia, occurs when S subsequently remembers the experiences of hypnosis, but has no recollection of acquiring the experiences. Data from 3 samples are presented to support the distinction between the 2 types of amnesia. Of 243 Ss, 18 experienced recall amnesia, 26 displayed source amnesia, but only 4 developed both kinds. There were no differences in rated depth of hypnosis of these 3 subgroups. Recall amnesia and source amnesia correlated .37, .38, and .39, respectively ( $p < .001$ ) in the 3 samples. The evidence indicates the 2 types of amnesia are different phenomena. Similarities between source amnesia and certain (dissociative)

normal and psychopathological memory processes are discussed. (Spanish & German summaries) (32 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1965

Coe, William C. (1965). A method of self-teaching for experimental hypnosis. International Journal of Clinical and Experimental Hypnosis, 13 (3), 144-149.

A student's interest in hypnotic research may actually be discouraged because of the difficulty in obtaining a formal course or close supervision in hypnotic techniques. A method tried by 2 students to overcome this problem is presented. The "self-teaching" procedure attempts to fulfill 3 basic criteria: safeguarding the S, requiring minimal supervisory time, and learning to administer a standard hypnotic scale. Some benefits seem to have been realized. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Cooper, Leslie M.; Pedersen, Darhl M. (1965). A note on the failure to find personality differences between volunteers and nonvolunteers for hypnotic research. International Journal of Clinical and Experimental Hypnosis, 13 (4), 274-278.

Personality measures were administered to 136 students in an introductory psychology class at Brigham Young University. 30 Ss subsequently volunteered to have their hypnotic susceptibility assessed. There were no significant differences found between the means of the resulting 23 variables for the 30 volunteers and 106 nonvolunteers. 2 variables (age and ego strength) showed significantly different variances for the 2 groups, but these may be attributed to chance because of the number of significance tests made. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Field, Peter B.; Evans, Frederick J.; Orne, Martin T. (1965). Order of difficulty of suggestions during hypnosis. International Journal of Clinical and Experimental Hypnosis, 13, 183-192.

This study tests the hypothesis that successful response to suggestion during hypnosis predisposes to further successful response, but failure leads to subsequent failure. The Harvard Group Scale of Hypnotic Susceptibility was administered to 2 groups of 51 volunteer students. For 1 group, 8 of the 12 items were administered in the order easy-to-difficult; for the 2nd group, in the order difficult-to-easy. Total and 8-item mean scores, and frequency distributions, did not differ significantly between groups. Except for the item measuring posthypnotic amnesia, item difficulties for the 2 groups did not differ significantly. Although the difficult-to-easy group was more amnesic, the 2 groups recalled a similar number of additional items when amnesia was "lifted." The block of 4 easier items was relatively easier when preceded by a block of 4 harder items and, similarly, the harder items were relatively less difficult if preceded by a block of easier items. The magnitude of this effect was small, and the order effect hypothesis was basically not supported. Future research should consider the S's subjective impression of success and failure. (16 ref.) 1964

Anderson, Milton L.; Sarbin, T. R. (1964). Base rate expectations and motoric alterations in hypnosis. International Journal of Clinical and Experimental Hypnosis, 12 (3), 147-158.

Degree of responsiveness to "suggestion" in an experiment which did not utilize hypnotic induction (the Berkeley Sample) was comparable to that obtained in an experiment which did utilize hypnotic

induction (the Stanford Sample). Procedural differences between the 2 experiments--self-scoring vs. objective-scoring, and group vs. individual testing--were regarded as not crucial in making a comparison of the 2 experiments. The distribution of responses in the Berkeley Sample may be taken as the base rate. The slightly higher degree of responsiveness over the base rate in the Stanford Sample (on some tests) may be attributed to the "degree of volunteering" that characterized the sample. The importance for experiments in the future to create equal levels of motivation and expectation to perform well under both the hypnotic and the nonhypnotic conditions is stressed, and brief mention is made of a new metaphor to be used in the conceptualization of the problems of hypnosis. (25 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Evans, Frederick J.; Schmeidler, D. (1964). Reliability of two observers scoring the Stanford Hypnotic Susceptibility Scale, Form C. International Journal of Clinical and Experimental Hypnosis, 12 (4), 239-251.

2 Os scored the responses of 60 Ss on a 12-item objective test, Stanford Scale of Hypnotic Susceptibility, Form C (Weitzenhoffer & Hilgard, 1962). Mean total scores reported by the 2 Es did not differ significantly. The correlation between the total scores of the 2 Es was .947. Nevertheless, differences in total scores assigned occurred with 40% of Ss, which is a significant departure from perfect agreement. The 2 Es disagreed about correct scoring of 54 items (7.5% of all items scored). The extent of disagreement was significantly greater than 0. Disagreement was not related to the level of susceptibility of Ss, nor to the relative experience of Es with hypnosis. More than 1/2 of the disagreements involved systematic differences in the interpretation and application of the scoring criteria for 2 items; item 6: Dream, and item 9: Anosmia to Ammonia. These systematic differences affecting scoring reliability happened to counterbalance to produce similar total scores in this study. Several sources of potential scoring unreliability of SHSS:C are discussed. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Field, Peter B. (1964). Bales interaction analysis of hypnosis. International Journal of Clinical and Experimental Hypnosis, 12, 88-98.

Sound films of 2 hypnotists, 4 Ss, and 2 simulators of hypnosis were scored by a modification of Bales' interaction process analysis. Comparisons are presented between the interaction profiles of hypnotists and Ss. Both of the hypnotists' transformed interaction percentages fell above the Ss' 95% confidence intervals for agreeing, asking questions, and giving suggestions, and below the Ss' confidence intervals for appearing submissive, giving opinions, showing tension, and giving information. No consistent differences were found between hypnotists and Ss for seeming positive, negative, or dominant, for disagreeing, or for releasing tension. The 2 simulators did not show consistent interaction differences from the real Ss. Both advantages and limitations in applying Bales' method to hypnosis are discussed. It is concluded that interaction process analysis provides a measure of the overt role-differentiation between S and hypnotist, but does not directly reflect some of the unique features of the hypnotic situation (17 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Furneaux, W. D. (1964). The heat-illusion test and the structure of suggestibility. International Journal of Clinical and Experimental Hypnosis, 12 (3), 169-180.

2 similar forms of the heat-illusion test are shown to correlate to a smaller degree than would be expected if they measure the same attribute. The 2 versions also differ in the way in which they correlate with other suggestibility tests. It is shown that linear regression techniques are not appropriate for analyzing the data concerned. The interaction of various nonlinear relationships with

a difference in "difficulty," as between the 2 forms of the illusion, seems to provide an adequate explanation for the results. It is suggested that these nonlinear relationships may indicate the existence of an attribute which prevents some Ss from responding to any suggestibility test, irrespective of what the specific mechanisms of response may be. Deckert, G. H.; West, L. J. (1963). The problem of hypnotizability: A review. International Journal of Clinical and Experimental Hypnosis, 11, 205-235.

This paper summarizes the relatively unsuccessful effort to relate hypnotizability to sex, age, psychiatric diagnoses, suggestibility, and various personality traits. The problems of measurement, subject selection, controls, and experimenter bias are reviewed. Comparison of data is difficult and replication of studies infrequent. This might be attributed to incomplete reporting of methodology, defects in experimental design, and various conceptual problems. Concepts which view hypnotizability as "something" universal, "something" unique, or "nothing" are briefly appraised. Finally, hypnotizability is seen as a "term" describing a relationship between a "route" and a "state"--each identifiable by measurable criteria. Dittborn, Julio (1954). Dehypnotization and associated words. Journal of Clinical and Experimental Hypnosis, 2 (2), 136-138.

Author tested Freud's hypotheses about signs of emotional conflict gleaned from a word association test. A highly hypnotizable subject who had been accused of theft was tested with the word association test repeatedly. He had been given the suggestion, while in deep hypnosis, that any word provoking emotional conflict would automatically bring him out of hypnosis. That is, "dehypnotization was used as a new method to investigate the conflict-provoking quality of certain stimulus-words in an association word test" (p. 139). Freud's predictions were only partially supported.

Erickson, Milton H. (1954). The development of an acute limited obsessional hysterical state in a normal hypnotic subject. Journal of Clinical and Experimental Hypnosis, 2, 27-41.

NOTES

1:

The 25 year old female graduate student in psychology had often been used in hypnosis experiments and as a demonstration subject, and had witnessed induction of hypnotic deafness, blindness, and color-blindness though she had not been given those suggestions herself. Scientific curiosity appeared to be the motivation for volunteering to experience hypnotic blindness, but she was skeptical about her ability to experience it. The author gave a series of "exceedingly tedious" suggestions to develop somnambulism (passively responsive and receptive) followed by suggestions leading gradually to development of "blindness" with the intention of concealing it from the hypnotist, with attendant strong and mixed emotions.

The initial attempts failed because the subject ostensibly was deceiving herself into thinking she had developed hypnotic blindness, but the author also was of the opinion that she was seeking to meet unconscious personality needs. The author then covertly changed the goal of the experiment "to develop in the subject an acute hysterical obsessional compulsive mental state which would be accompanied by hypnotic blindness and which would parallel or resemble the obsessive compulsive hysterical mental disturbances encountered in psychiatric practice" (p. 32). The author developed a

monologue of suggestions based in part on the utterances of hospitalized obsessive patients and in part on trauma relating to traumatic blindness in a kitten and a friend of the subject. In a slow but directed manner the author built up a double-bind situation which eventually led to the experience of hypnotic blindness as well as heightened emotional reactivity, crying etc.

1953

Beigel, Hugo B. (1953). Hypnosis as an instrument in psychological experimentation. Journal of Clinical and Experimental Hypnosis, 1, 13-17. (Abstracted in Psychological Abstracts, 53: 6385)

#### Author's Summary

In this paper various areas of psychological research were pointed out in which experimentation with hypnotized subjects has been or could be employed to advantage. It is held that there are several problems which offer no point of attack unless hypnosis is used and several others which, in view of their complexity, cannot be effectually approached by the classic method of experimentation. Specifically mentioned were the areas of thinking, learning, perception, apperception, imagination, and emotion, in which the hypnotic experiment proves valuable when either amnesia for preceding experiences, isolation from concomitant influences, or the introduction of an as-if situation is necessary. While it is undeniable that some of the experiments cited need improvement if their results are to be considered reliable -- a remediable shortcoming they share with most first experiments -- it is also evident that the use of hypnosis in experiments offers an approach to some areas that have thus far been inaccessible. Needless to say, hypnosis should not be used when similar results can be as readily obtained by the customary experimental method, but as Gidro-Frank and Bull (10) state, our scant knowledge of the nature of the hypnotic state should not bar it from use as a scientific tool. Still the only one available technique to solve a problem. It must be added, however, that the experimenter must be thoroughly familiar with the technique but also to their physical and mental health.

Glasner, Samuel (1953). Research problems in the educational and social psychological applications of hypnosis. Journal of Clinical and Experimental Hypnosis, 1 (2), 42-48.

#### NOTES

1:

The author reviews literature in which hypnosis is used as an experimental research method in two general areas: hypnosis in learning and recall, and hypnosis in social psychology. "In summary, the application of hypnosis to research in the fields of educational and social psychology is practically virgin territory. Imaginative investigators should be able to develop numerous interesting experiments in these two great areas" (p. 47).

Israeli, Nathan (1953). Experimental study of projection in time: I. Outlook upon the remote future--extending through the quintillionth year. Journal of Clinical and Experimental Hypnosis, 1 (2), 49-60.

Author's Summary - This report on research now under progress is concerned with time projection and with hypnotic imagination and dreams of projection into varying remote future periods extending to the very distant quintillionth year. The work proceeded in stages including (a) orientation to the general procedure, (b) hypnotic future autobiographic material (age progression), (c) going successively from one future period to another from the end of the 21st century through the quintillionth year -- devoting usually one experimental session to any future period. This paper reports on the self-ratings for hypnosis depth reached by the subjects, their description of life, things, and events, in connection with each projection into a future period, and their visual or nonvisual imagery.

1. Self-ratings for hypnosis depth show with one insignificant exceptional instance that all subjects were always at least at the trance-level or in a deeper hypnotic stage. Individual differences in level

reached were indicated with a general trend towards more profound trance in later sessions. The deeper levels on the scale used were not described by the experimenter. Each subject gave those levels his own interpretation in setting up his own scale.

2. The time projections are to be explained in terms of changing space-time framework, social topographic reorientation, recentering, and non-conventional time centering.

3. Hypnotic suggestion to imagine and dream about being suddenly transported and projected into a specified future period is followed by rapid recentering as the subjects follow out the suggestions.

4. Although no specific instructions or sets of suggestions were included about the nature of their anticipations, the description of life, things, and events of any future period was on a predominant impersonal level, with the personal aspects in the background. Nonetheless, the suggestion of transportation and projection into a future period leads to various changes in one's present-situation perceptions, imagery, space-time framework, and system of concepts and beliefs. With a change in time reference, the description of life, things, and events is adjusted to the era or epoch specified. This involves description of technological, biological, psychological, and anthropological changes. The extinction of mankind is anticipated in the very remote future by some subjects. The earth and the moon are expected to disappear by collision or otherwise.

5. Individual analysis shows that the descriptions of the different future periods approximately fit into patterns and are not discontinuous. An individual subject's descriptions beginning with the first future period and taking in all the other periods show constructive or catastrophic trends or cyclical variation between both extremes. Descriptions of life, things, and events of each future period in the main change in a constructive or in a catastrophic direction. They are continuous but with certain discontinuities and incoherence.

6. A geocentric orientation and a heliocentric preoccupation are invariant and predominant. The subjects are unable to abandon their basic planetary orientation or schemata.

7. Colored imagery includes mainly the primary colors. They comprise both expanse colors and surface colors. Auditory imagery is quite frequent. There are also references to olfactory, tactile, and kinesthetic imagery. Thermic imagery becomes increasingly prominent in the more remote future periods when the sun's heat is described as more intense. Imagery changes with the outlook patterns and appears to have personal, structural, and social determinants. One subject's imagery was macropic.

Bartolo-Abela, Marcelle; Benton, Theodore (2002, August). Hypnotherapy for AD/HD: Preliminary evidence for its effectiveness. [Paper] Presented at the 110th Annual Convention of the American Psychological Association, Chicago, Illinois.

Although AD/HD is typically treated with stimulants, non-pharmacological alternatives are regularly pursued because of adverse side effects of the stimulants. In a preliminary trial, 12 boys in special education programs who fulfilled DSM-IV criteria for AD/HD were treated with a standardized protocol of brief Ericksonian hypnotherapy, with self-hypnosis and audiotape homework, over 4 weeks. Posttherapy assessments using the Conners Teacher Rating Scale (CTRS) showed decreased overall maladaptive behavior of 33.30% ( $p < .001$ ), with specific reductions of 36.10% (hyperactivity;  $p < .001$ ) and 42.09% (daydreaming/inattention;  $p < .001$ ) over baseline scores. School records also showed improved grades. There was no difference in outcome based on age or comorbidity. These findings provide initial evidence for the effectiveness of hypnotherapy for AD/HD in boys.

1996

Sapp, Marty (1996). Three treatments for reducing the worry and emotionality components of test anxiety with undergraduate and graduate college students: Cognitive-behavioral hypnosis, relaxation therapy, and support counseling. Journal of College Student Development, 37 (1), 79-87.

The effects of cognitive-behavioral hypnosis, relaxation therapy, and supportive counseling in reducing the worry and emotionality components of test anxiety among undergraduate and graduate students were examined. Relaxation therapy was more effective with graduate students undergraduate responded more to supportive counseling. Similarly, cognitive-behavioral hypnosis and relaxation therapy were both more effective in reducing the worry and emotionality components of test anxiety and in improving grade point averages than was supportive counseling.

Wark, David (1996). Teaching college students better learning skills using self-hypnosis. American Journal of Clinical Hypnosis, 38 (4), 277-287.

Reports the effects of self-hypnosis used by 51 college students enrolled in a 10-wk course on efficient learning skills. All Ss were administered the Creative Imagination Scale (CIS). Subsequently, they learned to enter and deepen alert self-hypnosis. They gave themselves personal suggestions and then studied in hypnosis. They reported their depth of hypnosis and satisfaction with each session. Grades were collected the quarter before, during and after the course. Satisfaction and depth data indicated the Ss were involved throughout the course. Statistical testing showed that Ss who scored highest on the CIS had the lowest initial GPA, improved most during the course, and significantly increased their GPA in the quarter after.

## NOTES

Hypnosis is a therapeutic procedure that is appropriate for some school-age clients. Through the use of hypnosis that utilizes metaphors and imagery, children can be empowered to find unique solutions to their problems. Children enjoy the feeling of power and mastery that they have when able to perform hypnotic phenomena. They like to play magic and can be told that a finger or other body part will become numb. Because a major goal of hypnotherapy is to teach a child to be an active participant in his or her own behalf, the focus is on creating solutions and mastering the situation rather than enduring the problems. Four case studies demonstrate the utility of hypnosis in the treatment of phantom pain and nausea, sleep terror disorder, school phobia, and spider phobia. In each case, treatment goals were realized. Because the solutions were self-generated, the behavioral changes maintained over time and situation.

Case #1: Hypnosis was used to help alleviate phantom limb pain and nausea during chemotherapy following amputation of the right leg at the knee due to cancer in a thirteen-year-old male. The client had indicated that he loved nature and enjoyed the mountains. The metaphor described a young tree that has just begun to grow small silvery leaves. The spring floods tear the limbs and branches from the stump. The deep roots and stump of the tree are all that remain. The tree is not the same as before the flood. Its roots are stronger, its base more sturdy compared to the branches and limbs. The young tree has withstood the catastrophe of the torrent of waters and is even stronger than before. To counter the nausea and vomiting associated with chemotherapy a switch mechanism metaphor was used. The client was adroit with computers and had no difficulty picturing a switch located in his brain

which could "turn off" the nausea from chemotherapy. A room contained all the unpleasant feelings that were being experienced. In this room is a light of a particular color that represents all the unpleasant sensations. Press the key on the computer that controls the switch to turn off the colored light in that room. Suggestions for healing were also given. Your body has known for years how to heal. Visualize the battle between good and bad cells and the victory of the good cells.

**Case #2:** Hypnosis was used to alleviate sleep terror disorder in a ten-year-old female. The onset of the subject's parasomnic symptomatology appeared to coincide with her starting kindergarten and her family's relocation shortly before. The initial treatment consisted of progressive relaxation, deep breathing, and the visual image of her "secret safe place." An induction utilizing a variety of images was presented. Hiking barefoot on a cool moss covered mountain trail, sitting in an alpine meadow on a warm summer afternoon, and flying proved most effective in facilitating trance. The participant was told to "Visualize all your anxiety and tension as hard grey rocks. Pick up these rocks and place them in your pockets. Go to the front porch of your "secret safe place and on the porch is a "magic hefty bag." Place your hard grey rocks that contain all your anxiety and tension in the magic bag. Once in the bag, the rocks will no longer weight you down, you will be free of any feelings of stress or tension. Your bed is magic; it is covered with a special glue which will keep you in a reclining position until you are fully rested and ready to awaken."

**Case #3:** Hypnosis was used in the treatment of school phobia in a nine-year-old male. The student experienced intense anxiety whenever separation from the primary caretaker occurred. The teacher stated that this boy experienced frequent absences and crying spells that were only relieved by phone calls to his mother or the presence of his mother next to him in class. In preparation for the intervention, the student was asked to draw a picture of how he felt inside during a panic attack. He drew a fire. He also said that only his mother could put that fire out. This information was utilized in creating a metaphor that described a house in a small town. "The mother had left, and a young boy was left alone. While at home, the boy looked out the window and saw several boys trying to burn a neighbor's yard! Acting quickly, he called the fire department, grabbed the fire extinguisher and unraveled the garden hose. He was able to extinguish the fire. The neighbors and friends were very happy and praised the boy's performance. When his mother heard the good news, she quickly returned home and held a celebration in his honor." Following the metaphor, hypnotherapy continued with suggestions about fire extinguishers that the subject could use to put out emotional fires.

**Case #4:** Hypnosis was used in the treatment of spider phobia. Diagnosis of phobia was made in this eleven-year-old female when the fear or avoidance behavior was distressing. The child's strained facial expressions occurred even at the thought of seeing what she described as "a creepy, crawly creature with 8 legs." Preparatory to her first induction the participant was read the story of Charlotte's Web (White, 1980) to facilitate the imagery for future hypnotic work. In the following session systematic desensitization was accomplished using characters from the story of Charlotte's Web. During the third session the subject was age regressed to the first time she remembered seeing a spider. She recalled playing in the woods outside her family home on an island and seeing a large web stretched between two trees with a very large spider in the center of its web. She was then asked to remain at that place to look closely at that spider as it was most likely Charlotte or one of Charlotte's family. Upon closer investigation she saw not only Charlotte but "teeny-tiny babies." The event was reconstructed as a happy experience. The imagery provided by Charlotte's Web permitted the subject to fantasize her previous frightful experience and reframe spiders as cute little "teeny-tiny" babies with admirable human qualities.

**Krippner, Stanley (1994, August). Improvement of academic skills for children and adolescents with hypnosis. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.**

NOTES

Literature and research in this area are sparse, though there is clinical evidence that hypnosis is useful. My definition of hypnosis is a procedure facilitating a variety of structured goals or procedures in which a suggestion or motivation is enhanced by a mechanical device, another person, or oneself.

There are 3 areas of application in academics:

study habits

test taking

strengthening academic motivation

The hypnotist should know the specifics of academic achievement, because specific suggestions (e.g. "Imagine you are at desk focusing well for 20 minutes,") are better. Emphasis on the positive is better than negative. Use the words "imagination," "concentration," or "imagining pictures," rather than "hypnosis." I try to determine what they expect, based in part on what words they use.

In elementary school I focus on attitude and self esteem. I have them imagine reading a story, then how well they feel; that when they notice mistakes they won't be bothered because everyone makes mistakes.

For high school, I help them develop good habits for time motivation (e.g. suggestions to "make an outline to follow while you study"). At college level, I introduce self hypnosis. I make frequent use of mental imagery, at all levels--especially imagery rehearsal, in which the person is engaged in a particular activity.

In the NSF report on accelerated learning techniques (a project sponsored by the Army), Lozonov's "suggestopedia" techniques were studied. This review indicated it might enhance training effectiveness and reduce training time.

I have observed the suggestopedia classes in Bulgaria and Hungary. Classes had a relaxed comfortable learning environment. Rather than individual learning, it was group learning. It included preliminary exercises, new material, and a review of what was learned. The first stage used 2/3 of the time. Then suggestions were given by the teacher to promote learning. The presentation phase took one third of the time. The method encourages students to make mental images of the material. In foreign language classes, people take on new roles.

Stanton, Harry E. (1994). Self-hypnosis: One path to reduced test anxiety. Contemporary Hypnosis, 11, 14-18.

Describes a self-hypnosis technique and its efficacy in reducing test anxiety. Forty high school students were matched on sex and anxiety scores and randomly allocated to an experimental group (receiving two 50-minute sessions, a week apart, to learn the self-hypnosis technique), and a control group (receiving two 50-minute sessions focused on ways of reducing test anxiety). Students were retested after the two sessions, and 6 months later. Results showed a significant reduction in anxiety scores only for the hypnosis group, which was maintained at 6-month follow-up.

1989

Palan, B.M.; Chandwani, S. (1989). Coping with examination stress through hypnosis: An experimental study. American Journal of Clinical Hypnosis, 31, 173-180.

Fifty-six volunteer medical students participated in three groups balanced for number of subjects, performance at last examination, and hypnotizability. The hypnosis and waking groups attended eight group sessions once a week with general ego-strengthening and specific suggestions for study habits, with a ninth session of age progression and mental rehearsal. Subjects in these two groups practiced self-suggestions (in self-hypnosis or waking respectively) daily for the study period of 9 weeks. The control group experienced sessions of passive relaxation induced by light reading for the same period of time. The hypnosis group improved significantly in coping with examination stress, but there was no significant change in performance on examinations by any of the groups.

Stanton, Harry E. (1989). Hypnosis and rational-emotive therapy--a de-stressing combination: A brief communication. International Journal of Clinical and Experimental Hypnosis, 37 (2), 95-99.

It has been suggested that teacher stress might be reduced through cognitive restructuring which is aimed at improving the rationality of their thinking. To test this hypothesis, 40 high school teachers were paired on their level of reasonable thinking, operationalized in terms of scores on the Teacher Idea Inventory (Bernard, Joyce, & Rosewarne, 1983), and allocated at random to one of 2 groups. They also completed the Face Valid Stress Test. The experimental group participated in 4 weekly treatment sessions involving a hypnotic induction and suggestions derived from key elements of Rational-Emotive Therapy. These focused on the reduction of what Ellis (Ellis & Grieger, 1977), the originator of this treatment, calls "irrational thinking." The control group spent the same amount of time discussing stress reduction methods. Both the Face Valid Stress Test and the Teacher Idea Inventory were re-administered at the end of this period and again 12 months after conclusion of the experiment. Results indicated that both the experimental and control groups significantly reduced their levels of irrational thinking and stress, although the former's improvement was more marked, particularly at the 12-month follow-up.

1981

Baum, D.; Lynn, Steven J. (1981). Hypnotic susceptibility level and reading involvement. International Journal of Clinical and Experimental Hypnosis, 29 (4), 366-374.

The study investigated differences between high and low hypnotizable Ss in their involvement in imaginative versus nonimaginative reading material. 10 high and 8 low susceptible Ss read passages of high and low rated imaginativeness. Ss' involvement in the passages was measured by self-report and reaction time. High and low hypnotizable Ss differed only in their involvement in imaginative material, with good Ss expressing greater involvement. High susceptible Ss tended to report more involvement in high than in low imaginative material, confirming J. R. Hilgard's (1965, 1970) observations. The reaction-time measure failed to parallel self-report, yielding non-significant results.

1976

Illovsky, J.; Fredman, N. (1976). Group suggestion in learning disabilities of primary grade children. International Journal of Clinical and Experimental Hypnosis, 24, 87-97.

This study reports the effects of tape-recorded hypnotic suggestions given to 48 hyperactive children between the ages of 6 and 8 from 3 public schools. The children had short attention spans, low frustration and tolerance [sic], and poor learning motivation. They were taught by the same method in class and received remedial instruction as in the previous year. In order to participate in this study, the children were brought from their regular classrooms every morning to listen in groups of 9, 10, or 19 -- according to the available accommodation in the school -- to suggestions of relaxation, to ideas of

coping with emotional problems, and to suggestions of modifying attitudes towards learning. The corrective reading teachers conducted these 15-minute sessions. After the session was over, the children were returned to their respective classes. At the beginning and at the end of the school year, the classroom teachers evaluated the children's behavior in class and their attitudes toward learning. The addition of the modified hypnotic technique enabled 45 of 48 children to function better in school. The improvement ranged from decreased hyperactivity to better than average performance in class. Significant correlations were found between percent of relaxation with increased attention span ( $r = .40$ ) and number of sessions attended with increased self-confidence ( $r = .46$ ).

Lawlor, E. D. (1976). Hypnotic intervention with 'school phobic' children. International Journal of Clinical and Experimental Hypnosis, 24, 74-86.

Case studies are used to illustrate the use of hypnosis in working with children who exhibit symptoms of "school phobia." Responses obtained during and after hypnosis are utilized to uncover underlying conflicts and fears.

The literature (Ansbacher, 1956; Friedman, 1959; Johnson, 1957; Johnson, Falstein, Szurek, & Svendsen, 1941; Kessler, 1966; Waldfogel & Gardner, 1961) confirms the findings that a child through his symptoms has fears which he is unable to bring to consciousness and talk about. Typical are fears of abandonment by parents; fears of disaster befalling parents, especially the mother; fears based on destructive wishes toward siblings due to severe rivalry for the mother's love and attention; fears that exhibiting angry feelings will be punished by the parents; and fears of annihilation and starvation. Hypnosis has aided in restoring these children to a school environment more quickly than more traditional methods. One case is reported with excerpts from a session. The perceptions uncovered through the use of hypnosis can be utilized with children in various school settings.

## NOTES

This paper reports two experiments. In the first one, 24 college students with IQs 135 or more who were making low C grades were called in for counseling and given conventional methods for remedial study. Afterwards 11 volunteered for hypnosis and were good subjects; they were enrolled in the hypnosis experiment. They were trained to go into hypnosis on signal, then had four sessions where they studied their school material in hypnosis, then four sessions where they (a) studied post hypnotically in the same way as they had done during hypnosis, and (b) were given post hypnotic suggestions that whenever they sat down to study they would have this degree of concentration and would be able to study, learn and remember in spite of distractions, and finally 4 sessions for reinforcement of the commands and discussion of any difficulties. Throughout the experiment they had 2 sessions each week. "Using their grades for the following semester as criteria: three had gone up slightly but were still doing C work; three were now achieving a B average; four were making an A average and one had a basic personality problem which came to light and is not considered in this paper" (p. 167).

The second experiment involved four art students who were given highly technical material of a mechanical nature and semi-technical material of the same type to learn in the waking state. They were tested for recall in both the waking and hypnotic states. "The hypnotic recall of the two types of material was about the same. However, the waking recall of the highly technical material was much less than that of the semi-technical material, thus tending to indicate that, in the waking state, the 'non-

meaningful material' was not remembered although they actually knew it well enough to reproduce it under hypnosis" (p. 168).

Bryant, Richard A.; Somerville, Ernest (1995). Hypnotic induction of an epileptic seizure: A brief communication. International Journal of Clinical and Experimental Hypnosis, 43 (3), 274-283.

This case study investigated the utility of hypnosis to precipitate a seizure in a patient with refractory epilepsy. The patient was twice administered a hypnotic induction and a suggestion to age regress to a day when he was distressed and suffered repeated seizures. The patient did not respond to the first hypnotic suggestion; however, an epileptic seizure was observed in the second hypnotic session. Videorecording and subdural electroencephalograph recording confirmed that he suffered an epileptic seizure. Postexperimental inquiry revealed that the patient used deliberate cognitive strategies to avoid seizure onset in the first session but adopted a more constructive cognitive style in the second session. Findings are discussed in terms of emotions, hypnosis, and cognitive style as mediating factors in the experimental precipitation of epileptic seizures.

1993

Litwin, R. G.; Cardena, E. (1993, August). Dissociation and reported trauma in organic and psychogenic seizure patients. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.

: Early detection and differential diagnosis of non-epileptic seizures (NES) versus epileptic seizures (ES) is a major clinical issue in comprehensive epilepsy centers. Recent research suggests that differences in dissociative experiences between NES and ES patients may prove useful for diagnostic purposes. Non-epileptic seizures are frequently conceptualized as a dissociative response to past emotional trauma or abuse; dissociation in ES occurs as a result of electrophysiological abnormalities,

most often associated with the temporal lobes. The purpose of this study was to evaluate the effectiveness for the differential diagnosis of NES from ES of several measures of dissociation and of a self-report measure for physical and sexual abuse. Four quantitative measures of dissociation were utilized in this study: the dissociative disorders interview schedule (DDIS), dissociative experience scale (DES), Tellegen absorption scale (TAS) and the Stanford Hypnotic Clinical Scale (SHCS). The incidence of sexual and physical abuse was obtained from structured questions in the DDIS. Forty-one patients being evaluated for intractable seizures participated in this study; 13 ES patients with non-temporal lobe involvement (ES/NTL), 18 ES patients with temporal lobe focus (ES/TLE) and 10 patients with NES spells of psychiatric origin. The main researcher was blind to these diagnoses until the study was completed. Results show a trend toward greater incidence of dissociative experiences in the NES versus ES group on the DDIS, TAS and DES, although these differences tended to be modest and not statistically significant, perhaps given the small N of the study. There were no significant trends or differences in dissociative experiences reported by ES/NTL patients versus ES/TLE patients. Contrary to the study's hypothesis, ES patients were slightly more susceptible to being hypnotized than NES patients. As hypothesized, a significant difference was that NES patients reported physical and sexual abuse of higher incidence and longer duration than did ES patients. Logistic regression analysis for prediction of NES using the DES, TAS and SHCS instruments correctly predicted only 10% of NES patients. However, exploratory logistic regression analysis using the demographic variables of gender, months of sexual abuse and years of recurrent seizures suggest that these characteristics may be specific and sensitive in the prediction of NES. Being a female, having a higher incidence and longer duration of abuse and fewer years of recurrent seizures all predicted significantly the existence of non-epileptic seizure events, allowing for a 95% accuracy in diagnostic prediction. Our findings reinforce prior research indicating that dissociation is an important symptom component of both ES and NES events. The trend toward more prevalent dissociative experiences in the NES group suggests that in depth examination of these differences and of key demographic variables may help differentiate between these two groups. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall 1993, Vol. 2, No. 3.)

1991

Persinger, M. A.; Makarec, Katherine (1991-92). Interactions between temporal lobe signs, imaginings, beliefs and gender: Their effect upon logical inference. Imagination, Cognition and Personality, 11, 149-166.

Rotton's Paralogic Test, Wilson-Barber's Inventory of Childhood memories and Imaginings (ICMI) and the PPI (Personal Philosophy Inventory) were administered to 100 male and 100 female university students. Both sexes displayed moderately strong (0.50) correlations between content-selected and factor analyzed clusters of possible temporal lobe signs, exotic beliefs and the numbers of childhood imaginings. Although there were no sex differences between the accuracy of logical statements that contained paranormal or neutral content, males who displayed more temporal lobe signs were more accurate for logical items that contained paranormal content. Females who displayed more imaginings were more accurate for valid than for invalid items. Accuracy for items with paranormal content increased with exotic beliefs but not with conservative religious beliefs for both sexes. The relationship between exotic beliefs and accuracy for items with paranormal content was especially strong for females. These results suggest: 1) gender differences in the neurocognitive processes that contribute to logical problem solving and 2) accuracy may depend upon the degree to which the subject matter is commensurate with the person's history of enhanced temporal lobe signs, capacity for fantasy and imaginings and beliefs in exotic concepts.

NOTES

Review of related literature indicates that Personal Philosophy Inventory (PPI) temporal lobe signs are correlated with temporal lobe EEG alpha but not occipital lobe alpha (Makarec & Persinger, 1990), with increased suggestibility (Persinger & DeSano, 1986; Ross & Persinger, 1987), with creativity and proneness towards fantasy (Persinger & DeSano, 1986; Ross & Persinger, 1987; Makarec & Persinger, 1987), and with reports of psi experiences and beliefs in such things as reincarnation and aliens in UFOs ('exotic themes') (Persinger & Makarec, 1987; Persinger & Makarec, 1990).

This experiment was designed to answer four questions: " 1) Do imagery and temporal lobe signs emerge from the same source of variance?; 2) Do males and females differ significantly in their incidence of imaginings and temporal lobe signs?; 3) Do males and females differ in their ability to solve logical problems?; and 4) Is the accuracy of problem solving affected by the subject matter of the problem and the problem solver's temporal lobe signs and capacity for imagery?" (p. 151).

The PPI consists of 140 true-false items that were selected with a goal of discerning temporal lobe signs within a normal population. One 30-item subscale has items that are similar to experiences reported by patients with verified electrical foci in the temporal lobes, albeit milder (the TLS or temporal lobe sign scale). Of these 30 items, 16 refer to ictal-like experiences (the CPES, or complex partial epileptic signs), and 14 refer to interictal-like behaviors (ILB). CPES items are items like "Sometimes an event will occur that has special significance for me only," and "While sitting quietly, I have had uplifting sensations as if I were driving over a rolling road." ILB items are items like "People tell me I blank out sometimes when people are talking," and "When I lose an argument I spend a lot of time thinking about what I should have said."

Wilson and Barber's Inventory of Childhood Memories and Imaginings (ICMI) has 52 true-false items that include reports of paranormal experiences (5 items), moderate imaginings (18 items) such as 'When I was a child I enjoyed fairytales,' and extreme imaginings (15 items) such as 'When I was a child or teenager, at times I was afraid my imagining would become so real to me that I would be unable to stop it.'

Rotton's Paralogic Test [unpublished, at Florida International University, Miami] has 16 syllogisms, each with major premise, minor premise, and conclusion. "The person must decide if the argument is valid (n = 8) or invalid (n = 8). Half of each of the valid and invalid arguments refer to mundane material while the other half of the arguments refer to paranormal-related material. An example of the former is 'If a president is a crook, he would be impeached; Congress did not impeach Nixon. Therefore Nixon is not a crook' and 'If flying saucers really existed, somebody would have photographed one. Nobody has ever photographed a flying saucer. Therefore, flying saucers do not exist'" (p. 153).

Correlations were computed separately for males and females. Both groups increased in accuracy for paranormal items as their belief in things like reincarnation and UFOs ('exotic concepts') increased. Males with a higher number of temporal lobe signs demonstrated more accuracy for logic test items with paranormal (psi) content than logic test items with mundane content.

"The single most important correlation was between exotic beliefs and the interaction term for the Rotton scale; the coefficient was unusually strong (0.54) and highly statistically significant ( $p < 0.001$ ) for females only. Because of the manner in which the interaction term was calculated, this correlation meant that females who reported more exotic beliefs were also more accurate for valid items that contained paranormal content only" (p. 159).

In their Discussion, the authors write, "The significant positive correlations between exotic beliefs and the clusters of CPES items and extreme Wilson-Barber imagining items are expected associations according to Bear's concept of sensory-limbic hyperconnectionism [Temporal Lobe Epilepsy: A Syndrome of Sensory-Limbic Hyperconnectionism, *Cortex*, 15, pp. 357-384. It would predict that concepts (or word trains) that are unusual, strange or infrequent would be charged with emotional significance and personal value. Ideas that generate substantial imagery, such as time- travel,

reincarnation and alien intelligence, would be particularly prone to this affective infusion from limbic sources.

Induction of such unique or intensified affective states, especially during childhood, would facilitate the development of more frequent or more extreme periods of dissociation in the adult. We have collected (unpublished) clinical evidence to suggest that the emergence of this pattern is found in the propensity for creative thinkers, including writers, poets, musicians, artists and scientists, to have had developmental histories that could have promoted temporal lobe lability without overt seizure activity; clusters of such "promoters" include mild physical abuse, febrile episodes, minor head injuries and likely hypoxic periods during extreme physical exertion (competitive athletics)" (pp. 161-162).

Another conclusion of the study is that males and females do not differ in their accuracy in solving syllogisms, but "the neurocognitive processes, as inferred from inventories of temporal lobe signs or childhood imaginings, by which the two sexes arrive at solutions may be quite different" (p. 162).

1988

DeBenedittis, Giuseppe; Sironi, Vittorio A. (1988). Arousal effects of electrical deep brain stimulation in hypnosis. International Journal of Clinical and Experimental Hypnosis, 36, 96-106.

In an earlier study, DeBenedittis and Sironi (1986) demonstrated that during depth EEG studies, electrophysiological correlates of hypnotic behavior emphasize the role of the limbic system in mediating the trance experience. In the case of a young man who was affected by medically resistant temporal lobe epilepsy and who was a potential candidate for surgical treatment, diagnostic depth EEG in hypnotic and non-hypnotic conditions offered a unique opportunity to stimulate limbic structures. This permitted an evaluation of the subjective and behavioral responses, as well as of the electrophysiological correlates. During hypnosis, repeated stimulations of the left and the right amygdala produced arousal from the hypnotic state each time, whereas the stimulation of other cerebral structures (e.g., temporal neocortex, Ammon's horn) or pseudostimulations were ineffective on the hypnotic state. These data represent the first experimental, controlled evidence of the amygdala's effects on the arousal from the hypnotic state in man, thus suggesting that hypnotic behavior is mediated, at least in part, by a dynamic balance of antagonizing effects of discrete limbic structures--the amygdala and the hippocampus.

#### NOTES

The patient was a 30-year-old man who had suffered from medically resistant psychomotor temporal lobe epilepsy since age 7; a diagnostic EEG showed right temporal seizure focus, concomitant with independent, contralateral, temporal spiking abnormalities. Hypnotizability was measured at 6 on the SHSS:C; the patient was given two training sessions in hypnosis, with suggestions for "dissociation, rehearsal and reframing of spontaneous seizure events, desensitization of their negative emotional impact, and amnesia" (p. 99).

Electrodes were implanted in deep cerebral structures (amygdala, Ammon's horn) and corresponding superficial areas of temporal cortex, with confirmation of placement by X-ray. Two weeks later the patient's brain was stimulated on two consecutive days, first in the waking state (Session 1) and then in hypnosis (Session 2). (Antiepileptic medication was discontinued three days before the stimulation sessions.) False (placebo) stimulations were randomly provided along with the true stimulations.

The false (placebo) stimulations did not result in subjective or behavioral changes in either the waking or the hypnosis condition.

In the waking condition, a psychomotor seizure was produced by stimulation of Right amygdala and Left Ammon's horn; stimulation of Left amygdala evoked only the aura patient usually had before a seizure, or a brief lapse of consciousness. Stimulating the temporal neocortex did not evoke seizure activity.

In the hypnosis condition, arousal from hypnosis into the waking condition occurred with stimulation of amygdala (either Right or Left). Stimulation of the temporal neocortex or of the Right Ammon's horn did not arouse the patient. Stimulation of Left Ammon's horn led to abortive seizures, such that it could not be determined whether the hypnotic state had been interrupted. Stimulating the Right amygdala "triggered a psychomotor attack similar to that recorded during the waking stimulation, but with reduced emotional involvement" (p. 100). For the Left Ammon's horn, "waking stimulation always induced clinical seizures with prolonged after-discharge, whereas hypnotic stimulation evoked only abortive seizures, without after-discharge" (p. 100).

In their Discussion, the authors note that animal experimental literature suggests that stimulation of the cortico-medial amygdala facilitates arousal functions, of the baso- lateral amygdala diminishes arousal and produces sleep, and lesions of the amygdala lead to 'amygdala hangover' (Weiskrantz, 1956). "The animal with amygdala destruction appears tame and placid, with reduced social reactivity, insensitive to environmental changes and reluctant to initiate new behavior, unless highly motivated (Isaacson, 1976)" (p. 101-102).

In contrast, the animal research on hippocampus suggests it is involved in inhibitory functions (Isaacson, 1976), and may be the 'internal inhibitor' theorized by Pavlov (1955) to be responsible for animal hypnosis. With lesions, animals are more willing to undertake new behaviors, less inactive, less distractible during goal-oriented behavior (Isaacson, 1976). "Moreover, normal hippocampograms show typical, slow (theta) synchronous activity opposed to the arousal desynchronized activity of the electroencephalogram. During hypnosis, desynchronization of the normal, slow activity of the hippocampal Ammon's horn has been registered as compared with the waking hippocampogram, opposite to the slow synchronous activity of the amygdala" (p. 102).

The authors note that their results are at variance with the finding by Crasilneck et al. (1956) that their patient, during brain surgery for an epileptogenic focus, aroused from hypnosis each time they stimulated the hippocampus. They explain the discrepancy as due to the fact that the hippocampus was not simply stimulated, but in fact there was 'coagulation' of a hippocampal vessel each time. Quoting from Crasilneck et al. "'The patient did not complain of pain during this [brain] excision [in hypnosis] except on one noteworthy occasion, when a blood vessel of the hippocampal region was being coagulated. The patient suddenly awoke from the hypnotic trance ... She was immediately rehypnotized. ... The surgeon then purposefully 'restimulated' the same region of the hippocampus. Once again, the patient abruptly awakened from trance... [p. 1607].'" To the present authors, the description appears misleading and responsible for subsequent misinterpretation of the observation. Because on the first occasion the hypnotic arousal effect followed 'coagulation' of the hippocampal region, it may be assumed that 'restimulation' is a misnomer for repeated coagulation. From this it may be inferred that the arousal effect observed by Crasilneck et al. (1956) could probably be ascribed to a hippocampal microlesion rather than to hippocampal stimulation. This could explain the apparent discrepancy" (p. 104).

Loewenstein, R. J.; Putnam, F. W. (1988). A comparison study of dissociative symptoms in patients with complex partial seizures, MPD, and posttraumatic stress disorder. Dissociation, 1, 17-23.

Depersonalization and dissociative symptoms have been widely reported in chronic seizure disorder patients, especially those with temporal lobe involvement and complex partial seizures (CPS). It has been theorized that development of multiple personality disorder may be related to temporal lobe pathology. We administered the Dissociative Experiences Scale (DES) to 12 male patients with severe chronic epilepsy, primarily of the complex partial type. Patients had epilepsy from 1 to 30 years. Most were being evaluated for intractable seizures occurring several times per week. DES data on the epileptic patients were compared with DES data on 9 male MPD patients and 39 PTSD patients. MPD and PTSD patients were significantly different from CPS patients in median DES scores and all DES

subscale scores. MPD and PTSD patients were far more similar on the DES, although MPD patients had a significantly higher score on the dissociation/psychogenic amnesia subscale of the DES. The authors conclude that there is little data to support a relationship between MPD, dissociation, and epilepsy.

1987

Makarec, K.; Persinger, M. A. (1987). Electroencephalographic correlates of temporal lobe signs and imaginings. Perceptual and Motor Skills, 64, 1124-1126.

Significant correlations (0.50) were observed between scores for the Wilson-Barber Inventory of Childhood Memories and Imaginings and the experiences that are indicative of temporal lobe lability. In addition, positive correlations (0.42) occurred between temporal lobe EEG measures (scalp electrodes) and numbers of temporal lobe signs. The numbers of alpha seconds per minute from the occipital lobes were correlated (0.57) with the Wilson-Barber cluster that indicated interests in 'altered states'. Scores on the childhood imaginings section of the Wilson-Barber Inventory were correlated (0.44) with the numbers of spikes per minute over the temporal lobes when the eyes were closed.

#### NOTES

"Persinger and DeSano (1986) found that people who display temporal lobe signs were also more likely to have more imaginings (as defined by Wilson and Barber's (1983) Inventory of Childhood Memories and Imaginings) and to be more suggestible as indicated by Spiegel's Hypnosis Induction Profile" (p. 1124).

Subjects in this investigation were 12 male and 18 female students, ages 18-39 (M = 25 years) Bipolar measures were taken from just above the ears (approximately T3-T4) and the occipital lobe (01-02). Number of alpha seconds per minute and number of spikes per minute from each lobe was taken for 10 minutes (5 successive pairs of 1 minute eyes- open, 1 minute eyes-closed).

"The total Wilson-Barber score was significantly ( $p < .01$ ) correlated ... with the major (0.46) and minor (0.50) temporal lobe clusters but not with two clusters of control items: normal psychological experiences (0.21) and mundane proprioceptive experiences (0.29). These correlations are similar to those in the Persinger and DeSano study (0.60, 0.50, 0.13, and 0.14, respectively). Like the first study (0.53), the items that were most associated with dissociation (depersonalization) were best correlated with the Wilson- Barber scores (0.60). The Wilson-Barber subcluster: adults' extreme experiences (Items 44 through 52, that indicate physiological changes associated with thinking) was again most strongly correlated with the major (0.55) and minor (0.65) temporal lobe clusters; these values were 0.42 and 0.52 in the first study" (p. 1125).

"The only statistically significant ( $p < .01$ ) correlations between the Wilson-Barber scales and the EEG measures were between the number of alpha seconds from the occipital lobe (with the eyes closed) and the [Wilson-Barber] 'altered state' cluster ( $r = 0.57$ ; Items 33, 41, 42, 43). A weaker correlation (0.36) occurred between the number of alpha seconds per min. (eyes closed condition) and childhood vestibular experiences (items 1, 2, 3, 10, 24)" (p. 1126).

1986

DeBenedittis, Giuseppe; Sironi, Vittorio A. (1986). Depth cerebral electrical activity in man during hypnosis: A brief communication. International Journal of Clinical and Experimental Hypnosis, 34, 63-70.

To the authors' knowledge, hypnosis has never been induced in epileptic patients during a depth EEG study. This neurosurgical diagnostic procedure has been routinely used in medically resistant epileptic patients for the preoperative exact delimitation of the epileptogenic lesion. It offers a unique

opportunity to obtain fundamental information on the possible neurophysiological mechanisms implicated in hypnosis. Observations were carried out on 1 patient affected by medically resistant partial seizures with complex symptomatology. A chronic deep electrode study explored rhinencephalic structures as well as specific target areas of the cerebral cortex. Background electrical activity during hypnosis showed a significant decrease of slow waves and an increase of alpha and beta rhythms, with constant increase of amplitude, when compared to activity in the pre- and posthypnosis states. Focal interictal abnormalities were dramatically reduced during hypnosis.

## NOTES

Hypnotizability was assessed with the Barber Suggestibility Scale in order to test for suggestibility without a prior induction of hypnosis. The patient's score was 7 out of 8 possible. Patient was hypnotized with a standard induction procedure (Barber & Calverley, 1963).

Experimental Protocol: 15 minutes resting baseline; 15 minute test of mental imagery (waking suggestions with imagination instructions); hypnosis with progressive relaxation; suggestions for dissociation; suggestions for amnesia; arousal from hypnosis (the patient was successful with positive hallucinations, catalepsy, total amnesia, and spontaneous analgesia); and posthypnosis awake and alert (5 minutes eyes open, 5 minutes eyes closed, then 15-minute recording of post-treatment waking baseline).

EEG background activity was scored for the number of sec/minute of delta (0-4), theta (4-7), alpha (8-12), and beta (13-30) rhythms, for each 5-min period. Score = percent as related to the 1-minute epoch. Number, amplitude, and diffusion of interictal spikes also were measured but ictal activity was not recorded during the periods considered. Experimenters also measured heart rate, respiratory rate, and mean blood pressure.

ANOVA for 4 conditions (resting, waking suggestion, hypnosis, and posthypnosis) was computed for background and for focal interictal activities, and the t-test used to evaluate significant differences. ANOVA indicated a significant effect across the four experimental conditions for theta and alpha in the temporal anterior cortex, temporal posterior cortex, and frontal convexity cortex. The effect was attributable only to changes in theta and alpha between baseline and hypnosis (theta decreasing, alpha increasing as the patient went into hypnosis). No other significant difference was found. Following arousal from hypnosis, EEG activity was similar to the EEG activity before the induction.

Interictal focal abnormalities were reduced during hypnosis, compared with before hypnosis. The effect was due to changes in the area of Ammon's horn, the amygdala, the posterior temporal cortex, the mesial temporal cortex, and the inferior temporal cortex.

In their Discussion, the authors note that their data supports earlier work indicating that the limbic system is implicated in hypnosis. They cite the publications of Arnold (1959, *International Journal of Clinical and Experimental Hypnosis*) and Crasilneck, McCranie, and Jenkins (1956). The latter authors observed EEG records taken during brain surgery on one patient. Hypnosis terminated every time the hippocampus was stimulated, leading them to suggest that the hippocampus is part of the neural circuit involved in hypnosis.

"If it is assumed that a convulsion can be considered a result of both pathophysiological and emotional events operating in the individual, emotions being the most common precipitating factor in epilepsy, then any amelioration of one will raise the convulsive threshold or lower the seizure level (Goldie, 1979; MacCabe & Habovick, 1963). Although 'voluntary control of the alpha rhythm' was achieved over 40 years ago (Jasper & Shagass, 1941), only since 1969 has such control been used for clinical purposes (Kamiya, 1969). One striking characteristic of the EEG pattern of many epileptics is the absence of a 12 to 14 c/s rhythm normally recorded from the anterior portions of the brain (sensorimotor rhythm) and the presence of a 4 to 7 c/s rhythm at the same location (Olton & Noonberg, 1980). Biofeedback may enable the individual to increase the amount of sensorimotor

rhythm and to decrease the amount of 4 to 7 c/s activity. As a consequence, clinically significant decreases in seizure activity have been found after biofeedback training (Serman, 1973, 1977).

"The present data demonstrate that in this female patient hypnosis induced a highly significant reduction of the interictal activity, concomitant with an increase of alpha and sensorimotor rhythm and a decrease of slow activity, similar to biofeedback but without prior training.

" In conclusion, a depth EEG study in one epileptic patient comparing EEG activity during hypnosis and pre- and posthypnosis suggests the following conclusions: (a) hypnosis may be associated with significant decrease of slow activity and an increase of alpha and relatively high frequency, beta activity; (b) electrophysiological correlates of hypnotic behavior support the possible role of the limbic system in mediating the trance experience; and (c) hypnosis is effective in reducing focal interictal abnormalities in this patient and so it can be considered a promising technique to prevent and/or reduce emotional precipitating factors and the tendency to develop seizure activity" (p. 69).

**1984**

Cocores, James A.; Bender, Andrew L.; McBride, Eugene (1984). Multiple personality, seizure disorder, and the electroencephalogram. Journal of Nervous and Mental Disease, 172, 436-438.

Used the EEG to study multiple personality in a 48-yr-old ambidextrous male admitted for alcohol detoxification and individual psychotherapy. Despite conflicting reports in the literature, no changes in the EEG were found that could not be ascribed to the normal changes seen in transitions from various states of alertness. The problems of differentiating multiple personality as a psychiatric entity in itself from those cases arising as a result of chronic partial or partial-complex epilepsy are discussed.

**1981**

Gravitz, Melvin A. (1981). Non-verbal hypnotic techniques in a centrally deaf brain-damaged patient. International Journal of Clinical and Experimental Hypnosis, 29, 110-116.

Non-verbal techniques across several sensory dimensions were utilized with a brain-damaged centrally deaf 36-year-old female patient who had been referred for hypnotherapeutic relaxation. These included optical fixation on the therapist's hand with gradual thumb and fore-finger closure, vibratory stimuli, light shoulder pressures, arm stroking, manually facilitated air currents, and reinforcing homework assignments. With hypnotherapy, the patient's physical and emotional behavior was reported by her to have improved to a significant degree.

Gross, Meir, M. D. (1981). Hypnosis for dissociation -- diagnostic and therapeutic. Journal of the American Society of Psychosomatic Dentistry and Medicine, 28 (2), 49-56.

**NOTES**

Dissociative disorders might be at times very difficult to diagnose and treat, especially since they are very similar to epilepsy in general and to temporal lobe epilepsy in particular. Amnesia, fugue, changing personality and depersonalization are part of both disorders. Patients who suffer from

dissociative disorders might be diagnosed and treated for epilepsy with anticonvulsive medications without any beneficial results. These patients are labeled as epileptics and have to face the social stigmata associated with being epileptic. The wrong label could even reinforce the sick role and make it become fixed and chronic.

Hypnosis was used to diagnose the dissociative disorder by using the hand levitation technique for the differential diagnosis. It was found by the author that patients who suffer from dissociative disorders would get into spontaneous hypnotic trance during the hand levitation. Hypnosis was used also for successful therapy of these patients.

Seven cases are presented in which the hand levitation technique was used to diagnose the dissociative disorder. They were also treated by hypnotherapy. Their treatment by hypnosis is discussed. The purpose of this paper is to introduce the hand levitation technique for the differential diagnosis of dissociative disorder and to emphasize the effectiveness of hypnotherapy in the treatment of this disorder. Sorting out the cases of dissociative disorders from the epileptics is very important clinically, since it can save many patients from the anguish of having to take anti-convulsants unnecessarily and having to face the social stigmata of being labeled as epileptic.

Slater, Roger C.; Flores, Louis S. (1963). Hypnosis in organic symptom removal: A temporary removal of an organic paralysis by hypnosis. American Journal of Clinical Hypnosis, 5 (4), 248-255.

NOTES

"Summary and Conclusions. A detailed case study is reported on the use of hypnosis with beneficial results in an instance of eventually proved organic brain disease. Three other confirmatory case reports of organic disease definitely benefitted by the use of hypnosis are briefly cited.

" The first patient had been adequately studied repeatedly for organic brain disease. Because the studies led to an uncertain indefinite unconfirmed suspicion of psychogenic epilepsy, the patient was returned with a recommendation for continued treatment and observation by the author, a general practitioner. Hence, she was, after still further study for organic disease, treated symptomatically by hypnosis with beneficial results. This led to the erroneous conclusion that the patient's disability was probably functional. A sudden fatal outcome of the actual but unrecognized brain disease led to a correct but post- mortem diagnosis of astrocytoma of the brain, Grade IV.

"This report and those given to supplement it raise significant questions about the importance and value of hypnosis in organic disease. These include the challenging question of the extent to which the use of hypnosis can potentiate the natural corrective forces of the body; the need to recognize the value of hypnosis in effecting beneficial results in organic disease; the need to qualify the reliability of hypnosis as a differential diagnostic procedure in relation to psychogenic and organic disability; and the possibility and extent of the amelioration or actual correction of known organic illness" (p. 254).

## NOTES

A dream that occurred in natural sleep was used as the starting point for exploration in hypnosis, e.g. suggesting that the patient was seated in a movie theater and would see an element that had been in the dream, projected on the movie screen; then would see substitute pictures which had for him the same meaning as that element. "... as in the dream, commitments to reality [in hypnosis] are minimized and there are evidences of the archaic drive-oriented primary process and a loss of distance from the fantasy so that it becomes a transitory hallucinatory experience. In addition, the censorship function is reduced but not eliminated so that this case study is highlighted by the defensive symbolic substitutions provoked by the persistent demands of the therapist" (pp. 64-65).

## SELF

1999

Daniel, Sheryll (1999). The healthy patient: Empowering women in their encounters with the health care system. American Journal of Clinical Hypnosis, 42 (2), 108-114.

Many women's expectancies when they assume the role of patient include the experiences of regression, helplessness, passivity and fear. This paper describes techniques for interrupting this negative set and for facilitating the development of a self-efficacious state in which the woman experiences herself as an active and informed participant in her encounters with medical personnel.

Rosenbaum, Robert & Dyckman, John (1996). No self? No problem! Actualizing empty self in psychotherapy . In Hoyt , Michael F. (Ed.), Constructive therapies (2, pp. 238-274). New York NY: Guilford.

## NOTES

In this book chapter, Rosenbaum and Dyckman (1996) argue that self has no permanently fixed,

defining, thing-like characteristics (p. 270). They thus dispute the classical notion--commensurate with the position of philosophical realism --that the self is a substance, with fixed qualities and measurable qualities. The authors refer to this classical self as a full self, contained inside the skin and delimited by its participation in linear time. Instead, they propose an empty self, not to be construed as a void, but as a fluid, connected, relational self that overflows the traditional boundaries of the skin and is open to greater possibilities for change. To support their view of an empty self, the authors include several case examples of working with hypnosis and strategic/narrative therapy with clients experiencing a variety of psychological and physical symptoms. The authors further contend that self is not unitary, but the product of multiple drafts (p. 248)[Editor note: See Dennett, 1991, in this database]. In the narrative-constructivist tradition, they argue, if we speak in terms of multiple contextual selves for us all...[then, people diagnosed with MPD/DID] are not so different from the rest of us (p. 249). The chapter draws from western & Buddhist philosophy, strategic/systemic and narrative therapies, Ericksonian hypnosis, and, cognitive science theories regarding memory, consciousness, embodiment, and language, to support their alternative view of, and treatment for, the self.

1992

Kirmayer, Laurence J. (1992). Social constructions of hypnosis. International Journal of Clinical and Experimental Hypnosis, 40 (4), 276-300.

Both clinical and experimental views of hypnosis are social constructions that reflect the biases and interests of practitioners and scientists. Each perspective offers useful metaphors for hypnosis. Underlying clinical uses of the term hypnosis are states of mind associated with imaginative reverie and automatic behavior based on procedural knowledge. Social discourse and narratives shape hypnotic experience, but they are themselves influenced by mechanisms of attention and automaticity. Study of hypnosis must proceed on both social and psychological fronts to account for the experience and clinical efficacy of hypnosis.

#### NOTES

"In accord with Coe, Sarbin, and other social-psychological theorists, I will argue that hypnosis, like all higher mental phenomena, is fundamentally social in nature. To accept this, however, does not obviate the role of distinctive processes of attention, imagery, and imagination. Hypnosis is a socially constructed context and ritual for evoking imaginative enactment and involuntary of "automatic" modes of experience and behavior. Contemporary social-psychological theorists have failed to sufficiently explore the nature of enactment. A satisfactory account of hypnosis must go much deeper into the cognitive and social construction of experience; only then can involuntary behavior be properly distinguished from self-deception and self-authorship from cultural construction" (p. 277).

Kunzendorf, Robert; Carrabino, Carlene; Capone, Daniel (1992-93). 'Safe' fantasy: The self-conscious boundary between wishing and willing. Imagination, Cognition and Personality, 12, 177-188.

This experiment tested the hypothesis that a fantasy will impel people to 'act out' only if they fail to distinguish the fantasy from the anticipated reality. In the experiment, one task obtained a baseline measure of how long subjects could resist eating popcorn, then measured how long subjects could resist popcorn while fantasizing its taste. Another task instructed subjects to merge three circular images with three circular percepts of equal vividness, then presented subjects unexpectedly with only two of the three circular percepts. Some subjects thought that there were three circular percepts during the merger, and for these subjects, the length of resistance to popcorn was significantly shorter during the popcorn fantasy. But for subjects who self-consciously differentiated the two real circles

from the three merging images, the normal 'boundary' between wishful fantasy and willful eating was intact.

## NOTES

This research investigated whether people can fantasize without acting out. The authors place the study in the context of theories proposed by Freud and William James. Kunzendorf's source monitoring theory of self-consciousness suggests that "self-consciousness \_that one is imaging\_ is the phenomenal consequence of neurally monitoring the central source of one's imaged sensations, and self-consciousness \_that one is perceiving\_ is the subjective quality of neurally monitoring the peripheral source of one's perceived sensations" (p. 178).

The ability to carry out source monitoring varies. Those who have difficulty monitoring whether they are imaging or perceiving may also have trouble distinguishing wishful fantasy from anticipatory imagery, and therefore they might act on it.

This research "identified subjects with poor source monitoring--nondiscerners of reality--and investigated the effect of fantasy on their impulse control" (p. 179).

## METHODS.

Subjects sat in front of a computer monitor for all tests; they completed Eysenck's seventh impulsivity questionnaire for measures of impulsivity, venturesomeness, and empathy, Marks' Vividness of Visual Imagery Questionnaire (VVIQ).

The study used a test in which subjects maintained in mental imagery a red, green, and yellow filled circle that had been on screen, with eyes closed; were instructed to open eyes and merge their 3 imaginary circles with the 3 on the screen (but when they opened eyes only 2 were there), and they were then asked questions about how many circles they saw when they opened their eyes.

Then they were given a taste of popcorn, told to resist eating any more (but could press a key to receive a little if they couldn't resist), and then were told to resist by imagining that they were eating popcorn.

## RESULTS.

Those who discerned the two real circles while imaging a third circle of equal vividness (the Discerners), could resist eating popcorn for 137 sec in the baseline condition and 132 sec in the fantasy condition. Those who could not discern two real circles while imagining a third (Nondiscerners) could resist eating popcorn for 127 sec in the baseline treatment but only 95 sec in the fantasy treatment.

Discerners could identify the missing circle as the red one, whereas nondiscerners could not do so with any certainty; there was no effect of "image vividness".

"Vivid imagers" whose imagery matched real yellow circles of greater illuminance, exhibited more vivid imagery on the VVIQ as well.

In their Discussion, the authors suggest that "fantasy impels people to 'act out' only if they fail to distinguish fantasized sensations from perceived sensations. ... [the theory] is applicable to sexual fantasy and aggressive fantasy as well. This theory-- Kunzendorf's 'source monitoring' theory of self-consciousness--implies that fantasies of the sensory consequences of a behavior should not lead to the behavior, so long as the fantasies are self-consciously known to be imaginal and are not expected to be perceptual... But for people who cannot self-consciously distinguish between wishful images of pure fantasy and anticipatory images of perceptual reality, between wishing and willing, fantasies of gastronomical, sexual, or aggressive sensations are implicitly unsafe.

"Indeed, as Baars notes, 'the issue of voluntary control is at the very core of human psychopathology' [31, p. 254]. But recently, Baars' and others' theories of volition have emphasized the computer-metaphoric distinction between conscious 'willful' behavior and unconscious 'automatic' action [31, 39-40], and have neglected James' distinction between conscious willing and conscious wishing. Decades ago, when pre- computational theorists like Janet used the term 'automatism' to describe psychopathological behavior, they meant that an abnormally behaving patient was \_consciously

'possessed' by a fantasy\_--a wishful image, a hypnotic suggestion, or a fantasized personality [41]. In reemphasizing the phenomena of wishing, willing, and possession by fantasies, the present article redefines the latter phenomenon as possession by 'unmonitored' fantasies, which are distinguishable from anticipatory images impelling action" (pp. 184-185).

Stanton, Harry E. (1992). Brief therapy and the diagnostic trance: Three case studies. Contemporary Hypnosis, 9, 130-135.

## NOTES

He reviews very brief hypnotherapy, then writes, "A systematic way of encouraging people in the use of their inner resources to solve problems, the 'diagnostic trance', has been outlined by Havens and Walters (1989). People sit quietly, eyes closed, physically relaxed, concentrating upon the unpleasant sensations or feelings associated with their problem. By turning inward in order to focus upon these internal events, they tend to drift into a trance state.

"While mentally observing these unpleasant sensations, they describe, in a somewhat detached manner, the thoughts and images which are present in their minds. They make no effort to control these in any way, simply allowing associated memories to surface quite spontaneously. Usually they reveal a pattern of thinking, a series of images, or even a specific memory which is creating the problem. Sometimes these are in the form of visual images of previously forgotten incidents, usually of a traumatic nature. On other occasions they may take the form of a voice repeating a particular negative statement.

"Once people have been able to identify the source or sources of their unpleasant feelings, they attempt to find a thought or image which is sufficiently powerful to remove or displace the negative material. On many occasions, people find that they have the inner resources needed to solve their problem but, until given the opportunity provided by the diagnostic trance, they were unaware that they possessed these resources. However, the diagnostic trance procedure appears to encourage the spontaneous emergence of creative solutions" (p. 131).

Of the 103 patients with whom he used the procedure, "approximately 70% reported that it had helped them resolve the specific problem for which they had sought therapeutic assistance. ... In addition to being effective, the diagnostic trance is enjoyable, even when used to process past experience of an unpleasant nature. In its simplicity lies its strength. Patients find it easy to learn and, once they have gained confidence in its value as a problem-solving tool, often teach it to family members and friends" (p. 134).

## 1991

Kunzendorf, Robert G.; Beltz, Susan McLaughlin; Tymowicz, Gina (1991-92). Self-awareness in autistic subjects and deeply hypnotized subjects: Dissociation of self-concept versus self-consciousness. Imagination, Cognition and Personality, 11, 129-141.

By refining past tests of self-awareness in mirrors, current testing demonstrates that autistic subjects' percepts are dissociated from self-concept, whereas hypnotized subjects' sensations are dissociated from self-consciousness. In the current test of self-concept, subjects could not directly see a line inside the box on their lap, but subjects could see the line indirectly in a televised mirror image. When instructed to touch the line, autistic subjects reached towards the televised line, whereas nonautistic subjects reached towards the actual line occluded inside the box. This first result suggests that the autistic subject's visual percept of the televised line is dissociated from its spatial relationship to the subject's self-concept. In the current test of self-consciousness, subjects were told to use a televised mirror-image to move their hands together until touching, but were not told that they were actually seeing a pre-recorded tape of their hands struggling unsuccessfully to touch. When queried, hypnotized subjects denied that their tactually joined hands were touching, whereas nonhypnotized

subjects confirmed that their hands were touching. This latter result suggests that the hypnotized subject's hand-touching sensations are dissociated from the immediate and incontrovertible self-consciousness \_that one is perceiving the hands touching (not imaging them touching)\_.

Sapp, Marty (1991, August). The effects of hypnosis in reducing anxiety and stress in adults with neurogenic impairment. [Paper] Presented at the annual meeting of the American Psychological Association, San Francisco.

A repeated measures design was utilized to investigate the effects of hypnosis in reducing anxiety and stress in 16 adults with neurogenic impairment. Seven sessions were used to measure the efficacy of hypnosis. Session one was used to obtain a baseline level of anxiety and stress and to initiate hypnosis. Sessions three and six were used to obtain repeated measures of these emotions. Sessions two, four, and five were the treatment sessions. Session seven was used to conduct a four week follow-up on the effects of hypnosis. Levels of anxiety were measured by the State-Trait Anxiety Inventory, while stress was measured by the State-Trait Anger Expression Inventory. The results indicated a statistically significant decrease in anxiety and stress. Hypnosis also significantly increased levels of self-esteem. Finally, follow-up data demonstrated that the treatment gains were maintained.

#### NOTES

Hypnotizability was not related to treatment outcome. The average Barber Susceptibility Scale score was 3, which indicates that the subjects were fairly low in hypnotizability level.

1990

Fischer, Donald G.; Elnitsky, Sherry (1990). A factor analytic study of two scales measuring dissociation. American Journal of Clinical Hypnosis, 32, 201-207.

The present study was designed to investigate the construct validity of dissociation. We administered the PAS and the DES to 507 male (48%) and female (52%) undergraduate students. Factor analysis on each scale separately showed that neither the PAS nor the DES adequately measures the three dimensions hypothesized to underlie dissociative experience. For both scales, a single factor emerged as replicable and reliable. Use of the scales, in their present form, therefore, should be limited to a single dimension representing disturbances in affect-control in the case of the PAS and disturbances in cognition-control if the DES is used at least with normal populations. Analysis of the combined items showed that the scales are measuring conceptually different but statistically correlated dimensions of dissociation. Further development of both scales is desirable, and further research should investigate the effect of different response formats on the internal structure of the scales.

#### NOTES

The stated purpose of this study was to investigate the internal structure of the Perceptual Alterations Scale (PAS) and the Dissociative Experiences Scale (DES) using a large sample from a normal population.

"Sanders (1986) conceived of dissociation as a personality trait that is characterized by modification of connections between affect, cognition, and perception of voluntary control over behavior, as well as modifications in the subjective experience of affect, voluntary control, and perception. She chose items from the MMPI to represent this trait. Bernstein and Putnam (1986), utilizing the DSM-III definition of dissociation, constructed items from information derived from interviews with patients and clinicians to represent a number of different types of dissociative experiences" (0. 202).

"The PAS (Sanders, 1986) is a 27-item scale; subjects respond by checking one of the following categories using a 4-point Likert format: never, sometimes, frequently, almost always. The items

related to modifications of regulatory control, changes in self-monitoring, concealment from self and others, and modifications of sensory, perceptual, and affective experiences.

"The DES (Bernstein & Putnam, 1986) contains 28 items. Subjects indicate the percentage of time they experience the feelings or behavior described by the items on a 10-point scale. The items related to the experience of disturbances in identity, memory, awareness and cognition, and feelings of derealization or depersonalization" (pp. 202-203).

Results were as follows. The one-factor solution for the PAS accounted for 18.5% of the total variance.; 11 of the 28 items did not load significantly on the factor. The one-factor solution for the DES accounted for 26.3% of the total variance; 7 of the 28 items did not load significantly on the factor.

"The 3-factor solution obtained by Sanders (1986) for the PAS was not replicated. An obvious reason for the different is that principal factor extraction was used in the present study, whereas principal components extraction was utilized by Sanders. ... Even when principal components analysis is performed on the present data, however, there are difficulties with the 3-factor solution" (pp. 204-205). "All of the criteria suggest that a single factor best represents the latent structure of dissociative experience as measured by the PAS and DES. Although the total amount of variance accounted for is low, the one-factor solutions for both scales are interpretable, replicable, and have high internal consistency. The items for the PAS appear to represent primarily the affect and control dimensions, whereas those for the DES represent the cognitive dimension" (pp. 205-206).

"Overall, both scales contain similar items, although the DES has more items relating to disturbances in memory and altered perception of time (i.e., cognition), whereas the PAS has more items reflecting specific disturbances in identity and control. It appears, therefore, that the scales are measuring conceptually separate but statistically correlated dimensions of dissociation" (p. 206).

Kunzendorf, Robert G.; Jesses, Michael; Dupille, Leonard; Butler, William (1990-91). Subliminal activation of intrapsychic conflicts: Subconscious realms of mind vs subconscious processes of mentation. Imagination, Cognition and Personality, 10, 117-128.

## NOTES

Cognitive-state monitoring theory asserts that people perceive subliminal stimulation without self-consciously monitoring its external innervation (as opposed to central innervation). Thus monitoring theory predicts that subconsciously perceived discord, in the absence of any 'external location' cues, should be misinterpreted as centrally generated discord and should disrupt self-generated behavior. Consistent with this prediction, mathematical problem-solving in the current experiment was disrupted after mathematically competitive males repeatedly heard the subliminal message IT'S WRONG TO CRUSH DADDY stereophonically localized in the middle of their heads--but not after they repeatedly heard this subliminal 'Oedipal' message binaurally localized on one side of their heads. A subliminal message binaurally localized on one side of the self should not interfere with problem-solving behavior \_because, even though the message's external innervation is not self-consciously 'monitored,' its external location is inferable from subconscious cues.\_

Monitoring theory asserts that subliminal [perceptions] of 'unmonitored' messages are unaccompanied by any self-consciousness that one is perceiving them (rather than imaging them), and that subliminal or 'unmonitored' messages of distress are mistaken for self-generated distress.

Disruption by the 'internal' subliminal word WRONG seems to us consistent with the fact that disruption was limited to mathematically competent males.

Indeed, 'repression' itself is a mode of processing fearful information: a mode in which subjects suspend their self-awareness that they are perceiving fearful stimulation, as research by Kunzendorf and McLaughlin has demonstrated. This selective suspension of monitoring provides immediate relief from fearful stimuli, Freudian or otherwise, but it does so at the risk of turning self-conscious fear into

subconscious anxiety (into consciously lingering fear without a self consciously perceived source). No subconscious realm full of lurking fears is implicated in this 'unmonitored' mode of self-protection. All that is implicated is an unconscious storehouse of potentially fearful memories--potentially fearful but sensationless memories, which can be 'suppressed' from conscious sensory representation or 'constructed' into conscious memory images or 'subconsciously represented' as unself-consciously imaged sensations.

Macfarlane, F. K.; Duckworth, M. (1990). The use of hypnosis in speech therapy: A questionnaire study. British Journal of Disorders of Communication, 25, 227-246.

## NOTES

Reports results of a survey of speech therapists trained in the use of hypnosis. The majority use hypnosis in treating voice or fluency disorders to achieve relaxation and encourage self-esteem and also in the treatment of acquired neurological disorders. Respondents were less inclined to use hypnosis with children. Problems encountered in the use of hypnosis are explored.

1989

Pekala, Ronald J.; Bieber, Stephen L. (1989-90). Operationalizing pattern approaches to consciousness: An analysis of phenomenological patterns of consciousness among individuals of differing susceptibility. Imagination, Cognition and Personality, 9 (4), 303-320.

Pattern differences in subjective experience, as assessed by a self-report inventory, the Phenomenology of Consciousness Inventory (PCI), were compared across low, low-medium, high-medium, and high hypnotically susceptible individuals during hypnosis and eyes-closed. A hierarchical factor analytic approach was utilized that allowed for the determination of pattern differences among PCI dimensions as a function of hypnotic susceptibility. The factor analyses found that the four susceptibility (sic) groups were 'pattern equivalent' during eyes-closed, partially pattern dissimilar during hypnosis, and partially pattern dissimilar when comparing hypnosis against eyes-closed. The nature of these results support previous analyses (1) which compared pattern structure differences as a function of correlational matrices. The results suggest the complementarity of Bieber's (2) and Pekala's (3) approaches for assessing pattern differences in consciousness and are congruent with the theorizing of Tart (4), Izard (5), and the PDP researchers on the importance of pattern structure changes in understanding states of consciousness.

Pekala, Ronald J.; Kumar, V. K. (1989). Phenomenological patterns of consciousness during hypnosis: Relevance to cognition and individual differences. Australian Journal of Clinical and Experimental Hypnosis, 17 (1), 1-20.

Relationships among phenomenological subsystems of consciousness associated with a baseline condition and an hypnotic induction condition were compared across individuals of differing hypnotic susceptibility. Phenomenological experience on 12 subsystems of consciousness was quantified by means of the Phenomenology of Consciousness Inventory (PCI) and the relationships between dimensions were statistically assessed. The results replicated previous findings and suggested that hypnosis has differential effects upon the reported organization of phenomenological structures of consciousness across subjects of differing susceptibility. The data from the previous and present studies were pooled and the combined data were reanalyzed. The results provided further support for the differential pattern structure across low and high susceptibles during hypnosis. Furthermore, differences in pattern structure were augmented when comparing very low versus very high susceptible individuals.

1988

Nissen, Mary Jo; Ross, James L.; Willingham, Daniel B.; MacKenzie, Thomas B.; Schacter, Daniel L. (1988). Memory and awareness in a patient with multiple personality disorder. Brain and Cognition, 8, 117-134.

We studied an individual with multiple personality disorder in whom each of several personalities claimed to have no direct awareness of the others and to be unable to consciously remember the experiences of other personalities. A broad selection of implicit and explicit memory tests was used to determine the extent to which one personality had access to knowledge acquired by another and the circumstances in which that knowledge would be expressed. The implicit assessment of memory was a necessary but not sufficient condition for demonstrating interpersonality access. The degree of compartmentalization of knowledge in this patient depended largely on whether the interpretation of presented information was likely to differ across personalities.

1987

Baker, Elgan L.; Nash, Michael R. (1987). Applications of hypnosis in the treatment of anorexia nervosa. American Journal of Clinical Hypnosis, 29, 185-193.

Historic and current reports in the literature involving applications of hypnosis with anorectic patients are reviewed and integrated to explicate core aspects of hypnotic interventions in treating anorexia nervosa. A comprehensive hypnotherapeutic approach is delineated which emphasizes the use of hypnotic strategies to reduce tension, enhance self-control, support increased and realistic body awareness, alter distorted body image, and foster appropriate autonomy and individuation. Preliminary data are also reviewed which support the clinical efficacy of this approach.

## NOTES

Hypnosis is discussed in terms of inhibition/excitation mechanisms in the central nervous system, with both feedback and feedforward controls and lateralizing controls. The author employs a concept of engrams (neural representations of an idea, represented throughout the neocortex) to discuss sensation and perception as well as conscious and unconscious processes. Sensory information is processed serially with encoding of information mostly on the conscious level (but sometimes, less efficiently, on the unconscious level); and it also is processed in parallel. Parallel processing operates almost entirely at the unconscious level and is basic to perception.

Associative phenomena are explained in terms of overlapping engrams, so that two 'related hypercomplex engrams' could be assumed to have at least one simple engram in common. With Premack, he describes three types of engrams: veridical (primary sensory data perceived), abstract (formalized representations of concepts like line drawings of dog or house; Premack's iconic representations), and symbolic (more complex entities that encompass an entire class of objects, actions, or ideas and may have artificial symbols such as words).

With Neiser he suggests that thinking (verbal and nonverbal) involves logical sequential processing of cognitive engrams of external (environmental), internal (visceral), and intracerebral (ideational) origin. Evoked response investigations shed light on the nature of such engrams, their distribution in brain tissue. John, Bartlett, Slumokochi, & Kleiman (1973) found that an error in choice discrimination learning (cats learning colors) is accompanied by the cortical evoked potential of the stimulus

associated with that (erroneous) behavior, not the evoked potential of the true stimulus. In other words, ERPs represented the idea, not the actual visual stimulus provided to the cat.

Emotional/motivational influences are part of every cognition (R. S. Lazarus's position). Interaction of motivational-emotional and cognitive engrams seems to occur primarily in the inferior temporal lobe and the entorhinal cortex. The interaction involves the upper rhinencephalon, the amygdaloid-hippocampal complex, the septal region, the cingulate gyrus, and the inferior and medial aspects of temporal lobe of the cortex. He also explains classical and operant conditioning (on pp. 75-76) in terms of the association of engrams.

The author's position is that consciousness is the subjective equivalent of brain activity in the 'alerting' and 'awareness' systems. Awareness of the environment ('general, vague') appears to involve the limbic area (thalamus and basal ganglia), while more specific awareness of the self entails a system stretching from the basal ganglia through the parietal lobe (posterior aspect).

Normal alert consciousness involves the noradrenergic reticular activating system, as well as associated excitation of the general awareness system in the involved thalamic- basal gangliar nuclei and the self-awareness system in the posterior inferior parietal lobe system. Altered states of consciousness characterized by a relaxed hazy sense of the world involves thalamic activation of the self-awareness system. Dreaming involves activation from cholinergic cells in the pons. "Impaired general awareness occurs with lesions of the thalamic-basal gangliar centers while impaired self-awareness occurs with lesions in the posterior inferior parietal lobes. Finally, in certain physiological states such as sleep, hypnosis, and so on, the entire awareness system--the thalamic-basal gangliar and posterior inferior parietal nuclei--may be activated by different activation systems, such as the cholinergic in the pons or the dopaminergic in the thalamus, to produce different states of consciousness" (p. 82).

Consciousness is described as having seven dimensions: alertness, attention, arousal (heart rate, GSR), activation (EEG, evoked potential), affect, and the two awarenesses. The seven are related, so that changes in any one usually are correlated with changes in others (though dissociation among the seven also can be demonstrated). Motivational-emotional arousal produces electrophysiological activation of the brain, which is translated epiphenomenally into alertness and awareness; awareness is focused through attention onto the cognitively and motivationally significant events in the internal and external environments to determine the final sequence of drive-oriented behavioral responses. The EEG is useful for diagnosing different states of consciousness: beta and gamma waves alertness, stemming from locus coeruleus and reticular activating system delta (2-4/sec) waves coma alpha synchronized relaxing influences stemming from thalamus; low level of awareness as in twilight sleep or hypnagogic states theta, delta inactivity due to less stimulus from locus coeruleus reticular activating system influences; associated with increased inhibitory thalamic and septal- hippocampal impulses radiating upward to the cortex. In some altered states of consciousness there is theta-wave activity, indicating influences from the inhibitory septal-hippocampal circuit. The reticular activating system (RAS) and thalamus interact in complex ways. The RAS is essential to maintain consciousness, but if destroyed stepwise (in animal research) a low-grade type of consciousness can be maintained by thalamus and basal ganglia. The thalamus has two kinds of influence: it inhibits the cortex, as in sleep; and stimulates the cortex in the form of activating alpha waves. "The median thalamus is also related in a feedforward-feedback circuit with the inhibitory septal-hippocampal complex which generates theta-wave activity, thus accounting for the close association between alpha and theta wave activity in sleep and in other altered states of consciousness" (p. 86).

Thus there are two different activating systems originating in the lower brain stem: the norepinephrine locus coeruleus system that is associated with normal behavior, and the cholinergic FTG neurone system of REM sleep. The relationship of the latter to consciousness, awareness, self awareness, etc. is unknown, since the only time that it is readily observed is during REM sleep. The author reports that altered states of consciousness (e.g. hypnosis, fugue, alpha state) resemble Stage 1

sleep, rather than REM sleep, physiologically, with the central locus of activation in the medial thalamus rather than the RAS and locus coeruleus.

"It appears then that consciousness may be driven by one or another of three different activation centers: the norepinephrine RAS (emanating from the locus coeruleus), the cholinergic FTG cell system in the pons, and the dopaminergic alpha rhythm system radiating upward from the thalamus (Fig. 6-2). Brain activation by each of these centers is associated with a different state of awareness" (p. 91). The relative contribution from each center determines qualitative aspects of awareness.

The author refers to Mesulam and Geschwind (1978) who traced the self-awareness system from amygdala/hippocampus/midbrain to the inferior parietal lobe where they converge with the body's proprioceptive neural tracts. What results is "a sense of self that was not necessarily present in the sense of general awareness stemming from the median thalamic-basal gangliar complex" (p. 97).

The thalamic-basal gangliar complex is both a center for emotional reception and a relay station for somatosensory events. Both somatic sensory reception and somatosensory elements of emotion are also represented in the parietal lobe. "Affective and somatosensory stimuli, which are constant and persistent even though we are unaware of them most of the time, produce the sense of one's body which is the most basic element in the 'sense of self.'... It is most probable that a major component of the sense of self is produced by the constant barrage of affective and somatosensory stimuli converging from all parts of the body; the majority of these stimuli may not reach consciousness most of the time but they must register a sense of feeling in the thalamus and parietal cortex even though the individual may be unconscious of it" (p. 100).

The author presumes that most of the incoming stimuli that define self are unconscious. "Whether sense-of-self stimuli are unconscious because of constant habituation ... or whether they are unconscious because they are transmitted predominantly to the right hemisphere ..., it appears that the major components of the self-concept are unconscious rather than conscious" (p. 102).

"Even the acutely self-aware component of the self-concept, by definition conscious, varies markedly in different altered states of consciousness. The conscious awareness of oneself in the alert condition is different from (1) that in the twilight state, (2) that in dreams, (3) that in hypnosis, (4) that under the influence of alcohol, (5) that under the influence of other sedatives, (6) that under the influence of stimulants, and (7) that under the influence of hallucinogens. In that sense the acute sense of self is a function of the momentary chemical and physiological state of the brain" (p. 102).

"... the decision-making apparatus of the brain is lodged largely in a consortium of neocortical centers including the prefrontal lobes (integration), the posterior inferior lobes (motivation and emotion), the anterior and posterior associational areas (cognition), the posterior inferior parietal lobes (self-awareness), the left-hemispheric language centers (language), and the precentral frontal lobe motor area (motor). Within the context of this integrated cortical complex, self-awareness functions are somewhat stronger on the right hemisphere while language and decisional activities are somewhat stronger on the left" (pp. 102-103).

The Chapter titled "Attention as directed consciousness" is relevant for investigations of hypnosis but is not included in these notes.

Markus, Hazel; Nurius, Paula (1986). Possible selves. American Psychologist, 41 (9), 954-969.

The concept of possible selves is introduced to complement current conceptions of self-knowledge. Possible selves represent individuals' ideas of what they might become, what they would like to become, and what they are afraid of becoming, and thus provide a conceptual link between cognition and motivation. Possible selves are the cognitive components of hopes, fears, goals, and threats, and they give the specific self-relevant form, meaning, organization, and direction to these dynamics. Possible selves are important, first, because they function as incentives for future behavior (i.e., they are selves to be approached or avoided) and second, because they provide an evaluative and

interpretive context for the current view of self. A discussion of the nature and function of possible selves is followed by an exploration of their role in addressing several persistent problems, including the stability and malleability of the self, the unity of the self, self-distortion, and the relationship between the self-concept and behavior

1985

Kelly, Paul James (1985, November). The relationship between hypnotic ability and hypnotic experience (Dissertation). Dissertation Abstracts International, 46 (5), 1690-B.

"This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experiences were: dissociation, the experience of involuntariness, altered state effects, such as perceptual alterations and diminished reality sense rapport, transference-like involvement with the hypnotist, and relaxation. A 47-item scale, the Hypnotic Experience Questionnaire was developed to measure types of hypnotic experience. It was given to 484 subjects and then to a subsample of 272 students. When the scale was factored, four stable factors emerged: Nonconscious/Trance, Rapport, Relaxation, and Cognitive Rumination. A Group Profile Scale was also developed to measure students and when it was factor analyzed four factors were extracted: Hallucinations and Fantasies, Amnesias and Post-Hypnotic Compulsions, Motor Inhibition, and Direct Motor Suggestion. "Two statistical approaches were used to investigate the connections between hypnotic ability and hypnotic experience . Canonical analysis was used to identify the main relationships between hypnotic ability and hypnotic experience and factor analysis was used to explore the relationship among measures of hypnotizability and hypnotic experience. Two canonical variates from the canonical analysis were significant. The first variate was characterized by a dissociative-imaginative involvement process, and the second variate tapped a rapport-social compliance process. "When 25 variables, representing components of hypnotic ability and hypnotic experience, were factored, five factors were extracted. Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. The results of the factor analysis suggested that dissociative experience and altered state experience are related to hypnotic ability but rapport and relaxation are not. "The results of study, taken as a whole, suggest that relaxation and rapport may happen in the hypnotic situation, but neither experience is related to the condition of being hypnotized in any essential way. The results suggest that the hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. From a theoretical point of view, the results strongly supported Hilgard's theory, partially supported Shor's theory, and failed to support Edmonston's theory" (p. 1690).

Handelsman, Mitchell M. (1984). Self-hypnosis as a facilitator of self-efficacy: A case example. Psychotherapy, 21 (4), 550-553.

T

his article presents the four-session treatment of Elaine, using self-hypnosis to facilitate the mourning process. It is argued that self-hypnosis-- rather than enhancing imagery-- increases self-efficacy, a person's feeling that he/she can perform behaviors that lead to desired outcomes. Elaine's sense of self-efficacy was increased by allowing her to choose scenes from her life to be explored in the context of the use of imagery. Elaine imagined events surrounding her father's death, and "rewrote history" in an attempt to permit herself the direct expression of emotions.

Kelly, Paul James (1984, December). The relationship between hypnotic ability and hypnotic experience. Newsletter of Division 30, Psychological Hypnosis, of the American Psychological Association, 5.

This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experience were: dissociation, the experience of involuntariness; altered state effects, such as perceptual alterations and diminished reality sense; rapport, transference-like involvement with the hypnotist; and relaxation. A sample of 230 students was given the HGSHS:A, a group version of the SHSS:C, and the Hypnotic Experience Questionnaire (Kelly, 1984), a 47-item multidimensional scale of hypnotic experience. Items were taken from these tests to form 11 hypnotic ability variables (Positive Hallucinations, Dreams and Regressions, Post-Hypnotic Compulsions, Amnesia (HGSHS:A), Amnesia (SHSS:C), Arm Rigidity, Arm Immobilization, Other Motor Inhibitions, Head Falling, Moving Hands Together, and Hand Lowering). Fourteen hypnotic experience variables were also formed (Generalized Dissociative Effects, Dissociative Inhibition, Trance, Unawareness, Transference-like Involvement, Trust, Friendliness, Physical Relaxation, Mental Relaxation, Imagery Presence, Imagery Vividness, Imagery Detail, Self Consciousness, and Analytic Thoughts). The 25 variables were intercorrelated and factored with principal axis factoring. Five factors with eigenvalues greater than 1 were extracted and rotated to varimax criteria. These factors, which accounted for 54.4 percent of the variance, were called: Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. Hypnotic ability variables loaded significantly on three of the factors (Imaginative Involvement, Ideomotor Response, and Cognitive Inhibition) and these three factors also tapped some aspect of altered state experience and/or dissociative experience. It was concluded therefore that dissociative experience and altered state experience are related to hypnotic ability. The remaining two factors, Rapport and Relaxation, showed significant loadings only for rapport variables and relaxation variables, respectively. Neither of these two factors were related to any of the traditional measures of hypnotic ability or to the experience of dissociative effects or altered state effects. The results of this study suggest that rapport and relaxation may happen in the hypnotic situation but neither experience is related to the condition of being hypnotized in any essential way. The hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. The results also raise questions about Edmonston's (1981) theory that relaxation is the essence of hypnotic responsiveness. The finding that the experience of relaxation is unrelated to hypnotic ability is more congruent with Hilgard's (1977) view that relaxation is a nonhypnotic process.

#### NOTES

This is an abstract of an unpublished Ph.D. dissertation, University of Waterloo, 1984. It won the American Psychological Association Division 30 award for Best Student Paper at the 1984 APA Convention.

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott (1984). The direct hypnotic suggestion of altered mind/body perception. American Journal of Clinical Hypnosis, 27, 95-102.

Attentional and emotional shifts are examined following a hypnotically suggested out-of-body experience (OBE). Two hypotheses were tested: 1) that the OBE is maintained by blocking the perception of body-relevant stimulation at a sensory level; 2) that a hypnotically produced OBE is an emotionally neutral or even pleasant experience. Fourteen hypnotic subjects and 15 simulating Ss were administered a standardized induction followed by suggestions for an OBE. Geometric figures were then presented to the body but not to the "awareness." Although hypnotic Ss reported that they could not see the information, they still correctly "guess" the identity of the figures beyond chance levels. Thus, body-relevant information was obviously not blocked at a sensory level, but was kept out of awareness by some other mechanism. In addition, a significantly greater number of hypnotized than

simulating Ss reported the OBE to be troubling and unpleasant, despite explicit suggestions for a positive experience. The potentially disturbing nature of OBEs and ways to minimize risk of negative affect are discussed.

Pekala, Ronald J.; Kumar, V. K. (1984). Predicting hypnotic susceptibility by a self-report phenomenological state instrument. American Journal of Clinical Hypnosis, 114-121.

In an attempt to predict hypnotic susceptibility (as measured by the Harvard Group Scale of Hypnotic Susceptibility, HGSHS) the phenomenological experiences of an hypnotic induction (HI) procedure and a baseline comparison condition (eyes closed, EC, sitting quietly) were assessed. After each experience the subjects (n=217) completed the Phenomenology of Consciousness Inventory (PCI), a self-report phenomenological state instrument, dealing with that condition. Step-wise multiple regression and discriminant analyses were then performed on data using the subject's HGSHS score as the dependent variable and the PCI (sub)dimensions as the independent variables. Regression analyses that held up under cross-validation during HI suggest that the PCI may be an appropriate instrument for predicting susceptibility. The possible clinical usefulness of this approach is discussed.

## NOTES

This fourth volume of four has 9 sections, with chapters as follows. I. General Introductions to Hypnotherapy

1. The applications of hypnosis to psychiatry
2. Hypnosis in medicine
3. Hypnotic techniques for the therapy of acute psychiatric disturbances in war
4. Hypnotic psychotherapy
5. Hypnosis in general practice
6. Hypnosis: Its renaissance as a treatment modality
7. Hypnotic approaches to therapy II. Indirect Approaches to Symptom Resolution
8. A clinical note on indirect hypnotic therapy
9. The hypnotic and hypnotherapeutic investigation and determination of symptom- function
10. Experimental hypnotherapy in Tourette's Disease
11. Hypnotherapy: The patient's right to both success and failure
12. Successful hypnotherapy that failed
13. Visual hallucination as a rehearsal for symptom resolution III. Utilization Approaches to Hypnotherapy
14. Special techniques of brief hypnotherapy
15. Pediatric hypnotherapy
16. The utilization of patient behavior in the hypnotherapy of obesity: Three case reports
17. Hypnosis and examination panics
18. Experiential knowledge of hypnotic phenomena employed for hypnotherapy
19. The burden of responsibility in effective psychotherapy
20. The use of symptoms as an integral part of hypnotherapy
21. Hypnosis in obstetrics: Utilizing experimental learnings
22. A therapeutic double bind utilizing resistance
23. Utilizing the patient's own personality and ideas: 'Doing it his own way' IV. Hypnotherapeutic Approaches to Pain
24. An introduction to the study and application of hypnosis for pain control

25. The therapy of a psychosomatic headache
  26. Migraine headache in a resistant patient
  27. Hypnosis in painful terminal illness
  28. The interspersal hypnotic technique for symptom correction and pain control
  29. Hypnotic training for transforming the experience of chronic pain V. Hypnotherapeutic Approaches in Rehabilitation
  30. Hypnotically oriented psychotherapy in organic brain damage
  31. Hypnotically oriented psychotherapy in organic brain disease: An addendum
  32. An application of implications of Lashley's researches in a circumscribed arteriosclerotic brain condition
  33. Experimental hypnotherapy in a speech problem: A case report
  34. Provocation as a means of motivating recovery from a cerebrovascular accident VI. Hypnotherapy with Psychotics
  35. Hypnotherapy with a psychotic
  36. Symptom prescription for expanding the psychotic's world view VII. Sexual Problems Hypnotherapeutic Reorientations to Emotional Satisfaction
  37. Posthypnotic suggestion for ejaculatio praecox
  38. Psychotherapy achieved by a reversal of the neurotic processes in a case of ejaculatio praecox
  39. Modesty: An authoritarian approach permitting reconditioning via fantasy
  40. Sterility: A therapeutic reorientation to sexual satisfaction
  41. The abortion issue: Facilitating unconscious dynamics permitting real choice
  42. Impotence: Facilitating unconscious reconditioning
  43. Latent homosexuality: Identity exploration in hypnosis
  44. Vasectomy: A detailed illustration of a therapeutic reorientation VII. Self-Exploration in the Hypnotic State: Facilitating Unconscious Processes and Objective Thinking
  45. Pseudo-orientation in time as a hypnotherapeutic procedure
  46. Facilitating objective thinking and new frames of reference with pseudo-orientation in time
  47. Self-exploration in the hypnotic state
  48. Self-exploration in trance following a surprise handshake induction
  49. The reorganization of unconscious thinking without conscious awareness: Two cases of intellectualized resistance against hypnosis IX. Facilitating New Identity
  50. Psychological shocks and creative moments in psychotherapy
  51. Facilitating a new cosmetic frame of reference
  52. The ugly duckling: Transforming the self-image
  53. A shocking breakout of a mother domination
  54. Shock and surprise facilitating a new self-image
  55. Correcting an inferiority complex
  56. The hypnotherapy of two psychosomatic dental problems
  57. The identification of a secure reality
  58. The hypnotic corrective emotional experience
  59. The February man: Facilitating new identity in hypnotherapy

Horowitz, Mardi J. (1979). States of mind: Analysis of change in psychotherapy. New York NY: Plenum Medical Book Company. (Also published in London, England)

## NOTES

Provides a configurational analysis approach to describe problems, resources, and processes of change in psychotherapy. Uses psychoanalytic (ego psychology) model "that emphasizes information

processing and the structural aspects of self and object representations" (p. ix). The book provides methods for evaluating treatment outcome using increasingly precise ways of observing clinical material. As an example of how the author writes about states of mind, consider that "One could subject Hamlet to a description of his recurrent states of ambivalence, paralysis of action, deadly decisiveness, and pretense of gaiety or of madness; one could describe his various self-images and core models of role relationship, and explain his changes in state by the ways in which he processed information. Similarly, in a psycho-history one could plot the states, images, and information-processing styles of a person whose decisions interacted with important events" (pp. x-xi).

Spanos, Nicholas P.; Steggle, Shawn; Radtke-Bodorik, H. Lorraine; Rivers, Stephen M. (1979). Nonanalytic attending, hypnotic susceptibility, and psychological well-being in trained meditators and nonmeditators. Journal of Abnormal Psychology, 88 (1), 85-87.

Four groups of trained meditators differing in amount of meditation practice and a group of nonmeditators attended nonanalytically to a mantra in two meditation sessions. Subjects signaled intrusions into their attending, and were also assessed on several person variables. The four trained meditator groups differed from one another only in terms of self-esteem. When combined into a single group, meditators signaled fewer intrusions and reported "deeper" levels of meditating than nonmeditators. However, meditators and nonmeditators did not differ on hypnotic susceptibility, absorption, or indices of psychopathology.

1963

Fisher, S. (1963). Body image and hypnotic response. International Journal of Clinical and Experimental Hypnosis, 11, 152-162.

This study had 2 principal objectives: (a) To test the hypothesis that hypnotizability is negatively related to the definiteness of the individual's body image boundary, as measured by barrier and penetration scores derived from the Rorschach. (b) To ascertain what body image experiences are characteristic of the hypnotic state. Hypnotizability was evaluated with the Stanford Hypnotic Susceptibility Scale. In the male group only, hypnotizability was negatively correlated with boundary definiteness. Depersonalization proved to be the most characteristic body image change. Mellenbruch, P. L. (1962). The validity of a personality inventory tested by hypnosis. American Journal of Clinical Hypnosis, 5 (2), 111-114. (In Psychological Abstracts: 63, 5234)

## NOTES

The authors found that administration of the California Test of Personality in the waking and hypnotized state resulted in subjects describing themselves in a better light in the waking state than in the hypnosis condition. The differences were especially noted on the following scales: Self Reliance, Feeling of Belonging, Family Relations, and Occupation Relations. The scales least subject to distortion (in sense of presenting a good image) in waking state are Sense of Personal Worth and Freedom from Anti-Social Tendencies. J. Holroyd

Sutcliffe, J. P.; Jones, J. (1962). Personal identity, multiple personality, and hypnosis. International Journal of Clinical and Experimental Hypnosis, 10, 231-269. (Abstracted in Index Medicus, 63, Mar., S -543)

The concept of multiple personality is critically examined in the light of its historical development. Various conceptions of multiple personality are considered: as a diagnostic fashion, as a product of shaping in therapy, as a product of hypnotic suggestion, as simulation, and as an extension of characteristics found in "normal" personalities. These considerations lead to the conclusion that the significant alterations of personality characterizing the syndromes are loss of self-reference memories,

and confusions and delusions about particular identity in time and place. The parallels in multiple personality and hypnotic phenomena lead to the heuristic hypothesis that degrees of proneness to multiple personality are predictive of degrees of hypnotizability. ## **SELF HYPNOSIS**

**1996**

**Kohen, Daniel (1996). Relaxation/mental imagery (self-hypnosis) for childhood asthma: Behavioral outcomes in a prospective, controlled study. Australian Journal of Clinical and Experimental Hypnosis, 24 (1), 12-28.**

Twenty-eight 7-12-year-old children entered a controlled study of the effects of self-hypnosis on asthma. Asthma belief and behavioral inventories were collected before, and at one and two years after intervention. Asthma diaries were kept daily and mailed monthly. Subjects were randomly assigned to (a) experimental (self- hypnosis), (b) waking suggestion (no hypnosis), (c) attention placebo (no hypnosis or asthma discussion), or (d) traditional control groups. Twenty-four completed one-month follow-up, 16 completed six months, and 13 completed two years. Results included: (a) fewer emergency room visits in the experimental group ( $p<0.05$ ); (b) less school missed in the experimental group compared to the traditional control group ( $p<0.001$ ) and to the waking suggestion group ( $p<0.005$ ); (c) no differences in psychological evaluations between groups; and (d) surprising findings regarding hypnotic and hypnotic-like experiences among subjects.

**1995**

**Olness, Karen N.; Lee, Lai (1995, November). Effects of self-induced mental imagery on autonomic reactivity in children. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.**

## **NOTES**

One study that shows an IgA increase with hypnotic suggestion has been replicated and is in press. The present study emerges from work using hypnosis with biofeedback. Morgan's work with athletes has suggested the relationship between imagery and physiological activation. This has been observed clinically but not heretofore documented.

We are not using formal hypnosis. Each child was asked to think about being in a quiet place, doing exciting activities, baseline, etc. The children exhibited no neurological disorders, cognitive dysfunction, nor were they on medications at time of the study. We confirmed our clinical experience: there was an increase in pulse rate when imagery changed to activity. Skin temperature continued to go up during the period (despite imagery of being active like being on roller coaster). Skin conduction went down during baseline. EDA [electro dermal activities] was higher during active imagery. How do average daily thinking processes impact on autonomic changes over long periods of time? Do these changes affect cardiovascular status?

Clinically we observed that some children are more labile in different modalities, and under stress they react more in that system.

## NOTES

Training programs demonstrate that hypnotisability can be improved. Use individualized treatment programs. Cognitive behavioural treatment can be improved by hypnotic suggestions. Emphasis is on alertness and relaxation, not sleepiness; on conversation with the clinician rather than just listening. Emotional self regulation is the procedure studied most. They used three phases: Phase 1: Sensory recall exercises (smell, taste, heaviness provoked by lifting a book). Phase 2: Reproduce sensations (hand stiffness, smell) without therapist stimulus. Phase 3: Generalization. Any demand generates the suggested effects. (Tell Subject his brain is very activated, that he can respond without training. Give therapeutic suggestions.)

Case of nicotine addiction presented.

Stanton, Harry E. (1994). Self-hypnosis: One path to reduced test anxiety. Contemporary Hypnosis, **11**, 14-18.

Describes a self-hypnosis technique and its efficacy in reducing test anxiety. Forty high school students were matched on sex and anxiety scores and randomly allocated to an experimental group (receiving two 50-minute sessions, a week apart, to learn the self-hypnosis technique), and a control group (receiving two 50-minute sessions focused on ways of reducing test anxiety). Students were retested after the two sessions, and 6 months later. Results showed a significant reduction in anxiety scores only for the hypnosis group, which was maintained at 6-month follow-up.

1993

Page, Roger A.; Handley, George W. (1993). The use of hypnosis in cocaine addiction. American Journal of Clinical Hypnosis, **36**, 120-123

An unusual case is presented in which hypnosis was successfully used to overcome a \$50-0 (five grams) per day cocaine addiction. The subject was a female in her twenties. Six months into her addiction, she acquired a commercial weight-control tape that she used successfully to stop smoking cigarettes (mentally substituting the word "smoking"), as well as to bring her down from her cocaine high and allow her to fall asleep. After approximately 8 months of addiction, she decided to use the tape in an attempt to overcome the addiction itself. Over the next 4 months, she listened to the tape three times a day, mentally substituting the word "coke." At the end of this period, her addiction was broken, and she has been drug free for the past 9 years. Her withdrawal and recovery were extraordinary because hypnosis was the only intervention, and no support network of any kind was available.

Spiegel, David; Frischholz, Edward J.; Fleiss, Joseph L.; Spiegel, Herbert (1993). Predictors of smoking abstinence following a single-session restructuring intervention with self hypnosis. American Journal of Psychiatry, **150**, 1090-1097.

Examined the relation of smoking and medical history, social support, and hypnotizability to outcome with Spiegel's smoking-cessation program. A consecutive series of 226 smokers were treated with the single-session approach and followed up for 2 years. With a total abstinence criterion, 52% success was found after 1 week, and 23% abstinence at 2 years. Hypnotizability and having been previously able to quit smoking for at least a month significantly predicted the initiation of abstinence. Hypnotizability and living with a significant other person predicted 2-year maintenance. The results are superior to those of spontaneous efforts to stop smoking and suggest it is possible to predict which patients are most likely to respond and which patients are least likely to respond to such a brief intervention.

1992

Kostka, Marion (1992). Personal experience with 'Use of Hypnosis Before and During Angioplasty' [Letter]. American Journal of Clinical Hypnosis, 34, 281-282.

#### NOTES

Author read the article referred to after his/her heart attack and before angioplasty. Goal was to control preprocedure anxiety and assist by being relaxed and cooperative; also to be able to tolerate inflations of the balloon for as long as needed. Used self-hypnosis "and by the time I entered the laboratory my anxiety was under control. ... None of the physiological responses that can occur (i.e., nausea, pain, etc.) did occur and, for the most part, my postprocedure recovery was uneventful. ... Had two procedures because the artery again occluded. ... My cardiologist commented later that the time of inflation was longer than he had even attempted with any of his patients and he attributed this to my lack of symptoms. I felt this was due in part to the use of self-hypnosis. .... my subjective feeling was that both my discomfort and anxiety were minimal" (Pp. 281-82). No blood was sampled to measure catecholamine levels.

Mittleman, K. D.; Doubt, T. J.; Gravitz, Melvin A. (1992). Influence of self-induced hypnosis on thermal responses during immersion in 25 degrees C water. Aviation, Space & Environmental Medicine, 63, 689-695.

The efficacy of self-induced posthypnotic suggestion to improve thermogenic responses to head-out immersion in 25 degrees C water was evaluated in 12 males. An online computerized system permitted the change in body heat storage to be used as the independent variable and immersion time as the dependent variable. Two one-hour hypnotic training sessions were used. There were no differences in rates of heat production, heat loss, mean skin temperature, or rectal temperature between control and hypnotic immersions. Individual hypnotic susceptibility scores did not correlate with changes in thermal status. Ratings of perceived exertion during exercise were similar for both immersions, but perceived sensation of cold was lower during the second rest period of the hypnotic immersion. Three subjects used images of warm environments during their hypnotic immersion and lost heat at a faster rate than during control immersions. These results indicate that brief hypnotic training did not enhance the thermogenic response to cool water immersion.

Stanton, Harry E. (1992). Brief therapy and the diagnostic trance: Three case studies. Contemporary Hypnosis, 9, 130-135.

#### NOTES

He reviews very brief hypnotherapy, then writes, "A systematic way of encouraging people in the use of their inner resources to solve problems, the 'diagnostic trance', has been outlined by Havens and Walters (1989). People sit quietly, eyes closed, physically relaxed, concentrating upon the unpleasant sensations or feelings associated with their problem. By turning inward in order to focus upon these internal events, they tend to drift into a trance state.

"While mentally observing these unpleasant sensations, they describe, in a somewhat detached manner, the thoughts and images which are present in their minds. They make no effort to control these in any way, simply allowing associated memories to surface quite spontaneously. Usually they reveal a pattern of thinking, a series of images, or even a specific memory which is creating the problem. Sometimes these are in the form of visual images of previously forgotten incidents, usually of a traumatic nature. On other occasions they may take the form of a voice repeating a particular negative statement.

"Once people have been able to identify the source or sources of their unpleasant feelings, they attempt to find a thought or image which is sufficiently powerful to remove or displace the negative material. On many occasions, people find that they have the inner resources needed to solve their problem but, until given the opportunity provided by the diagnostic trance, they were unaware that they possessed these resources. However, the diagnostic trance procedure appears to encourage the spontaneous emergence of creative solutions" (p. 131).

Of the 103 patients with whom he used the procedure, "approximately 70% reported that it had helped them resolve the specific problem for which they had sought therapeutic assistance. ... In addition to being effective, the diagnostic trance is enjoyable, even when used to process past experience of an unpleasant nature. In its simplicity lies its strength. Patients find it easy to learn and, once they have gained confidence in its value as a problem-solving tool, often teach it to family members and friends" (p. 134).

1991

Brown, Jason W. (1991). Self and process: Brain states and the conscious present. New York: Springer-Verlag.

## NOTES

Author, from the Department of Neurology at New York University Medical School, presents a theory about the genetic unfolding of mental content (mind) through stages, from mental state into consciousness or into behavior. He relates the genesis of mind to brain development but avoids assuming that there is a straightforward correlation between brain development (e.g. myelination) and cognitive development or perception. To some degree, the theory is based on subjective report data and psychological symptoms. The author discusses issues that bear on the phenomena of nonvoluntary responding and dissociation that are reported or described by hypnotized persons.

"The nature of the mental state will determine the relation between self and world, and thus the interpretation given to agency and choice. ... The crossing of the boundary from self to world is a shift from one level in mind to another" (pp. 10-11). "... if we begin with mind as primary and seek to explain objects from inner states and private experience, the discontinuity between inner and outer evaporates: mind is everywhere, a universe. ... Whereas before we thought to perceive objects, now we understand that we think them" (p. 19).

"The concept of a stratified cognition is central to the notion of a mental state .... This entails an unfolding from depth to surface, not from one surface to the next, a direction crucial to agency and the causal or decisional properties of consciousness" (p. 52). By unfolding from depth to surface, he means from Core, through Subconscious, then Conscious Private Events, and finally Extra-Personal Space. He goes on to provide a definition of mental states. "A mental state is the minimal state of a mind, an absolute unit from the standpoint of its spatial and temporal structure. ... The state also has to include the prehistory of the organism. ... The concept of a mental state implies a fundamental unit that has gestalt-like properties, in that specific contents-- words, thoughts, percepts--appear in the context of mind as a whole (p. 53).

"The entire multitiered system arborizes like a tree, with levels in each component linked to corresponding levels in other components. For example, an early (e.g., limbic) state in language (e.g., word meaning) is linked to an early stage in action (e.g., drive, proximal motility) and perception (e.g., hallucination, personal memory) .... In sum, a description of the spatial and temporal features of a single unfolding series amounts to a description of the minimal unit of mind, the absolute mental state" (p. 54).

The author's discussion of an individual's physical movement relates to the concept of nonvoluntary movement (or movement without awareness of volition) in hypnosis. "More precisely, levels in the brain state constitute the action structure. As it unfolds, this structure generates the conviction that a

self-initiated act has occurred. This structure--the action representation--does not elaborate content in consciousness. ... As with the sensory-perceptual interface, the transition to movement occurs across an abrupt boundary. In some manner, perhaps through a translation of cognitive rhythms in the action to kinetic patterns in the movement, levels in the emerging act discharge into motor (physical) events" (p. 57).

"The self has the nature of a global image or early representation within which objects-to-be are embedded. ... The self is the accumulation of all the momentary cognitions developing in a brain configured by heredity and experience in a particular way (p. 70).

"The deposition of a holistic representation ... creates the deception of a self that stands behind and propagates events. The feeling of the self as an agent is reinforced by the forward thrust of the process and the deeper locus of the self in relation to surface objects. The self appears to be an instigator of acts and images when in fact it is given up in their formation. The self does not cause or initiate, it only anticipates (p. 70).

The foregoing notes cover only the first five chapters, less than half the book. Other chapters relevant to hypnosis would be those titled 'The Nature of Voluntary Action,' 'Psychology of Time Awareness,' 'From Will to Compassion,' and 'Mind and Brain.'

Stanton, Harry E. (1991). The reduction in secretarial stress. Contemporary Hypnosis, 8, 45-50.

30 secretaries from a large business firm were matched on their stress thermometer scores and one member of each pair was allocated at random to either an experimental group or a control group which discussed stress management procedures. The experimental group had two treatment sessions in which they learnt a technique of induction, deepening and ego-enhancement which included (1) physical relaxation; (2) mental calmness; (3) disposal of unwanted mental and physical 'rubbish'; (4) removal of a negative barrier; and (5) enjoyment of a special place. The stress thermometer was administered on two further occasions, one immediately after completion of the second training session and one as a follow-up 2 months later. In addition, on these two occasions, subjects completed anecdotal reports, recording their impressions of the experiment. After completion of this first stage of the study, control group secretaries experienced the same two treatment sessions as had the experimental group. Results indicated that stress level was significantly lower both immediately after treatment and at the two-month follow-up.

## NOTES

In addition to extensive research on self hypnosis, this book refers to a number of clinical investigations that involved self hypnosis with patients, as at least part of the treatment protocol: 1. J. R. Hilgard & LeBaron (1984) 34 patients, ages 4-1, with cancer pain 2. Spinhoven (1989) headache control; low back pain 3. Wakeman (1988) 50 patients with third degree burns (helping half of them to return to work in high temperature environments) 4. Katz, Kellerman, & Ellenberg - 36 children with acute lymphoblastic leukemia who needed to undergo bone marrow aspirations 5. Spiegel & Bloom (1983) - 54 women with metastasized carcinoma of the breast 6. Wark (1988) improving reading comprehension - 7 students 7. Aronson (1986) adolescent psychiatric inpatients 8. Swirsky-Sacchetti & Margolis (1986) severe hemophiliacs, reducing Factor VIII (the coagulant deficiency of hemophilia A) 9. Kohen, Olness, Colwell, & Heimel (1984) - 505 pediatric patients with a variety of problems (enuresis, pain, obesity, anxiety reactions, habit problems, encopresis, headache, fear of pelvic

examinations) 10. Anderson, Basker, & Dalton (1975) - migraine patients 11. Hammond, Watkins-Bartch, Grant, & McGhee (1988) compared self-directed and tape-assisted self-hypnosis in 48 Ss  
Plus many papers with single cases or just a few cases.

Lombard, Lisa S.; Kahn, Stephen P.; Fromm, Erika (1990). The role of imagery in self-hypnosis: Its relationship to personality characteristics and gender. International Journal of Clinical and Experimental Hypnosis, 38 (1), 25-38.

30 volunteer Ss practiced self-hypnosis for approximately 4 weeks and wrote a record of their experiences in a diary following each session. Imagery produced during self-hypnosis was coded in 2 ways: the imagery was either reality oriented or it was fantastic and had primary process qualities. Levels of imagery production remained virtually the same over a 4-week period. Self-hypnotic imagery was significantly greater for the female Ss than for the male Ss, particularly primary process imagery. Verbal expressivity (measured as the average number of words per page of each S diary) was calculated to control for the effects of verbal production on Ss' imagery scores. When imagery scores were standardized based on verbal expressivity, female Ss still produced significantly more primary process imagery than male Ss. Personality characteristics (assessed by standardized personality inventories) were examined in relation to self-hypnotic imagery. "Impulse Expression" was positively related to primary process imagery for the female Ss. "Outgoingness" was positively related to primary process imagery for the entire sample, but especially for the female Ss.

Spanos, Nicholas P.; Williams, Victoria; Gwynn, Maxwell I. (1990). Effects of hypnotic, placebo, and salicylic acid treatments on wart regression. Psychosomatic Medicine, 52, 109-114.

Subjects with warts on their hands and/or feet were randomly assigned to a hypnotic suggestion, topical salicylic acid, placebo, or no treatment control condition. Subjects in the three treated groups developed equivalent expectations of treatment success. Nevertheless, at the six-week follow-up interval only the hypnotic subjects had lost significantly more warts than the no treatment controls. Theoretical implications are discussed.

## NOTES

Study involved 15 females, 25 males (18-35 yrs old) with warts on at least one hand or foot, recruited through posters and newspaper ads; N = 10 in each condition. Hypnotic treatment consisted of 10 minute induction (modified from T. X. Barber's 1969 book) and a suggestion for wart regression that was 2 minutes in duration (the skin around warts was 'beginning to tingle and grow warm'; 'vividly imagine the warts shrinking and dissolving away'; 30 second break; repeated the suggestions). For Ss with warts on more than one limb the complete suggestion procedure was repeated for each wart-infected limb.

Results indicate psychological factors can influence course of some virally produced disorders; that self-medicating with over-the-counter products doesn't explain suggestion-induced wart regression; that expectation of treatment success is the most important variable in psychologically induced wart regression. "Hypnotic subjects attained significantly higher CURSS:S scores than did control subjects. Nevertheless, it is unlikely that between group differences in hypnotizability accounted for the group differences in wart regression. Two previous experiments (3) that used the CURSS found that hypnotizability failed to predict wart loss in either hypnotic suggestion, nonhypnotic suggestion, or placebo treatments, and even in the present study the hypnotic treatment failed to differ from either the real or placebo treatment on CURSS:S scores, and none of the treatments differed significantly on the CURSS:O scores. Our finding and earlier findings that hypnotic subjects reported more intense

suggested sensations than placebo subjects is consistent with the hypothesis that vivid suggested imagery facilitates wart loss (7, 8) .

"An alternative hypothesis emphasizes that only our hypnotic suggestion treatment encouraged subjects to see themselves as developing cognitive control over their own wart regression. This hypothesis suggests that subjects' subjective sense of cognitive involvement in and control over treatment outcome (as opposed to the vividness of their suggested imagery) may have been the important psychological factor in wart regression. It would be of interest in a future study to manipulate subjects' sense of cognitive involvement in their treatment independently of suggested imagery in order to assess the relative contributions of these variables to wart regression" (pp. 113-114).

Spiegel, David; Cardena, Etzel (1990, October). New uses of hypnosis in the treatment of posttraumatic stress disorder. Journal of Clinical Psychiatry (Supplement), 51, 39-43.

Vietnam veterans with PTSD and those abused as children have above average hypnotizability. Hypnosis provides controlled access to memories that may otherwise be kept out of consciousness. New uses of hypnosis with PTSD victims involve coupling access to the dissociated traumatic memories with positive restructuring of those memories. Hypnosis can be used to help patients face and bear a traumatic experience by embedding it in a new context, acknowledging helplessness during the event, and yet linking that experience with remoralizing memories, such as efforts at self-protection, shared affection with friends who were killed, or the ability to control the environment at other times. In this way, hypnosis can be used to provide controlled access to memories that are then placed into a broader perspective. Patients can be taught self-hypnosis techniques that allow them to work through and thereby reduce spontaneous, unbidden, intrusive recollections.

1989

Grant, Guy (1989, June). An investigation of hypnotic susceptibility in self-hypnosis and imagery (Dissertation, University of Utah). Dissertation Abstracts International, 49 (12), 5517-5518-B.

## NOTES

"There were two phases in the study. In Phase One hypnotic susceptibility scores were assessed for 43 graduate student subjects by the Harvard Group Scale of Hypnotic Susceptibility: Form A (HGS:SHS:A). In addition, the Self-Hypnosis Research Questionnaire (an experimental scale) provided performance scores for subjects under three hypnosis conditions: heterohypnosis, self-directed self-hypnosis, and tape-assisted self-hypnosis. The first purpose in Phase One was to calculate correlations between hypnotic susceptibility and each of the hypnosis conditions. The second purpose was to determine if there were significant differences across the three types of hypnosis. The third purpose was to discover if any existing differences were dependent on level (e.g., low, medium, or high) of hypnotic susceptibility. Analysis of the data yielded significant correlations between hypnotic susceptibility and (a) heterohypnosis, (b) self-directed self-hypnosis, and (c) tape-assisted self-hypnosis. There were significant performance differences across the three hypnosis conditions with heterohypnosis being somewhat superior to tape-assisted self-hypnosis, and tape-assisted self-hypnosis being slightly superior to self-directed self-hypnosis. This relationship held true regardless of level of hypnotic susceptibility (e.g., low, medium, and high).

"In Phase Two, 49 graduate student subjects were administered the shortened form of the Betts' Questionnaire Upon Mental Imagery (QMI) as well as the HGS:SHS:A, and to determine if mental imagery is an important component of hypnotic susceptibility. Analysis yielded a significant correlation between the two measures.

"Based on the current data, it was concluded that the HGSHS:A had some utility for predicting performance in hypnosis. It was noted that, as compared with self-hypnosis, heterohypnosis provided the greatest chance of eliciting a positive hypnotic response from subjects not trained or experienced in hypnosis. It was also concluded that the QMI was correlated with and had some utility for predicting performance on the HGSHS:A. It had difficulty, however, differentiating between low and medium hypnotizability" (pp. 5517- 5518).

Kahn, Stephen P.; Fromm, Erika; Lombard, Lisa S.; Sossi, Michael (1989). The relation of self-reports of hypnotic depth in self-hypnosis to hypnotizability and imagery production. International Journal of Clinical and Experimental Hypnosis, 37, 290-304.

Studied multidimensional nature of self-hypnotic depth in 22 high hypnotizables who volunteered for self hypnosis research. On personality scales, they were distinguished from the population at large by: strong theoretical orientation, high level of curiosity, disregard for opinions of others, and high Mf scale on the MMPI. Used the Stanford Profile Scale, SHSS:C and HGSHS:A, which measure the entire range of phenomena ordinarily used in experimental studies of hypnosis, including ideomotor phenomena, hypnotic fantasy and dreams, hypermnesias and age regressions, analgesias, negative and positive hallucinations, amnesias, posthypnotic phenomena, and cognitive and affective distortions. They asked Subjects to experience self hypnosis for 60 minutes/day for 4 weeks. Journals were coded for imagery production by scoring for both reality-oriented and primary process imagery. Subject had been taught to monitor their hypnotic depth using a slightly revised version of the Extended North Carolina Scale (ENCS) of Tart (1979). Previously, ENCS has been used only with hetero-hypnotic Subjects. The self- reports of depth using ENCS correlated highly with hypnotizability as measured by the Revised Stanford Profile Scale of Hypnotic Susceptibility... and with imagery production. Results demonstrate that ENCS scores are also a valid indicator of self-hypnotic depth among highly hypnotizable Subjects. Furthermore, they indicate that both hetero- hypnotizability and imagery production are related to self-hypnotic depth, but that the association between imagery and hypnotizability is due to their individual relationships to self-hypnotic depth.

Kunzendorf, Robert G. (1989-90). Posthypnotic amnesia: Dissociation of self-concept or self-consciousness?. Imagination, Cognition and Personality, 9, 321-334.

Two studies of posthypnotic amnesia tested predictions derived from the 'source' monitoring theory of self-consciousness. Experiment 1 tested the prediction that posthypnotic source amnesia is irreversible, because hypnosis attenuates self- consciousness of whether one's sensations have an imaginal source or a perceptual source. In this initial study, recall amnesia was reversed by posthypnotic cueing with a prearranged signal, but source amnesia was not reversed by such cueing. Experiment 2 examined whether the cued reversal of recall amnesia is attributable, in part, to the hypnotic attenuation of self-conscious 'source monitoring' and, in part, to the reversal of recall criteria: from a criterion rejecting 'seemingly imaginary' or 'sourceless' memories, to a criterion accepting 'sourceless but familiar' memories. In this latter study, posthypnotic recall amnesia was breached when subjects were instructed to trust their seemingly imaginary memories, but not when they were instructed to try harder to remember [emphasis removed from quoted text].

Meyer, H. K.; Diehl, B. J.; Ulrich, P. T.; Meinig, G. (1989). Changes in regional cortical blood flow in hypnosis. Zeitschrift fur Psychosomatische Medizin und Psychoanalyse, 35, 48-58.

NOTES

Regional cerebral blood flow (rCBF) was measured by means of the 133-Xenon inhalation method in 12 healthy male volunteers who had several months of experience in doing self-hypnosis (autogenic training). During hypnotically suggested right arm levitation, as compared to resting conditions, they found an increase in cortical blood flow and an activation of temporal areas; the latter finding was considered to reflect acoustical attention. In addition, a so-far-unexplained deactivation of inferior temporal areas was observed during successful self hypnosis and hypnosis. While there was a global absolute increase of cortical blood flow bilaterally, they could not observe a relative increase of the right as compared to the left hemisphere during hypnosis. Several subjects successfully performed the levitation of the right arm, despite a relative left hemispheric activation, provided the absolute right hemispheric activation remained dominant.

Moss, Barry F.; Magaro, Peter A. (1989). Personality types and hetero- versus auto-hypnosis. Journal of Personality and Social Psychology, 57, 532-538.

The Multivariate Personality Inventory (MPI; Magaro & Smith, 1981), the Harvard Group Scale of Hypnotic Susceptibility, and the Inventory of Self-Hypnosis (ISH; Shor, 1970) were used to investigate the relationship between personality style and hypnotic procedure in the determination of hypnotic susceptibility. On the basis of MPI scores, a normal college population was segregated into 5 personality styles: hysteric, manic, depressive, character disorder, and compulsive. The hysteric personality was found significantly more hypnotizable than the other personality types in the HGSHS induction context, whereas the compulsive personality was found significant more hypnotizability in the ISH induction context. Results are discussed in terms of personality and situational factors in relation to previous hypnotic susceptibility research.

Soskis, D. A.; Orne, E. C.; Orne, M. T.; Dinges, D. F. (1989). Self-hypnosis and meditation for stress management: A brief communication. International Journal of Clinical and Experimental Hypnosis, 37, 285-289.

In a 6-month follow-up study, telephone interviews were conducted with 31 male executives who were taught either a self-hypnosis or meditation exercise as part of a stress-management program. Use of and problems with the 2 exercises were similar, with the percentage of Ss using the techniques falling over 6 months from 90% to 42%. The exercises were used primarily for physical relaxation, refreshing mental interludes, aiding sleep onset, and stress-reduction. Problems with the exercises chiefly involved difficulty in scheduling even brief uninterrupted practice times and discomfort with the techniques. The incorporation of these issues into the clinical teaching of self-hypnosis may be useful.

Spiegel, David; Bloom, J. R.; Kraemer, H. C.; Gottheil, E. (1989, October 14). The beneficial effect of psychosocial treatment on survival of metastatic breast cancer patients: A randomized prospective outcome study. Lancet, 888-891.

The effect of psychosocial intervention on time of survival of 86 metastatic breast cancer patients was studied using randomized prospective design. The one-year treatment consisted of weekly supportive group therapy with training in self-hypnosis for pain management, and resulted in significant reductions in mood disturbance and pain. Both the treatment and control groups had routine oncologic care. At ten-year follow-up, only three of the original 86 patients were still alive, and death records were obtained for the other 83. Survival from the time of randomization and onset of intervention was 36.6 (sd = 37.6) months for the treatment group, compared with 18.9 (sd = 10.8) months for the control group, and this difference was highly significant ( $Z = 3.94$ ,  $p < .0001$ ) using the Cox life table regression model. Kaplan-Meier survival analysis indicated that the divergence in

survival began at 20 months after entry into the study, or 8 months after the treatment intervention ended. These unexpected findings suggest that intensive psychosocial support affects the course of the illness, although the mechanism by which it does so is not clear.

Spinhoven, Philip; Linssen, A. Corry (1989). Education and self-hypnosis in the management of low back pain: A component analysis. British Journal of Clinical Psychology, 28, 145-153.

Conducted a component analysis of a group program for chronic low back pain patients. 45 patients (aged 31-68 years) participated in the pain control course (PCC), consisting of education about pain and a training in self-hypnosis. A pain diary was used as a measure of pain intensity, up-time, and use of pain medication. Psychoneuroticism and depression were assessed using the Symptom Checklist-90 (SCL- 90) scores. No evidence was found for a differential efficacy of education or self-hypnosis on pain diary and SCL-90 scores. Subjects showed significant changes on all measures except reported pain intensity. It is suggested that the PCC is a noninvasive, inexpensive means of treatment that could be used to teach even more severely disabled low back pain patients to cope more adequately with their pain problem.

Hammond, D. Corydon; Haskins-Bartsch, Catherine; Grant, Claude W.; McGhee, Melanie (1988). Comparison of self-directed and tape-assisted self-hypnosis. American Journal of Clinical Hypnosis, 31, 129-137.

Previous research on self-hypnosis has concentrated on the relationship between heterohypnosis and either self-directed self-hypnosis or self-initiated self-hypnosis. Despite widespread use of audiotapes to assist the process of self-hypnosis, no previous research has compared tape-assisted and self-directed self-hypnosis. Forty-eight inexperienced volunteers were hypnotized and taught self-hypnosis by posthypnotic suggestion and immediate practice in the office. They were randomly assigned to one of two experimental orders to practice self-directed and tape-assisted self-hypnosis. No differences were found between heterohypnosis or either type of self-hypnosis in response to behavioral suggestions. Experiential ratings, however, consistently favored heterohypnosis over either type of self-hypnosis. Tape-assisted self-hypnosis was consistently evaluated as superior to self-directed practice by newly trained subjects.

## NOTES

The tapes were more or less identical with the in-office hypnosis, including voice of the hypnotist, except that those doing self-directed self hypnosis received a posthypnotic suggestion for how to enter hypnosis by themselves. (All Subjects received written instructions to remind them about the procedures for home practice.)

When self hypnosis was evaluated, use of a tape produced greater concentration and absorption, less distraction, greater subjective depth, greater perception of nonvoluntary response to suggestion, and more changes in body perception (e.g. loss of awareness of the body, feelings of heaviness or of floating). Therefore, the tape-assisted experience could be viewed as more convincing to the Subjects. People tended to fall asleep more when they did self-directed self hypnosis than when they used a tape. However, people enjoyed heterohypnosis more than either self hypnosis experience, and reported more nonvoluntary experiences. The more positive response to heterohypnosis replicates research by Johnson et al. (1983), in which preceding self-hypnosis by a heterohypnosis induction may results in less positive experiences with the self-directed self hypnosis.

In their Discussion, the authors note that finding no differences between self hypnosis and heterohypnosis in the number of behavioral suggestions successfully passed replicates earlier research (Shor & Easton, 1973; Ruch, 1975; Johnson, 1979; Johnson, Dawson, Clark, & Sikorsky, 1983).

"Thus, our present study has replicated previous findings concerning the relationship of heterohypnosis and self-directed self-hypnosis. In clinical practice, it appears that a heterohypnosis experience virtually always precedes training in self-hypnosis. Our findings and those of the Johnson (1983) study suggest, however, that generally patients will experience self-hypnosis as significantly less powerful than their previous office experience. But, by using a tape to assist the patient in initial practice, the discrepancy between the quality of the experiences appears reduced. It should be noted that Johnson et al. (1983) provide the innovative suggestion that there may be something gained by having self-hypnotic instruction and practice precede a hypnotic experience by a therapist. Initial self-hypnotic experience may create a mental set of being more actively involved" (p. 136).

"However, we know nothing about how tape-assisted vs self-directed experiences are perceived by Ss with more self-hypnotic and heterohypnotic experience, and particularly if they are utilizing the same tape recording(s) over and over again. Other research (Hammond, 1987) recently followed up premenstrual syndrome patients who were trained in self-hypnosis. In this study, patients showed a clear preference for using tapes to assist them in self-hypnosis shortly after initial training. However, on 6-month follow-up, patients were found to be utilizing self-directed self-hypnosis much more frequently than tapes, with which they may have become somewhat bored. The issue of boredom has thus far not been adequately addressed in the self-hypnosis literature" (p. 136).

Meyer, von H. K.; Diehl, B. J. M.; Ulrich, P.; Meinig, G. (1987). Kurz- und langfristige Änderungen der kortikalen Durchblutung bei Autogenem Training [Short and long-term changes in cortical circulation caused by autogenic training]. Zeitschrift für Psychosomatische Medizin und Psychoanalyse, 33 (1), 52-62.

Zwölf gesunde junge Männer, die seit mindestens einem halben Jahr Autogenes Training praktizierten, wurden mit der 133-Xenon-Methode untersucht. Dem Muster der kortikalen Ruhedurchblutung fehlte die aus der Literatur bekannte Hyperfrontalität, was auf eine langfristig durch Übung verminderte Aktivierung hinweisen konnte. Für gut realisiertes Autogenes Training wurden einerseits Bereiche des Homunkulus (pra- und postrolandische Zentralwindung) aktiviert und andererseits Regionen desakiviert, die mit akustischer Aufmerksamkeit und autonomen Funktionen verknüpft sind. Die niedrige linkshemisphärische Durchblutung in Ruhe und die relative Aktivierung der linken Hemisphere unter Autogenem Training werden diskutiert.

English Summary.

The well-known hyperfrontal pattern of hemispheric blood flow measured with 133-Xenon is not found in 12 healthy resting men who have been practicing Autogenic Training at least six months. This might indicate a long-term decrease in the level of activation. Successfully practiced exercises of Autogenic Training lead to an increased blood flow in the Rolandic area representing the body scheme (sic) and to a decreased blood flow in regions related to acoustical attention and to autonomic

functions. Left hemispheric cerebral blood flow is lower in rest. The relative activation of the left hemisphere during Autogenic Training is discussed.

Aronson, David M. (1986). The adolescent as hypnotist: Hypnosis and self-hypnosis with adolescent psychiatric inpatients. American Journal of Clinical Hypnosis, 28 (3), 163-169.

This paper describes the theoretical rationale, pragmatic implementation issues, and procedure for a particular technique of clinical hypnosis which is designed as an adjunctive therapy within a multidisciplinary adolescent inpatient treatment program. A model of combined auto- and heterohypnosis which features collaborative production of audiocassettes is presented. Advantages and indications for this technique are discussed, and a case study is presented. - Journal Abstract

Markus, Hazel; Nurius, Paula (1986). Possible selves. American Psychologist, 41 (9), 954-969.

The concept of possible selves is introduced to complement current conceptions of self-knowledge. Possible selves represent individuals' ideas of what they might become, what they would like to become, and what they are afraid of becoming, and thus provide a conceptual link between cognition and motivation. Possible selves are the cognitive components of hopes, fears, goals, and threats, and they give the specific self- relevant form, meaning, organization, and direction to these dynamics. Possible selves are important, first, because they function as incentives for future behavior (i.e., they are selves to be approached or avoided) and second, because they provide an evaluative and interpretive context for the current view of self. A discussion of the nature and function of possible selves is followed by an exploration of their role in addressing several persistent problems, including the stability and malleability of the self, the unity of the self, self- distortion, and the relationship between the self-concept and behavior

McConkey, Kevin M. (1986). Opinions about hypnosis and self-hypnosis before and after hypnotic testing. International Journal of Clinical and Experimental Hypnosis, 34, 311-319.

Before hypnotic testing, Ss completed a questionnaire on their opinions about hypnosis and self-hypnosis. Approximately 1 week later, they completed a similar questionnaire that included questions about their experiences of hypnotic testing. Data are presented concerning Ss' agreement with statements about hypnosis and self-hypnosis. Findings are discussed in terms of their generality and in terms of whether Ss' opinions are consistent with scientific evidence.

Swirsky-Sacchetti, Thomas; Margolis, Clorinda G. (1986). The effects of a comprehensive self-hypnosis training program on the use of factor VIII in severe hemophilia. International Journal of Clinical and Experimental Hypnosis, 34, 71-83.

Hemophilia, the bleeder's disease, is characterized by internal bleeding episodes which have been associated anecdotally with psychological stress. The focus of the present investigation was to study the potential utility of a comprehensive self- hypnosis training program to decrease stress and to assess the amount of clotting factor used for bleeding by those individuals trained in self-hypnosis compared to a control group. 30 severe hemophiliacs on home therapy were randomly assigned to a treatment or to a waiting list control group. The treatment group received a comprehensive 6-week training program including support, education, deep relaxation, and self-hypnosis. Over the 18-week follow-up, the treatment group significantly reduced the amount of factor concentrate used to control bleeding in

comparison to controls. The treatment group also significantly reduced general distress level as measured by a symptom checklist. The training was extremely cost effective, and the results support the efficacy of this comprehensive training program to augment the medical management of severe hemophiliacs on a home therapy regimen.

## NOTES

The authors begin with a discussion of the importance of being able to reduce the amount of blood factor concentrate required by hemophiliacs, including the problems of obtaining uncontaminated blood in an era of HTLV-III and LAV contamination and the fact that some patients with Hemophilia A have developed antibodies to Factor VIII (so-called inhibitor patients). When an inhibitor patient hemorrhages, it is potentially life-threatening. Earlier controlled clinical research by LaBaw (1975) indicated that hypnosis might be useful for decreasing blood usage. The current study builds upon that research and adds further control procedures.

The hypotheses of this study were: "(a) hemophiliacs who received the comprehensive training program including self-hypnosis along with education, support, and relaxation for stress management would significantly reduce the amount of factor concentrate used to control spontaneous bleeding in comparison to randomly assigned waiting list controls; (b) the general distress level, as measured by the SCL-90 (Derogatis, 1977), would significantly decrease for the treatment group from pretraining to follow-up; and (c) hypnotizability as measured by the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. C. Orne (1962) would show a positive correlation with the treatment effect" (p. 74).

The Subjects were patients of a hematologically severe status (less than 1% clotting factor present in the blood); ages 11-50, mean age 30; normally distributed on socioeconomic variables; and prescreened to rule out serious psychological dysfunction. The treatment and control groups did not differ in SES or pretest bleeding severity. Control Ss were informed that they would receive the same training after the initial follow-up period. Three Ss were lost from the treatment group because they did not complete the 6 weekly self-hypnosis training sessions, and three from the control group due to geographic move or decision to obtain treatment elsewhere.

Patients recorded their factor usage on log sheets, and their reports were checked with distribution records kept at the clinic. (Factor received during hospital stays was not included. Also 3 "inhibitor" patients--2 treatment, 1 control--were removed from some analyses because they must infuse Factor IX at a level that far exceeds the amount appropriate for body were an inhibitor not present.)

The Ss, in groups of 3-4 people, were educated about the effects of stress on bleeding, physiological signals of overstress, and then trained as a group in self-hypnosis. Each training session began with a group hypnosis induction followed by various suggestions and imagery. They were given a cassette tape with suggestions for decreased bleeding, ego-strengthening, relaxation, and sensations of floating. In addition to listening to the tape at least once each day, they were taught rapid (1-2 minute) inductions to combat stress, and were to develop their own self-hypnosis procedure.

In terms of results, 9 of 11 (82%) treatment Ss and 4 of 10 (40%) control Ss decreased in blood factor usage ( $p < .05$ ). There was a great deal of variability between Subjects. While the treatment group demonstrated an overall decrease in factor usage, the control group actually had an overall increase in usage. The authors speculate that possibly a change in season caused the increase, because several Ss reported that a change in season ordinarily caused an increase due to their arthritic joints. Also, a change to warmer weather might have led to increased physical activity. General distress, measured by General Severity Index of the SCL-90, was reduced significantly for the treatment group. (Results of SCL-90 aren't reported for control group.)

The third hypothesis was not supported. In fact, the correlation between HGSHS:A and treatment effect was in the opposite direction from what was expected ( $- .25$ , n.s.). However, "there was a significant correlation ( $\rho = .56$ ,  $p < .025$ ) between Ss' self-reported trance usage and change scores,

indicating that those Ss who practiced self-hypnosis more were more likely to have decreased factor usage. There was also a trend ( $\rho = .44, p < .10$ ) between treatment Ss' change scores and their initial distress levels (GSI), suggesting that those Ss who were initially more distressed tended to profit more from treatment" (pp. 78-79).

In their Discussion, the authors suggest that the fact that the treatment effect of decreased factor usage was consistent throughout the follow-up period suggests that reduced usage was not due to a placebo effect. They note that placebo responses are usually brief, and situation-specific (Frank, 1976). They see the need for further research to clarify which component(s) of the treatment program are effective (self-hypnosis, relaxation, education, social support), and to extend the length of follow-up period. Since hypnotizability did not correlate with outcome, the results might be due to some other component. Since outcome did correlate with amount of self hypnosis practice, motivation may be an important determiner of effect.

Decreased stress was not only reported by Ss but also reflected in changes on the test scores (SCL-90). Also, several Ss spontaneously used the self hypnosis for school and occupational performance, and to relieve headaches. In terms of financial benefits, "the one patient who had the most significant decrease in factor usage noted an average monthly savings of \$850. For the entire treatment group (including those few Ss whose factor usage increased), the training resulted in savings of \$1240 per month over the follow-up period" (p. 81).

1985

Olness, Karen N.; Conroy, Mary Margaret (1985). A pilot study of voluntary control of transcutaneous PO<sub>2</sub> by children: A brief communication. International Journal of Clinical and Experimental Hypnosis, 33, 1-5.

This pilot study took place to determine whether or not children could voluntarily change tissue oxygen as measured by a transcutaneous oxygen monitor. It tested 2 hypotheses: (a) children can voluntarily change tissue oxygen as reflected by a transcutaneous oxygen monitor and (b) children, experienced in use of self-hypnosis exercises, will be able to change tissue oxygen to a greater degree than children unfamiliar with such exercises. 11 children between the ages of 7 and 17 year were studied. 8 children were previously experienced in the use of self-hypnosis; 3 were not. A Novamatrix transcutaneous O<sub>2</sub>/CO<sub>2</sub> monitoring system provided a constant read-out of PO<sub>1</sub>, PCO<sub>1</sub> and local perfusion. After stabilization, children were asked to attempt increases of oxygen. 9 children increased tissue oxygen significantly. Of those, 8 children had previous self-hypnosis training. 1 had not. Only 2 children with no previous self-hypnosis training were unable to change oxygen values. This pilot study upholds both hypotheses; however, it does not conclude that self-hypnosis mediated the changes noted or that self-hypnosis would be essential to success in voluntary control of tissue oxygen.

1984

Fogel, Barry S. (1984). The 'sympathetic ear': Case reports of a self-hypnotic approach to chronic pain. American Journal of Clinical Hypnosis, 27 (2), 103-106.

Secondary gain issues may limit the success of hypnotherapeutic approaches to chronic pain. A self-hypnotic suggestion that promotes patients' awareness of the interpersonal aspects of their pain complaints was used in the treatment of two patients with chronic headache. Hypnotic suggestions that help make secondary gains conscious may be a useful addition to hypnotic techniques of pain management.

Handelsman, Mitchell M. (1984). Self-hypnosis as a facilitator of self-efficacy: A case example. Psychotherapy, 21 (4), 550-553.

This article presents the four-session treatment of Elaine, using self-hypnosis to facilitate the mourning process. It is argued that self-hypnosis-- rather than enhancing imagery-- increases self-efficacy, a person's feeling that he/she can perform behaviors that lead to desired outcomes. Elaine's sense of self-efficacy was increased by allowing her to choose scenes from her life to be explored in the context of the use of imagery. Elaine imagined events surrounding her father's death, and "rewrote history" in an attempt to permit herself the direct expression of emotions.

Kohen, D.; Olness, K.; Colwell, S.; Heimel, A. (1984). The use of relaxation-mental imagery (self-hypnosis) in the management of 505 pediatric behavioral encounters. Journal of Developmental and Behavioral Pediatrics, 5, 21-25.

This report assessed outcomes of hypnotherapeutic interventions for 505 children and adolescents seen by four pediatricians over a period of one year and followed from four months to two years. Presenting problems included enuresis, acute pain, chronic pain, asthma, habit disorders, obesity, encopresis, and anxiety. Using strict criteria for determination of problem resolution (e.g., all beds dry) and recognizing that some conditions were intrinsically chronic, the authors found that 51% of these children and adolescents achieved complete resolution of the presenting problem; an additional 32% achieved significant improvement, 9% showed initial or some improvement; and 7% demonstrated no apparent change or improvement. Children as young as three years of age effectively applied self-hypnosis techniques. In general, facility in self-hypnosis increased with age. There was an inverse correlation ( $p$  less than 0.001) between clinical success and number of visits, suggesting that prediction of responsivity is possible after four visits or less.

#### NOTES

Discusses the treatment of 505 pediatric patients with a variety of problems(enuresis, pain, obesity, anxiety reactions, habit problems, encopresis, headache, fear of pelvic examinations).

Smith, Mark Scott; Kamitsuka, Michael (1984). Self-hypnosis misinterpreted as CNS deterioration in an adolescent with leukemia and Vincristine toxicity. American Journal of Clinical Hypnosis, 26 (4), 280-282.

A thirteen year-old girl with leukemia was taught self-hypnosis techniques for symptom control. She was hospitalized with probable vincristine toxicity and a superimposed hyperventilation syndrome. Her spontaneous use of the self-hypnosis technique was misinterpreted as central nervous system deterioration until her apparently comatose state resolved with suggestions from the therapist.

#### 1983

Johnson, Lynn S.; Dawson, Steven L.; Clark, Janet Lee; Sikorsky, Catherine (1983). Self-hypnosis versus hetero-hypnosis: Order effects and sex differences in behavioral and experiential impact. International Journal of Clinical and Experimental Hypnosis, 31, 139-154.

Recent studies (Fromm, Brown, Hurt, Oberlander, Boxer, & Pfeifer, 1981; Johnson, 1979, 1981; Johnson & Weight, 1976; Ruch, 1975) of self-hypnosis versus hetero-hypnosis are compared. A study is reported addressing unresolved questions about interactions between order of presentation and sex with the 2 types of hypnosis. 90 male and 149 female volunteer college students were proportionally assigned to 1 of 4 groups, each of which received 1 of the following hypnosis-order combinations on successive days: self hypnosis, then hetero-hypnosis; hetero-hypnosis, then self-hypnosis; self-hypnosis, then another self-hypnosis; or hetero-hypnosis, then another hetero-hypnosis. Half of each

group of Ss had a male hypnotist; half had a female hypnotist. Analysis of variance of total scores for behavioral and experiential impact showed: (a) a general order effect, a decrease from first to second experience; (b) initial self-hypnosis to facilitate either subsequent experience, mitigating the general decrement; (c) switching modes to also reduce the decrement; (d) a clarification of certain order and sex interactions from earlier studies; (e) self-hypnosis to be behaviorally superior to hetero-hypnosis on later presentations; and (f) crossed-sex training to be experientially facilitatory. Conclusions are drawn about unresolved issues in self hypnosis research, including the limits of comparability of self-hypnosis versus hetero-hypnosis, which depend on definitional assumptions of the self-hypnosis state and the allowance for order effects in the design.

## NOTES

In their Discussion, the authors note that self hypnosis and heterohypnosis yield similar results, and that although clinical hypnosis effects may increase with practice, such would probably not be true for hypnosis in the experimental setting. They speculate that "self-hypnosis triggers an 'active involvement' which provides more continuity in responsiveness across experiences, while hetero-hypnosis encourages a more passive mode which is more susceptible to external events (like order effects)" (p. 150).

1982

Brown, Daniel P.; Forte, Michael; Rich, Philip; Epstein, Gerald (1982-83). Phenomenological differences among self hypnosis, mindfulness meditation, and imaging. Imagination, Cognition and Personality, 2 (4), 291-309.

A survey of 122 subjects was conducted to investigate the differences in the phenomenological quality of the experiences engendered by three types of awareness discipline: self-hypnosis (21 Ss), waking dreaming (49 Ss) and mindfulness meditation (25 Ss from a 2-week retreat, and another group of 27 Ss from a 2-day weekend retreat). A questionnaire, the profile of Trance, Imaging, and Meditation Experience (TIME) was used in the survey. Discriminant analyses were used to construct models of the differences in the phenomenological quality of the experiences among the three groups. A number of phenomenological dimensions, in the major areas of attention, thinking, memory, imagery, body sensations, emotions, time sense, reality sense, and sense of self, were found which could accurately distinguish among the experiences of practitioners of the three types of awareness training. Results show that while self hypnosis involves self-referential thinking, memory changes, and intense emotions, waking dreaming emphasizes the immediate impact of emerging images, which unfold in a thematic manner and have a sense of their own reality. Mindfulness meditators have difficulty managing distractions, but with experience learn greater awareness of bodily processes, and experience changes in the perception of time and self; mental processes seem to slow down, and awareness assumes an impersonal quality. No attributions as to the causes or sources of these phenomenological differences are made, as the survey was not large enough to provide comparison groups, subject matching, or other statistical controls necessary for causal analyses.

## NOTES

(Information taken from a pre-publication manuscript.)

1981

romm, Erika; Brown, Daniel P.; Hurt, Stephen W.; Oberlander, Joab Z; Boxer, Andrew M.; Pfeifer, Gary (1981). The phenomena and characteristics of self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 189-247.

Self-hypnosis and hetero-hypnosis were compared, and self-hypnosis was studied longitudinally. Results indicated that absorption and the fading of the general reality orientation are characteristics of both hetero-hypnosis and self-hypnosis. The differentiating characteristics lie in the areas of attention and ego receptivity. Expansive, free-floating attention and ego receptivity to stimuli coming from within are state-specific for self-hypnosis, while concentrative attention and receptivity to stimuli coming from one outside source--the hypnotist on whom the subject concentrates his attention--are state-specific for laboratory defined hetero-hypnosis. Attempts to produce age regression and positive or negative hallucinations are markedly more successful in hetero-hypnosis. Imagery is much richer in self-hypnosis than in hetero-hypnosis. Self-hypnosis requires adaptation to the state: in the beginning of self-hypnosis there is a good deal of anxiety and self-doubt. As the subject feels more comfortable in the self-hypnotic state, he spends less time worrying about failures in self-suggestion, his ability to enter trance quickly and easily increases, as does the fading of the general reality orientation, trance depth, and absorption. An attempt was also made in the present study to find personality characteristics related to the ability to experience self-hypnosis.

Gardner, G. G. (1981). Teaching self-hypnosis to children. International Journal of Clinical and Experimental Hypnosis, 29, 300-312.

Hypnotherapy with children increasingly includes teaching self-hypnosis in order that young patients may make the fullest possible use of their hypnotic talent. This paper discusses indications and contraindications, reviews issues of patient resistance and parental involvement, and describes in detail Gardner's 3-step method of teaching self-hypnosis to children.

#### NOTES

Table 1 lists the problems treated by self-hypnosis in children aged 3-20 years as: anxiety, asthma, bleeding disorders (hemophilia), body cast immobilization, burns and burn therapy, depression, drug abuse, enuresis, functional megacolon, hair-pulling, helpless feelings, insomnia, learning difficulties, muscle spasm, nausea, pain, poor self-esteem, psychogenic seizures, stuttering, tension. The author lists references discussing the use of self hypnosis with each of these problem areas.

Houston, Rodney Earl (1981). The effects of autohypnosis, imagery, or single suggestion on pain threshold and tolerance (Dissertation, University of Cincinnati). Dissertation Abstracts International, 42 (5), 1961-A.

#### NOTES

Pain threshold, pain tolerance, and subject's subjective opinion of the pain were studied in 94 volunteer subjects (75 female, 19 male), who had been randomly assigned to three treatment groups (self hypnosis, in-vivo imagery, single suggestion) and a control group. (The original randomized sample included 124 Ss, but 30 were lost to the study-- 22 because of initial baseline scores being above maximum, 2 after reading the consent form, and 6 not returning for post-testing.) Mean age was 25; age range was 18-59 years.

The pain stimulus was 33 degree F. ice water in which the dominant hand was submerged for as long as the subjects were able. Subjects were told to nod when pain was first felt (threshold), and remove their hand when the pain was more than they could tolerate (tolerance). They were then asked to rate the pain on a 7-point scale, from 'none' to 'extreme.' Thus the three outcome measures were threshold time, tolerance time, and degree of perceived pain.

During the week between pretesting and posttesting, the self hypnosis group was to listen to a tape training them in self hypnosis at least twice; the imagery group was to listen to their imagery training tape at least twice; the simple suggestion group received no training. Posttesting was the same as

pretesting, except that the simple suggestion group was given the single waking suggestion, "You will be able to withstand the pain much longer this time."

The experimental predictions were that treatment groups would increase in threshold levels and tolerance levels more than the control group; and that the treatment groups would decrease more than the control group in reported pain level. Multivariate analysis of variance of difference scores (pre- to posttest) demonstrated significant differences on the three dependent measures when comparing the three treatment groups to the control group. " Significant differences were also found when comparing treatment groups, autohypnosis and imagery to those given the single suggestion. No significant differences were found when comparing the autohypnosis to the imagery treatment.

"The results indicate that training in autohypnosis and in-vivo imagery has an effect on threshold, tolerance and pain levels. The results also indicate that the use of a single suggestion may not have an effect on threshold, tolerance, and pain levels" (p. 1961).

Sacerdote, Paul (1981). Teaching self-hypnosis to adults. International Journal of Clinical and Experimental Hypnosis, 29, 282-299.

The author presents operational definitions of self-hypnosis and examines the differences and similarities between hetero- and self-hypnosis in relation to the methods used and the hypnotizer's attitudes. It is argued that, with the exception of spontaneously occurring trances, there is no "pure" self-hypnosis. Most clinicians teach self-hypnosis through hetero-hypnosis, in part by direct or indirect posthypnotic suggestion. Some subjects never completely reach and maintain the same depth in self-hypnosis achieved in hetero-hypnosis, contrary to Ruch's (1975) conclusions. According to the present author, self-hypnosis taught through hetero-hypnotic experiences is effective as a method for physical and emotional tranquilization in nearly all subjects. Dynamically meaningful and physically effective self-hypnosis, however, is only learned by subjects who have been successful with deep hetero-hypnotic trances which included somnambulistic experiences. Effective deepening methods likely to stimulate psychodynamic creativity during hetero-hypnosis and subsequently during self-hypnotic trances are described. Some of the difficulties encountered by subjects during self-hypnosis are discussed: incomplete dissociative experiences; anxieties about self-control; doubts about the reality of the self-hypnotic state; and the possibility that negative attitudes, habits, and expectations may act countertherapeutically as posthypnotic suggestions. When successful, self-hypnosis permits prolongation and extension of effective therapy. Self-hypnotic teaching can be administered with different modalities in individual and in group settings. Clinicians can make useful contributions both to the therapeutic use of self-hypnosis and to a clearer theoretical understanding of self-hypnotic phenomena.

1980

Case, David B.; Fogel, David H.; Pollack, Albert A. (1980). Intrahypnotic and long-term effects of self-hypnosis on blood pressure in mild hypertension. International Journal of Clinical and Experimental Hypnosis, 28, 27-38.

Self-hypnosis using the method of Spiegel (1974) was evaluated in 15 patients with labile or mild essential hypertension who were equally hypnotizable and adhered to a regimen of 6-10 daily exercises for a 4-month period. During the hypnotic state, there were consistent rises in both systolic and diastolic pressures in hypnotizable patients, but not in non-hypnotizable controls. Similar but smaller changes were also observed in normotensive subjects. Pressure rose immediately with hypnosis and subsided gradually over 15 minutes. However, the long-term effects of the daily practice of self-hypnosis were variable: ambulatory diastolic pressure fell in 5 patients, was unchanged in 7 patients, and rose in 3 patients. The changes in blood pressure could not be specifically attributed to the daily

practice of self-hypnosis; however, all patients experienced improvement in well-being, mood, and behavior patterns during the 4-month period. The study indicates that self-hypnosis can produce changes in behavior and mood which may be beneficial to cardiovascular health, although paradoxically, the act of hypnosis by this technique is pressor. Aside from its therapeutic potential, self-hypnosis may provide useful information about central mechanisms of blood pressure regulation.

1979

Johnson, Lynn S. (1979). Self-hypnosis: Behavioral and phenomenological comparisons with heterohypnosis. International Journal of Clinical and Experimental Hypnosis, 27, 240-264.

In a study of behavioral and phenomenological differences between auto- and heterohypnosis, standard autohypnotic and hetero-hypnotic experiences were administered to 48 college students (25 males, 23 females). Total scores of behavioral and phenomenological responses were compared for each experience. The phenomenological scores were also factor analyzed for each type of hypnosis. Behavioral total scores were comparable. Inexperienced Ss were as able to hypnotize themselves as to be hypnotized by another. Scores on "challenge" items were also comparable, whereas items suggesting positive actions showed greater variability. Factor analyses showed that the subjective experiences were generally similar. Heterohypnosis evoked more feelings of unawareness, passivity, and loss of control. Self-hypnosis elicited more feelings of time distortion, disorientation, active direction, and trance variability. The relationship between hypnotic mode and order effects was discussed in terms of Ruch's (1975) facilitatory/inhibitory effects. Conclusions are drawn that self-hypnosis and heterohypnosis are sufficiently similar to be conceptualized under the same label. Data is offered on expectations of self-hypnosis and their effect on later responsiveness.

1978

Benson, Herbert; et al. (1978). Treatment of anxiety: A comparison of the usefulness of self-hypnosis and a meditational relaxation technique. Psychotherapy and Psychosomatics, 30, 229-242.

#### NOTES

This is a controlled clinical outcome study of psychotherapy involving the use of hypnosis.

Benson, Herbert; Frankel, Fred H.; Apfel, Roberta; Daniels, Michael D.; Schniewind, Henry E.; Nemiah, John C.; Sifneos, Peter E.; Crassweller, Karen D.; Greenwood, Martha M.; Kotch, Jamie B.; Arns, Patricia A.; Rosner, Bernard (1978). Treatment of anxiety: A comparison of the usefulness of self-hypnosis and a meditational relaxation technique. Psychotherapy and Psychosomatics, 30, 229-242.

We have investigated prospectively the efficacy of two nonpharmacologic relaxation techniques in the therapy of anxiety. A simple, meditational relaxation technique (MT) that elicits the changes of decreased sympathetic nervous system activity was compared to a self-hypnosis technique (HT) in which relaxation, with or without altered perceptions, was suggested. 32 patients with anxiety neurosis were divided into 2 groups on the basis of their responsivity to hypnosis: moderate-high and low responsivity. The NIT or HT was then randomly assigned separately to each member of the two responsivity groups. Thus, 4 treatment groups were studied: moderate-high responsivity MT; low responsivity MT; moderate-high responsivity HT; and low responsivity HT. The low responsivity HT group, by definition largely incapable of achieving the altered perceptions essential to hypnosis, was designed as the control group. Patients were instructed to practice the assigned technique daily for 8 weeks. Change in anxiety was determined by three types of evaluation: psychiatric assessment; physiologic testing; and self-assessment. There was essentially no difference between the two

techniques in therapeutic efficacy according to these evaluations. Psychiatric assessment revealed overall improvement in 34% of the patients and the self-rating assessment indicated improvement in 63% of the population. Patients who had moderate- high hypnotic responsivity, independent of the technique used, significantly improved on psychiatric assessment ( $p = 0.05$ ) and decreased average systolic blood pressure from 126.1 to 122.5 mm Hg over the 8-week period ( $p = 0.048$ ). The responsivity scores at the higher end of the hypnotic responsivity spectrum were proportionately correlated to greater decreases in systolic blood pressure ( $p = 0.075$ ) and to improvement by psychiatric assessment ( $p = 0.003$ ). There was, however, no consistent relation between hypnotic responsivity and the other assessments made, such as diastolic blood pressure, oxygen consumption, heart rate and the self-rating questionnaires. The meditational and self- hypnosis techniques employed in this investigation are simple to use and effective in the therapy of anxiety.

Porter, J. W. (1978). Suggestions and success imagery for study problems. International Journal of Clinical and Experimental Hypnosis, 26, 63-75.

A procedure is presented for dealing with study problems in cases where patients come with an expectancy of help through hypnosis. Specific suggestions directly related to the study difficulty are given. "Success imagery" is outlined for use under hypnosis and by the student himself in his daily life. Two self-management techniques associated with the relaxation induced by exhalation are given further strength by being made posthypnotic suggestions. A direct posthypnotic suggestion for "concentration and recall" is combined with contingency management to effect more efficient performance when the decision is made to study. Four sessions are shown by clinical experience to be generally adequate to allow a transition from therapy to self-management of the problem aided by the student's own use of self-hypnosis. A general outline of how this is achieved for the first three sessions incorporates both Wolberg's (1965) suggestions to remove barriers preventing progress and Stanton's (1977) Rational-Emotive Therapy suggestions to strengthen the person's belief in himself.

1977

Sachs, Lewis B.; Feuerstein, M.; Vitale, J. H. (1977). Hypnotic self-regulation of chronic pain. American Journal of Clinical Hypnosis, 20, 106-113.

A more diverse conceptualization of pain including the motivational- affective, cognitive-evaluative, as well as sensory components has resulted in a greater emphasis on 'central' factors in pain and the development of comprehensive treatments directed at these various components. This study is one such treatment program. Eight patients with chronic pain (mean duration of 8.8 years) were trained in a hypnotic self- regulation procedure to modify pain. Pre and post measures were collected on a series of indices relevant to the pain experience. The post-treatment evaluation indicated significant reductions in: (1) daily pain intensity, (2) the degree to which pain interfered with major life areas (e.g., sleep and social activity), (3) life dissatisfaction and suffering, (4) personality characteristics relevant to chronic pain and (5) percentage of self-administered pain medication. Despite the lack of a no-treatment comparison and placebo-attention controls, the chronicity of pain and the lack of effectiveness of prior medical interventions suggest that this treatment program is an effective agent in the control of chronic pain.

1976

Miller, Lawrence J. (1976). A comparison of hypnotic susceptibility for internal and external locus of control subjects in hetero- and self-hypnotic treatments (Dissertation). Dissertation Abstracts International, 37, 978-979.

: "This study investigated the use of self- and hetero-hypnosis with internal and external locus of control subjects. Fifty-eight subjects, matched on hypnotic susceptibility and internal-external locus of control, were randomly assigned to the self- or hetero-hypnotic treatments. Self reports of their hypnotic behavioral scores and hypnotic subjective responses were obtained for each subject. "The statistical analyses showed there were no significant differences between the internal and external locus of control groups or within groups in regard to self- and hetero-hypnosis total behavioral scores, "challenge" or "non-challenge" items, .... their reported subjective experiences. The results supported the similarity of hetero- and self- hypnosis. Various findings from past research in regard to I-E subjects were also challenged in terms of their generalizability to hypnotic settings" (pp. 978-979).

1974

Surman, Owen S.; Hackett, Thomas P.; Silverberg, Elizabeth L.; Behrendt, Douglas M. (1974). Usefulness of psychiatric intervention in patients undergoing cardiac surgery. Archives of General Psychiatry, 30, 830-835.

Twenty patients undergoing cardiac surgery were seen one or more times by a psychiatrist who performed two functions. In a supportive fashion he cleared up any misconceptions the patient had about the forthcoming surgery and he taught him a simple autohypnotic technique. Twenty controls, matched for relevant variables, received routine preoperative care. Contrary to the report of others, a single visit by the psychiatrist did not influence the incidence of postoperative delirium, anxiety, depression, pain, or medication requirements. However, there was a trend for patients receiving a greater number of preoperative visits to have a lower incidence of detected delirium. Age was the only factor in this study that differed significantly between delirious and nondelirious patients.

1973

Shor, Ronald E.; Easton, Randolph (1973). A preliminary report on research comparing self- and hetero-hypnosis. American Journal of Clinical Hypnosis, 16, 37-44.

A method is described for the study of the relationship between self- and hetero-hypnosis and initial findings are presented. A new instrument is described, the Inventory of Self-Hypnosis (ISH) which is a self-hypnosis adaptation of the hetero- hypnotic Harvard Group Scale, Form A (HGS). The new scale permits the making of precise item-by-item quantitative comparisons between the effects of these two scales. Preliminary research with 29 non-motivated college student subjects suggests that mean levels of responsiveness to the two scales are about the same, that item difficulty levels have much in common, but that whatever it is that the ISH measures is largely different from what the HGS measures. The findings help to formulate the need to study what it is that contributes to the similarities and differences. Further studies are in progress.

#### NOTES

Total Score Intercorrelations were reported as follows:

HGS ISHb ISHt

HGS 1.00 ISHb .39 1.00 ISHt .33 .67 1.00

Item Pass Percents Intercorrelations were reported as follows:

HGS ISHb ISHt

HGS 1.00 ISHb .72 1.00 ISHt .70 .82 1.00

ISHb = time calculated by breaths ISHt = time calculated by timer

The Inventory of Self Hypnosis (ISH) consists of 12 items, the same ones as in the Harvard scale with a few minor exceptions. Subjects are told that the inventory "is designed to teach self-hypnosis and that all of the information needed for a person to induce hypnosis in himself and to give himself a series of

simple suggestions is contained in the inventory booklet" (p. 40). Therefore, there is more emphasis on hypnosis as an active imagination (cognitive) skill. An example, using a suggestion for Immobilization of the Right Arm, follows.

"This set of instructions is devoted to having it become very difficult for you to lift your right arm. These instructions involve a count of 33 breaths. The first 30 breaths is the suggestion phase and the final three breaths is the trial phase.

"When ready close your eyes and pay close attention to your right arm. Notice how your arm shares in the general feeling of heaviness that you feel all over your body. Throughout the count of 30 breaths concentrate your thoughts on the idea of how heavy it feels; think about it growing more and more heavy, heavy like lead. Although you should try not to lift it until later, notice how the arm seems to become much too heavy to lift.

"At the end of the 30 breaths take 3 extra breaths. During this new count try to lift your arm to see how heavy it is. Perhaps in spite of being so heavy you will be able to lift it a little, although by then it may be too heavy even for that. You will notice that there is some resistance because of the relaxed state you are in. After the three breaths stop trying and relax. In a few moments your arm will feel normal again, no longer heavy; you can easily lift it if you want to. At that point open your eyes and continue reading below the double lines.

"Summary of instructions:

"Initial actions: Close your eyes. Pay close attention to the feelings in your right arm.

"During count of 30 breaths -- Main Actions: Concentrate on the idea of your arm becoming so heavy that you would not be able to lift it.

"3 breaths -- Try to lift your arm.

"Post actions: Let normal feeling return to your arm. Open your eyes and continue reading" (p. 41).

1970

**Maher-Loughnan, G. P. (1970). Hypnosis and auto-hypnosis for the treatment of asthma. International Journal of Clinical and Experimental Hypnosis, 18 (1), 1-14.**

Conducted 2 controlled studies into the use of hypnosis in 252 asthma patients. Several different control procedures were used. Methods and results were summarized, and the same conclusion was reached: That hypnosis supplemented by autohypnosis was significantly more effective than control procedures. An outline is given of details of treatment methods. A current analysis of Ss involving up to 6 yr. of follow-up, is presented to provide a working guide to the regime in regular practice. To be fully effective hypnosis should be employed before steroids are started. Steroid-dependent asthma is rarely totally relieved by hypnotherapy. (Spanish & German summaries) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

**Spiegel, Herbert (1970). A single-treatment method to stop smoking using ancillary self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 18 (4), 235-250.**

Discusses the 1st 615 patient-smokers who were treated with a single 45-min session of psychotherapy reinforced by hypnosis. Technique of treatment, including rationale of approach, induction procedure, assessment of hypnotizability, and training instructions to stop smoking are presented in detail. 6-mo follow-up study results are discussed. Of 44% who returned a questionnaire, hard-core smokers stopped for at least 6 mo. Another 20% reduced their smoking to varying degrees. Results of a 1-session treatment compare favorably with, and often are significantly better than, other longer-term methods reported in the literature. It is suggested that every habitual smoker who is motivated to stop be exposed to the impact of this procedure, or its equivalent, so that at least 1 of 5 smokers can be

salvaged. (French & Spanish summaries). (PsycINFO Database Record (c) 2003 APA, all rights reserved)

Spiegel, Herbert (1970). A single-treatment method to stop smoking using ancillary self-hypnosis: Final remarks in response to the discussants. International Journal of Clinical and Experimental Hypnosis, 18 (4), 268.

Reexamines the major points of the author's papers (see PA, Vol. 45:Issue 1) on smoking modification. Data inclusion, therapy length, Ss' ability to change, and use of multiple therapists and tape recordings as reinforcement are discussed. It is concluded that the method should be used to "sharpen our techniques that we can relatively quickly learn who has the capacity to change for given goals, and then to help evoke the desired change as efficiently as possible." (PsycINFO Database Record (c) 2003 APA, all rights reserved)

1969

Frankenthal, Kate (1969). Autohypnosis and other aids for survival in situations of extreme stress. International Journal of Clinical and Experimental Hypnosis, 17, 153-159.

Presents case histories where strong autosuggestion was utilized to survive in situations of extreme stress by dissociating unbearable realities. The difference between hypnosis and depersonalization is discussed. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1965

Fromm, Erika (1965). Spontaneous autohypnotic age-regression in a nocturnal dream. International Journal of Clinical and Experimental Hypnosis, 13 (3), 119-132.

A new operational approach to the psychoanalytic interpretation of dreams is presented and exemplified. The example used contains an autohypnotic age-regression in a spontaneous nocturnal dream which was dreamed after failure to achieve age-regression in a hypnotic session a few hours earlier. In the interpretative method discussed, emphasis is placed on learning to understand dreams as coherent cognitive structures. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Naruse, Gosaku (1965). The hypnotic treatment of stage fright in champion athletes. International Journal of Clinical and Experimental Hypnosis, 13 (2), 63-70.

The use of direct hypnotic suggestion, posthypnotically produced autohypnosis, and self-hypnosis in conjunction with autogenic training and progressive relaxation in the treatment of "stage fright" in athletes is discussed. Illustrative case histories drawn from a sample of athletes participating in the 1960 Olympic Games are presented. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Naruse, Gosaku (1965). The hypnotic treatment of stage fright in champion athletes. International Journal of Clinical and Experimental Hypnosis, 13 (2), 63-70.

The use of direct hypnotic suggestion, posthypnotically produced autohypnosis, and self-hypnosis in conjunction with autogenic training and progressive relaxation in the treatment of "stage fright" in athletes is discussed. Illustrative case histories drawn from a sample of athletes participating in the 1960 Olympic Games are presented. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1963

Das, J. P. (1963). Yoga and hypnosis. International Journal of Clinical and Experimental Hypnosis, 11, 31-38.

The nature of Yoga and Samadhi (concentration) was described. A comparison with hypnosis revealed widely differing objectives, but many points of functional and methodological similarity. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1960

Guinazu, S. (1960). Relajacion de Schultz e ionotoforesis calcica trans cerebral. Acta Hipnologia Latino-Americana, 1, 65-67. (Abstracted in American Journal of Clinical Hypnosis, 1962, 5, 75)

The author recommends the use of autogenic training in conjunction with transcerebral calcium iontoforesis for the treatment of neurotic and psychotic disorders. This combined therapy abbreviates treatment time and leads to greater percentage of recoveries. Four cases, taken from over two hundred, are presented and analyzed.

1955

Ambrose, Gordon (1955). Multiple sclerosis and treatment by hypnotherapy. Follow-up and further cases. Journal of Clinical and Experimental Hypnosis, 3 (4), 203-209.

#### NOTES

"Summary. Present day treatment of multiple sclerosis appears inadequate from the psychological view point and patients are too often forced to show a negative response to their illness.

"Six patients have been treated by hypnotherapy with marked subjective improvement. Three of these cases are described.

"The aim in these cases is to put the patient more in control of his organism. Patients should be told that their symptoms must never control them, they must control their symptoms.

"The very nature of the illness prevents the medical attendant from feeling scientific in his approach to these cases. Long follow-up is a necessity but much subjective improvement is possible using hypnotherapy.

"In the hypnoanalytical approach the usual exaggeration of the emotions allied with the psychosomatic reaction will often be found. Hypnosis appears to produce a rapid lessening of tension and anxiety in these cases.

"A deep state of hypnosis should be aimed at and auto-hypnosis must always be taught. It is sometimes useful to place a trusted person en rapport with the patient to carry on with positive and direct suggestions.

Hart, Hornell (1955). Measuring some results of autohypnosis. Journal of Clinical and Experimental Hypnosis, 3 (4), 229-242.

## NOTES

The author developed self ratings for mood (euphoria-dysphoria) and alertness-fatigue, which were administered to college students in neutral conditions and after self-hypnosis conditions. The self hypnosis, or "auto-conditioning" usually involved deep relaxation self suggestions followed by other suggestions. The suggestions involved using the word 'you' to be able to re-instate the autoconditioning more and more effectively; suggestions for attitude change (e.g. that 'No matter what comes, we will grapple with it courageously'); and euphoria auto-suggestions (e.g. that 'you will come out of this deep relaxation, feeling rested, alert, cheerful and courageous').

In both single session experiments, as with a class of nurses who experienced an 8 minute auto-conditioning procedure, and in experiments extending over time, depression decreased. He noted that "for various reasons, the students who participated in autoconditioning experiments between February and May, 1955, were in many respects less successful than some of the previous experimental groups had been" (p. 235).

Increased alertness and diminished fatigue was also observed.

Many students chose to give themselves suggestions to correct the habit of procrastination. Two-thirds of the participants reported complete success, up to the level specified, and only one of 43 experiments on correcting procrastination was a "flat failure."

Kline, Milton V.; Guze, Henry (1955). Self-hypnosis in childbirth: A clinical evaluation of a patient conditioning program. Journal of Clinical and Experimental Hypnosis, 3 (3), 142-147.

## NOTES

The author reports use of self hypnosis for childbirth by 30 patients. Many required no drugs or greatly reduced drugs. The obstetricians usually had no prior experience with hypnosis and were cautious in providing medication at the earliest sign of discomfort.

"Summary. A two year experimental study of the use of self-hypnosis in childbirth has indicated its general effectiveness for virtually all the patients who received this type of pre-natal preparation. Although problems of selecting patients capable of utilizing this method have not been discussed in detail in this paper, it must be understood that this study depended upon a patient population selected on the basis of specific psychological characteristics which were indicative of both the judiciousness and effectiveness of self-hypnosis for obstetrics. "Within the limits set by these selective characteristics, which in themselves may be greatly broadened by further study, self-hypnosis as a means of patient participation in childbirth appears to have very great merit. It is a method that lends itself to simple administration and can be extended to many more patients than any other hypnotic approach. It minimizes the need of the obstetrician to utilize time and effort in patient conditioning without sacrificing any of the advantages of hetero-hypnotic techniques. Its use on a larger scale than reported upon here, with more exacting investigative techniques, seems clearly indicated" (pp. 146-147).

Stokvis, Berthold (1955). Autosuggestive active tonus regulation as an aid in hypnosis therapy. Journal of Clinical and Experimental Hypnosis, 3 (3), 140-141. (Abstracted in Psychological Abstracts, 56: 4699)

## NOTES

The author describes a way to encourage patients to help themselves. Each day, morning and evening before rising or going to sleep they are to spend 5-10 minutes relaxing and concentrating intensively on the words spoken to him by the doctor during the previous hypnosis session. Gradually this may become self hypnosis, as in autogenic training. The author poses a psychoanalytic explanation ("the

hetero-erotic bond with the hypnotist has then been replaced by the auto-erotic bond between the patient's Ego and Self" p. 140) as well as emphasizing the benefits of practice.

1954

Klempner, Edith (1954). Changes of the body image in hypnoanalysis. Journal of Clinical and Experimental Hypnosis, 2, 157-162.

## NOTES

Author describes people who experience age regression causing changes in body size, others who "see" themselves as a child (the watcher), both simultaneously. Others experience some part of the body as missing or added, or changing in dimensions; or a change may seem symbolic; or there may be sensory changes experienced in connection with body parts; and functions of sense organs might be felt. Equilibrium sense may change, or kinesthetic sensations. "We have a double system of memory; one is a complete and true copy of the actual experience, the other is incomplete, symbolical, fleeting. Past experiences are always present unchanged in form of thoughts or diagrams, connected with the knowledge which will bring them into consciousness" (p. 162).

1953

Schneck, Jerome M. (1953). Self-hypnotic dreams in hypnoanalysis. Journal of Clinical and Experimental Hypnosis, 1 (1), 44-53. (Abstracted in Psychological Abstracts, 53: 6579)

In evaluating self-hypnotic dreams from the view of form and content, they should be compared with nocturnal and hetero-hypnotically induced dreams of the same individual, aside from comparisons with others. Eight self-hypnotic dreams of a patient in hypnoanalysis are reported here. Well known dream mechanisms are readily discerned. Classic symbolism is encountered, as well as repetitive types of symbols peculiar to this patient's functioning. The dreams are given in detail along with the patient's associations and interpretations. Such self-hypnotic dreams may be used to extend and intensify hypnoanalytic work. They involve the patient more completely in treatment. They may be used to introduce new issues, bring problems into sharper focus, identify and analyze resistances. They may, in fact, be used for most any purpose that hetero-hypnotic dreams may be employed for in analysis (3). The text reveals other points of interest regarding self-hypnotic dreams in relation to therapeutic work, and additional investigations which may be instituted in connection with such dreams.

## SENSATIONS

2000

Eimer, Bruce N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)

This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies;

(3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred

coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

1998

Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..

#### NOTES

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

1992

Kay, L. M. (1992, October). The effects of hypnosis, relaxation, and suggestion on visual acuity (Dissertation, California School of Professional Psychology, San Diego). Dissertation Abstracts International, 53 (4), 2065-B. (Order No. DA 9221587)

"Evaluated the relative efficacy of several aspects of the hypnotic process on facilitating change in hypnotic state-dependent visual acuity in myopic student subjects. Five conditions included hypnosis with suggestions, neutral hypnosis, nonhypnotic suggestion, progressive relaxation, and a control (comedy). Visual acuity was assessed as baseline (a task-motivational situation where they were to try to see as well as possible) and after the experimental condition. Results found that hypnosis facilitated a significant improvement in visual acuity ( $p = .002$ ), although no differences were found in the other conditions" (p. 2065).

1991

Brown, Jason W. (1991). Self and process: Brain states and the conscious present. New York: Springer-Verlag.

## NOTES

Author, from the Department of Neurology at New York University Medical School, presents a theory about the genetic unfolding of mental content (mind) through stages, from mental state into consciousness or into behavior. He relates the genesis of mind to brain development but avoids assuming that there is a straightforward correlation between brain development (e.g. myelination) and cognitive development or perception. To some degree, the theory is based on subjective report data and psychological symptoms. The author discusses issues that bear on the phenomena of nonvoluntary responding and dissociation that are reported or described by hypnotized persons.

"The nature of the mental state will determine the relation between self and world, and thus the interpretation given to agency and choice. ... The crossing of the boundary from self to world is a shift from one level in mind to another" (pp. 10-11).

"... if we begin with mind as primary and seek to explain objects from inner states and private experience, the discontinuity between inner and outer evaporates: mind is everywhere, a universe. ... Whereas before we thought to perceive objects, now we understand that we think them" (p. 19).

"The concept of a stratified cognition is central to the notion of a mental state .... This entails an unfolding from depth to surface, not from one surface to the next, a direction crucial to agency and the causal or decisional properties of consciousness" (p. 52). By unfolding from depth to surface, he means from Core, through Subconscious, then Conscious Private Events, and finally Extra-Personal Space.

He goes on to provide a definition of mental states. "A mental state is the minimal state of a mind, an absolute unit from the standpoint of its spatial and temporal structure. ... The state also has to include the prehistory of the organism. ... The concept of a mental state implies a fundamental unit that has gestalt-like properties, in that specific contents-- words, thoughts, percepts--appear in the context of mind as a whole (p. 53).

"The entire multitiered system arborizes like a tree, with levels in each component linked to corresponding levels in other components. For example, an early (e.g., limbic) state in language (e.g., word meaning) is linked to an early stage in action (e.g., drive, proximal motility) and perception (e.g., hallucination, personal memory) .... In sum, a description of the spatial and temporal features of a single unfolding series amounts to a description of the minimal unit of mind, the absolute mental state" (p. 54).

The author's discussion of an individual's physical movement relates to the concept of nonvoluntary movement (or movement without awareness of volition) in hypnosis. "More precisely, levels in the brain state constitute the action structure. As it unfolds, this structure generates the conviction that a self-initiated act has occurred. This structure--the action representation--does not elaborate content in consciousness. ... As with the sensory-perceptual interface, the transition to movement occurs across an abrupt boundary. In some manner, perhaps through a translation of cognitive rhythms in the action to kinetic patterns in the movement, levels in the emerging act discharge into motor (physical) events" (p. 57).

"The self has the nature of a global image or early representation within which objects-to-be are embedded. ... The self is the accumulation of all the momentary cognitions developing in a brain configured by heredity and experience in a particular way (p. 70).

"The deposition of a holistic representation ... creates the deception of a self that stands behind and propagates events. The feeling of the self as an agent is reinforced by the forward thrust of the process and the deeper locus of the self in relation to surface objects. The self appears to be an instigator of

acts and images when in fact it is given up in their formation. The self does not cause or initiate, it only anticipates (p. 70).

The foregoing notes cover only the first five chapters, less than half the book. Other chapters relevant to hypnosis would be those titled 'The Nature of Voluntary Action,' 'Psychology of Time Awareness,' 'From Will to Compassion,' and 'Mind and Brain.'

1990

Arendt-Nielsen, Lars; Zachariae, Robert; Bjerring, Peter (1990). Quantitative evaluation of hypnotically suggested hyperaesthesia and analgesia by painful laser stimulation. Pain, 42, 243-251.

## NOTES

Sensory and pain thresholds to laser stimulation were determined, and the laser-pain evoked brain potentials were measured for 8 highly hypnotizable (Harvard Scores 10-11) student volunteers in 3 conditions: (1) waking, (2) suggestion of hyperaesthesia during hypnosis, (3) suggestion of analgesia during hypnosis.

The investigators used a laser beam 3 mm in diameter, with a 200 msec stimulus duration; the same area (but different points within the area) was used for consecutive stimulations. Ss were otherwise maintained in low stimulus conditions so they would not have visual or auditory cues about laser beam onset; they wore goggles, had eyes shut, and had earphones on. Sensory threshold was defined as warmth; pain threshold was defined as a distinct sharp pin prick.

The laser intensity used for stimulation corresponded to strong pain. Interstimulus intervals averaged 15 sec (but were randomly varied between 10-20 sec). Sensory and pain thresholds as well as two evoked potential measurements were taken during waking, hypnotized hyperaesthesia, and hypnotized analgesia conditions in a single 1 1/2 hour session.

The evoked potential component of interest was the negative complex N1 with latency of 300 msec; amplitude (P1=N1-P2) and latency of this complex (N1) were measured. EEG epochs contaminated by eye movement were omitted from analysis.

The standardized induction and deepening of hypnosis required 15-20 minutes; then the suggestion was given that Ss could alter their perception of stimuli such as pain. Hyperaesthesia suggestions were to imagine the right hand was in very hot water, then taken out but still very red, hot, sensitive so that even the vaguest stimulus would be detectable and unpleasant. They were told that they would receive a series of painful but tolerable stimuli, and to raise the left index finger if they could just perceive a laser pulse (sensory threshold), and again if they felt pricking pain (pain threshold).

Suggestions for analgesia were to imagine that their right hand was placed on their chest, and that their 'former right hand' was no longer their own but was made of some heavy and completely insensitive material like wood or stone. Sensory and pain threshold measures were then taken. During the evoked potential measurement period they received continuous suggestions of analgesia. They also were told to relax and imagine they were in a pleasant place, ignoring everything except the pleasant, relaxed feelings and imagining pleasant sights, sounds, feelings and the imagined place. They were told that though they would receive stimuli, they probably would be able to ignore the stimuli completely.

Results were as follows.

1. In the hypnotic hyperaesthesia condition, sensory and pain thresholds decreased significantly by 47% and 48%, respectively. Three Ss reacted to laser intensities far below what normally can be perceived in the waking state. [The authors ran a separate small control experiment to make sure that the Subjects were not using any other cues, but mention the possibility of light-sensitive skin reacting to the blue laser light, creating evoked potentials.]

2. In the hypnotic analgesia condition, sensory and pain thresholds increased by 316% and 190%, respectively. 7 of 8 Ss did not even respond to pain threshold when the laser intensity was increased to the noxious level of 3W, which is the level at which tissue damage can occur.

**3. Pain-related evoked potentials.** Amplitude of the first pain-related potential was increased significantly by 14% in the hyperaesthesia condition and reduced significantly by 31% in the analgesia condition. Changes in the evoked potentials were considered minor however compared to those observed for thresholds, which are subjective response measures. Even in Subjects who reported complete analgesia, the experimenters observed the laser pain evoked responses. There were no differences in latencies of the first pain-related potentials for the three conditions (indicating that peripheral and central afferent conduction velocities were the same).

**Discussion.** "There has been some dispute concerning the experimental design and the reliability of the data obtained in studies dealing with hypnotic suggested analgesia [Spanos & Chaves, 1970]. In our design 2 'opposite' conditions were induced, and the 2 inductions gave 'opposite' results.

"The experience of pain can be significantly altered by suggestions of analgesia, which is in accordance with a number of other studies (for review see [Barber & Adrian, 1982; Hilgard & Hilgard, 1975]). The finding that suggestions of hyperaesthesia can decrease the sensory and pain thresholds and increase the amplitude of the pain evoked potential is a new observation. Since synchronized auditory and visual stimuli from the laser were blocked, and the stimulus was given at random intervals, the changes might be induced by the hypnotic suggestions" (p. 247).

The authors discuss their results in terms of (1) four pain modulation systems (neural/opiate, hormonal/opiate, neural/non-opiate, and hormonal/non-opiate) and (2) focusing and defocusing attention. Because in their pilot study it was necessary to give suggestions continually in order to affect the laser evoked potentials, they conclude that endogenous substances or hormonal/non-opiates would play a minor role, if any, in hypnotic analgesia. (Price and Barber [25] had also found it important to give suggestions continuously.)

On the other hand, "event-related potentials [7, 26] and pain-related potentials have, previously, been shown to be sensitive to focused and de-focused attention. Recently, Miltner et al. [23] showed the influence of attention on the late pain-related component of potentials, evoked by painful intracutaneous electrical stimulation. The degree to which the subject paid attention to the painful stimulus had a powerful effect on the pain-related complex. When subjects ignored the pain, it was still possible to record the pain-related complex although all the subjects consistently reported less or no pain. In wakeful subjects where cutaneous pain was abolished by lignocaine infiltration, the pain-related evoked potentials were abolished [4]. In our study, we could also record evoked potentials although the subject subjectively did not feel pain. The reason might be that the S acted as if there was full analgesia to the stimuli, in order to satisfy the hypnotist. During suggested hyperaesthesia the thresholds declined below what normally could be perceived in the wakeful state. The volunteers could, therefore, not act hypersensitive, so something did happen.

"The discrepancy in subjective and objective responses might, however, be useful when investigating levels of the neuroaxis at which hypnosis might work" (pp. 248-249).

The authors note that this laser induced pain and the tooth pulp stimulation pain of Mayer & Barber both use the A-delta fibers. Barber & Mayer found it impossible to elicit pain within the output range of the stimulator (up to 150 microA) and reached maximal intensity for all volunteers during suggested analgesia. Using cutaneous laser stimulation the authors found that the skin damage level (3W) could be reached in 7 of 8 volunteers without any reaction of pain.

During the hyperaesthesia condition the sensory threshold was sometimes lower than can be detected in the waking state. Although some researchers have suggested that red light from a helium-neon laser might activate cutaneous photosensitive receptors and thereby elicit brain potentials, the authors were unable to elicit potentials in waking Subjects using their blue and green argon laser light with below sensory threshold intensity.

The authors also note that previous attempts to use physiological correlates of pain such as heart rate, blood pressure, respiration, and galvanic skin response have yielded confusing results. The physiological indicators are present even when Subjects report analgesia, leading some investigators to

conclude that the subjective reports are due to illusion [Sutcliffe, 1961], compliance [Wagstaff, 1986], or a placebo induced by the hypnosis context [Wagstaff, 1986]. "These confusing results lead to the conclusion that both the traditional methods used for induction of pain and the monitored physiological responses have been unsatisfactory. The present study has sought to eliminate some of the methodological difficulties by (1) using brief well-defined argon laser stimuli which in awake volunteers induce very stable perceptions between trials [Arendt-Nielsen & Bjerring, 1988], and (2) recording psychophysical thresholds and objective parameters quantitatively related to the intensity of the pain perceived (1, 3)" (p. 249).

Cikurel, Katia; Gruzelier, John (1990). The effect of an active-alert hypnotic induction on lateral asymmetry in haptic processing. British Journal of Experimental and Clinical Hypnosis, 7, 17-25.

In order to elucidate further left hemispherical inhibitory dynamics in response to instructions of hypnosis, bilateral haptic processing times were compared before and during a traditional hypnotic relaxation procedure and an active-alert procedure in which subjects pedaled a bicycle ergometer and instructions on mental alertness were incorporated with hypnosis. Previous evidence suggesting a slowing of left hemispherical processing and a facilitation of right hemispherical processing in susceptible subjects was replicated, and was shown to characterize high rather than medium susceptibles, the latter showing a bilateral slowing of processing. These effects occurred with both induction procedures whose influence on susceptibility was highly correlated. In fact the lateral shift in processing in the direction of left hemispherical inhibition and right hemispherical facilitation was favoured by the active-alert procedure, indicating that neuropsychological changes which occur with hypnosis cannot be discounted as a by-product of relaxation.

Ross, Colin A.; Fast, E.; Anderson, G.; Auty, A.; Todd, J. (1990). Somatic symptoms in multiple sclerosis and MPD. Dissociation, 3, 102-106.

Fifty subjects with multiple sclerosis (MS) were compared to 50 subjects with multiple personality disorder (MPD). MS patients endorsed an average of 3.0 somatic symptoms on structured interview, and MPD subjects an average of 14.5. Somatic symptoms characteristic of neurological illness were trouble walking, paralysis, and muscle weakness, while those characteristic of psychiatric illness were genitourinary and gastrointestinal symptoms.

1989

Bryant, Richard A.; McConkey, Kevin M. (1989). Hypnotic emotions and physical sensations: A real-simulating analysis. International Journal of Clinical and Experimental Hypnosis, 37, 305-319.

Real hypnotizable Ss and simulating unhypnotizable Ss were administered a suggestion for either happiness, emotional neutrality, or sadness. The emotion was assessed through subjective and behavioral measures taken once before, twice during, and once after the emotion. Findings indicated that emotionally congruent changes occurred in both self-report and performance measures. Ss' physical sensations during the emotion were assessed on a 34-item self-report scale. It was demonstrated that Ss in the happy versus sad conditions reported different physical sensations; in particular, they reported different facial sensations. The responses of real hypnotizable subjects, however, were essentially paralleled by those of simulating unhypnotizable subjects. Therefore, the possibility exists that hypnotized subjects may have been responding on the basis of social demands. The findings are discussed in terms of the effects of the emotion suggestions, and the implications of real and simulating Ss displaying similar affective responses.

NOTES

Used the real-simulating model in an attempt to eliminate the possibility that hypnotized Subjects in previous studies may have been responding to the demand characteristics of the situation. Used both subjective and behavioral measures. Self-report happiness and sadness, of emotion intensity; behavioral performance measure of speech rate, indexed by counting speed (which has been shown to distinguish between happiness and sadness). Used 34-item self-report Physical Sensations Scale based on Pennebaker, J. W. *The psychology of physical symptoms*. New York: Springer-Verlag, 1982.

They cite Weiss, et al (1987) who focused on the onset latency, and the fluctuation of muscular contraction associated with facial expression indicated a difference between posthypnotically cued and simulated emotions of anxiety and pleasure.

Hall, H.; Minnes, L. (1989). Psychological modulation of auditory responses. *International Journal of Psychosomatics*, 36 (1-4), 59-63.

Psychological modulation of auditory response, the effects of imagery and suggestion on auditory thresholds were examined in naive subjects. After a hypnosis-like induction, the subjects, who were not aware of the purpose of the study, were asked to generate and maintain a specific set of images before, during, and after which their auditory thresholds were tested. Following the imagery, which represented cooling and vasoconstriction in the cochlea, audiograms revealed a temporary auditory threshold shift (TTS) in the experimental group only. This TTS pattern was similar to that produced by exposure to loud noise. Information carried in the image is suggested as the basis for the observed auditory changes. Although a hypnosis-like induction was employed, the subjects' level of hypnotizability did not appear to be related to the findings.

1986

Friedman, Howard; Taub, Harvey A.; Sturr, Joseph F.; Church, Katherine L.; Monty, Richard A. (1986). Hypnotizability and speed of visual information processing. *International Journal of Clinical and Experimental Hypnosis*, 34, 234-241.

Following the determination of the luminance threshold of each S, high and low hypnotizable Ss were tested for speed of information processing using a backward masking paradigm with a bias-free and ceiling-free psychophysical task. No significant relationship between hypnotizability as measured by the Stanford Hypnotic Susceptibility Scale, Form A (SHSS:A) of Weitzenhoffer and Hilgard (1959) and speed of information processing was observed. The order of administering SHSS:A, pre- or postthreshold task, was significantly related to luminance threshold. Results were compared to other studies wherein some evidence for a relationship between hypnotizability and speed of visual information processing had been offered.

## NOTES

106 college students were tested using tachistoscopic presentation of stimuli. 52 Ss received the SHSS:A immediately prior to the experimental tasks, 54 immediately after, and testing was terminated for each Subject after they failed 3 successive items. The test flash was set at 0.3 log units above threshold, i.e. double the threshold intensity. A trial consisted of 2 observation intervals, separated by warning tones. The test flash occurred randomly in one of the two intervals. The S indicated which observation interval contained the test flash by pressing a button. Feedback tones gave S information about the correct response.

"The masking experiment was begun with the suprathreshold test flash occurring 250 milliseconds prior to the onset of the larger bright masking stimulus. As before, a two-interval forced-choice staircase procedure was used, but this time the test intensity was constant, and ISI was changed. If S

'hit' three trials in a row, ISI was decreased by 10 milliseconds. The ISIs continued to decrease in 10-millisecond steps, until S "missed," causing an increase in ISI" (p. 348).

RESULTS were analyzed by 2 x 2 x 2 ANOVA (Hypnotizability, sex, and order of hypnotizability measurement). High hypnotizables = 7-12 on the SHSS:A, and low hypnotizables = 0-6. Ss receiving SHSS:A prior to the tasks had a significantly lower luminance threshold (-1.99 log mL) than did those having it after tasks (-1.93 log mL),  $p < .05$ . None of the other analyses were significant. No significant relationships were observed vis a vis the masking task, and the mean masking thresholds were almost identical for the lows and highs.

DISCUSSION. "Spanos (1982), in studying the effects of hypnotizability and suggestions in altering auditory sensitivity, reviewed the difficulties inherent in the measurement of perceptual accuracy and emphasized the role of response bias in the confounding of results" (p. 239). Secondly, these tasks reflect more fundamental, central processes and use more neutral stimuli than letter recognition used earlier. "Thus, while the masking effects of both the previous recognition tasks (masking by pattern) and the current detection tasks (masking by nearby contours) are presumably mediated through similar high level central processes, the differences in findings could possibly have been related to additional processing cues required in letter recognition" (p. 239). A footnote mentions, "Other studies have shown that with stimulus configurations similar to that used in the present study, there are significant central masking effects (Battersby & Wagman, 1962; Markoff & Sturr, 1971; Turvey, 1973)" (p. 239).

"Quite intriguing is the luminance threshold finding which, although not as robust as one would desire, suggests that a hypnotic induction procedure given prior to a task may significantly affect sensitivity on that task. Speculatively, the relaxation suggestions inherent in SHSS:A may account for the changes in luminance threshold" (p. 239).

## 1985

LaRiccia, P. J.; Katz, R. H.; Peters, J. W.; Atkinson, G. W.; Weiss, T. (1985). Biofeedback and hypnosis in weaning from mechanical ventilators. Chest, 87, 267-269.

Weaning patients from mechanical ventilation can be hindered by both physical and psychologic factors. Biofeedback has been used successfully as an adjunct in difficult weaning problems. We have used a combination of hypnosis and biofeedback to wean a patient with neurologic disease who previously failed weaning by standard procedures. A 30-year-old woman with respiratory failure secondary to multiple sclerosis with transverse myelitis was given eight sessions of biofeedback over 12 days in which the movements of her chest wall, as monitored by magnetometers, were displayed on an oscilloscope. The patient was praised for targeted respiratory rate, amplitude, and rhythm. These sessions included hypnosis in which the patient was given suggestions of well-being and that she could breathe as she had five years earlier. In this manner the patient was successfully weaned. Respiratory biofeedback and hypnosis appear to be useful adjuncts in weaning patients from ventilators.

Naish, Peter L. N. (1985). The trance described in signal detection terms. British Journal of Experimental and Clinical Hypnosis, 2 (3), 133-138.

## NOTES

While most current theories of hypnosis are of the non-state kind, clinical practitioners seem to use the concept of trance or altered state. The subjective reports of hypnotised subjects usually involve something akin to perceptual distortion, e.g. time distortion, suggested hallucinations. Such "misperceptions" can be explained by signal detection theory, in which the subject shifts the criterion by which they judge a sensation to be over the threshold of random neural excitation. Thus one would

predict that "highly susceptible hypnotic subjects will be those who are better able, or more willing, to shift their criteria by large amounts" (p. 134).

The author reports experiments from his laboratory that support his hypothesis.

[Jean Holroyd]

1983

Barabasz, Arreed F.; Lonsdale, Christopher (1983). Effects of hypnosis on P300 olfactory-evoked potential amplitudes. Journal of Abnormal Psychology, 92 (4), 520-523.

From a sample of 93 undergraduates, 4 high- and 5 low-hypnotic susceptibility (the Stanford Hypnotic Susceptibility Scale: Form C) Ss were exposed to a waking condition and a hypnotic induction condition that included a suggestion for anosmia. ANOVAs of the P300 showed significant amplitude increases for weak and strong odors for high-hypnotizable Ss in hypnosis, but not for high-hypnotizable Ss in the waking state. No such amplitude increases were found for the low-hypnotizable ss

1982

Farthing, G. William; Brown, Scott W.; Venturino, Michael (1982). Effects of hypnotizability and mental imagery on signal detection sensitivity and response bias. International Journal of Clinical and Experimental Hypnosis, 30, 289-305.

It was hypothesized that the ability to selectively concentrate attention on mental images would be greater among high hypnotizable Ss than among low hypnotizable Ss, as indicated by a greater interference with visual signal detection by concurrent visual mental imagery in response to specified nouns. This hypothesis was not supported in the overall results, though the finding of a significant interference effect among the high hypnotizable female Ss, but not among other subgroups, indicates that further research with a more refined procedure might be worthwhile. On the control trials without images, the high hypnotizable Ss made more false alarms than lows, and had a significantly different bias index indicating that high hypnotizable Ss were more likely than lows to respond "yes" when uncertain about whether the signal was present; false alarms can be interpreted as a nonhypnotic measure of suggestibility. The high and low hypnotizable Ss did not differ in their times to generate images in response to the specified nouns.

1980

Bauer, Herbert; Berner, Peter; Steinringer, Hermann; Stacher, Georg (1980). Effects of hypnotic suggestions of sensory change on event-related cortical slow potential shifts. Archiv fur Psychologie, 133 (3), 161-169.

"The purpose of this study was to evaluate whether cortical slow potentials related to a S1-S2 paradigm are influenced by hypnotic suggestions of sensory change. Five healthy subjects susceptible to hypnosis participated each in two identical experiments with three conditions. In condition (1) and (2) each three intensities of 800 and 4000 Hz tones were presented. Preceding condition (2) hypnosis was induced and the subjects received the suggestion to hear the 800 but not the 4000 Hz tones. In condition (3), the tones were presented as S1 and a flash as S2. The subjects received the same suggestions as in (2) and a motor response to S2 was required. EEG was recorded from Cz. In (1) 800 and 4000 Hz tones caused negativities of equal amplitude, in (2) only minute negativities developed, possibly due to hypnosis induced deactivation. In (3) the S1-S2 related negativities were significantly smaller in amplitude during 4000 Hz tones than during 800 Hz tones, while the negativities preceding

S2 differed only after the most intense S1. Hypnotic suggestions attenuate S1-S2 related negative potentials, possibly by affecting cognitive functions.

Wallace, Benjamin; Hoyenga, K. B. (1980). Production of proprioceptive errors with induced hypnotic anesthesia. International Journal of Clinical and Experimental Hypnosis, 28 (2), 140-147.

The present study assessed the ability of Ss to localize their noses with the forefinger of their dominant hands. This was accomplished while S had his eyes closed and while the limb performing the task was or was not hypnotically anesthetized. In performing this task with an anesthetized limb, 2 error types were observed. The first involved a localization error of missing the nose location. A second error involved an increased amount of time required to find the nose location. An inverse relationship was found to exist between these error types such that a large localization error was associated with a short latency period while a small localization error was associated with a long latency period. Neither error type was evident when hypnotic anesthesia was absent.

1975

Talone, James M.; Diamond, Michael Jay; Steadman, Clarence (1975). Modifying hypnotic performance by means of brief sensory experiences. International Journal of Clinical and Experimental Hypnosis, 23, 190-199.

This study examined the extent to which hypnotic performance could be modified by means of 2 types of pre-hypnosis sensory experiences: (a) auditory stimulation in the form of recorded music, and (b) a variant of sensory restriction in the form of a short period of silence with eyes closed. 39 University of Hawaii students were given a baseline test of hypnotic susceptibility and then randomly assigned to 2 of 3 conditions. The Ss in the music and silence groups were exposed to 10 minutes of either recorded music or silence prior to a criterion hypnotic susceptibility scale. Control-group Ss were exposed only to the hypnotic test scale. All Ss reported their experienced hypnotic sensations. Music- and silence-group Ss completed a self-report scale assessing the role played by relaxation and receptive perception in the manipulation. Although the results were not consistent, both music and silence were significantly effective in increasing responsivity in comparison with practice only. The findings are discussed with reference to possible mediating mechanisms, and the implications of these findings with regard to modifying hypnotic ability, along with the need for replication studies, are considered.

1968

Kline, Milton V. (1968). Sensory hypnoanalysis. International Journal of Clinical and Experimental Hypnosis, 16, 85-100.

SENSORY HYPNOANALYSIS AS A PSYCHOTHERAPEUTIC APPROACH EMPHASIZES THE REORGANIZATION OF COGNITIVE CORRELATES OF SENSORY AND MOTOR COMPONENTS ENCOUNTERED IN BEHAVIORAL DISORDERS. NONVERBAL STIMULATION IS UTILIZED IN ELUCIDATING AREAS OF SENSORY DEPRIVATION AND SENSORY OVERLOADING WHICH APPEAR LINKED TO DISORGANIZING OR INTERFERING EFFECTS UPON THE BEHAVIORAL PROCESS. (SPANISH + GERMAN SUMMARIES) (16 REF.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Schneck, Jerome M. (1966). A study of alterations in body sensations during hypnoanalysis. International Journal of Clinical and Experimental Hypnosis, 14 (3), 216-231.

Presents body-sensation phenomena which appeared in a patient in treatment. The total number exceeds that reported previously and supplies longitudinal as well as cross-sectional perspectives because the data were gathered over a period of several mo. Comparisons are made of this material with findings in other patients. The large variety of sensory phenomena are representations of conscious and unconscious experiences, many of which can be understood in relation to the S's conflicts or his total personality functioning at the time the phenomena appeared. Additional areas for investigation include: (1) evaluation of hypnotic sensory phenomena in relation to a variety of symptoms in the form of somatic complaints by patients seeking psychotherapy, (2) the study of sensory experiences in therapists in connection with their roles in the special settings of hypnotherapy and hypnoanalysis and in treatment without hypnosis, (3) the study of body sensations experienced by "normal" individuals and comparisons of them with hypnotic sensory phenomena, and (4) the evaluation of sensory phenomena as reflections of total psychosomatic functioning with its ideational and affective ingredients. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1965

Jackson, Bill (1965). The autoblink: A technique to explore nonveridical visual perception. International Journal of Clinical and Experimental Hypnosis, 13 (4), 250-260.

The Autoblink technique was developed to allow objective, quantitative investigation of perceptual abnormalities found in psychiatric and normal populations under various experimental conditions. A pilot study demonstrated that spontaneous visual percepts could be elicited by this technique in a group of psychiatric patients and that wide individual differences were present. A 2nd study found significant differences in Autoblink rate between normal and hallucinating psychotic male Ss and also suggested that sensory deprivation and prestige suggestion are variables related to Autoblink rate. A 3rd study further explored differences between psychiatric patients and normal Ss as well as examining sex differences. The latter 2 studies are reported in detail. 1964

Brady, J. P.; Levitt, E. E. (1964). Hypnotically-induced 'anosmia' to ammonia. International Journal of Clinical and Experimental Hypnosis, 12, 18-20.

The procedure to demonstrate anosmia by the inhalation of ammonia is discussed. Deeply hypnotized Ss who are not knowledgeable of the relevant facts of physiology may fail to respond to ammonia fumes when it is suggested that they have no sense of smell (anosmia). However, persons who, in fact, are anosmic do respond to ammonia fumes because they are a powerful stimulus to the pain fibers in the nasal mucosa. This procedure illustrates that the crucial factor in the response of the hypnotized S is not the actual facts of anatomy and physiology, but the S's concept of them. 1960

Sukhakarn, Khun Vichit (1960/1962). Extra ocular vision [Letter]. British Journal of Medical Hypnotism, 14 (2), 41-47.

#### NOTES

The article is in the original form of a letter to Herbert Spiegel, M.D. The author describes experiences training subjects, both blind and with normal vision, to 'see' through the skin of their cheeks. Training

involved concentrative meditation (Buddhist) and hypnosis. Simple tests were performed, apparently independently, by two other scientists.

"From information available from our subjects, the Extra Ocular Vision gained through the cheek-skin is different from those through the eyes as best explained here below:-- (1) The vision through the cheek-skin first takes a form of a series of spots somewhat like the image of coarse grain prints. Only after further training the spots are transformed into a clear object, so clear that needle threading is possible. (2) Objects seen through the cheek-skin are as clear as through the eyes. Distant objects can be magnified by the subject's wish, just like looking through an opera glass. (3) The vision gained through the cheek-skin is first 'seen' in black and white, and the 'colour picture' is achieved only after further training. But the colour 'seen' through the cheek is more intense than those through the eyes. (4) The field of vision 'seen' through each side of the cheek is more narrow than those seen through each eye. (5) There is a sign indicating that the vision through the cheek is only two-dimensional, the subjects find it difficult at first to stand the finger to another finger test" (p. 42).

**1955**

Ambrose, Gordon (1955). Multiple sclerosis and treatment by hypnotherapy. Follow-up and further cases. Journal of Clinical and Experimental Hypnosis, 3 (4), 203-209.

#### NOTES

"Summary. Present day treatment of multiple sclerosis appears inadequate from the psychological view point and patients are too often forced to show a negative response to their illness.

"Six patients have been treated by hypnotherapy with marked subjective improvement. Three of these cases are described.

"The aim in these cases is to put the patient more in control of his organism. Patients should be told that their symptoms must never control them, they must control their symptoms.

"The very nature of the illness prevents the medical attendant from feeling scientific in his approach to these cases. Long follow-up is a necessity but much subjective improvement is possible using hypnotherapy.

"In the hypnoanalytical approach the usual exaggeration of the emotions allied with the psychosomatic reaction will often be found. Hypnosis appears to produce a rapid lessening of tension and anxiety in these cases.

"A deep state of hypnosis should be aimed at and auto-hypnosis must always be taught. It is sometimes useful to place a trusted person en rapport with the patient to carry on with positive and direct suggestions.

#### SEQUELAE

**2000**

Gruzelier, John (2000). Unwanted effects of hypnosis: A review of the evidence and its implications. Contemporary Hypnosis, 17 (4), 161-193.

Reviews the growing evidence of unwanted consequences of hypnosis in experimental, clinical, and entertainment settings. Adverse effects are common, may be physiological or psychological, and are mostly short-lived. The more serious consequences almost exclusively occur in clinical and entertainment applications and have included chronic psychopathology, seizure, stupor, spontaneous dissociative episodes, and the resurrection of memories of previous trauma. Associated phenomena may include physiological events and may be unconsciously mediated. Two cases of 1st episode schizophrenia, one following hypnotherapy and one following stage hypnosis, are described. Evidence of affinities between schizophrenia and hypnosis is revisited in the light of contemporary evidence of

the neurophysiological mechanisms of hypnosis and schizophrenia, with implications for screening vulnerable individuals. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1999

MacHovec, Frank J.; Oster, Marc I. (1999). In the best of families: Understanding hypnosis complications in graduate and post-graduate training experiences. American Journal of Clinical Hypnosis, 42 (1), 3-9.

Unexpected, unwanted complications co-incident with the use of hypnosis can occur even to mental health professionals and in advanced hypnosis training. This article reports three such incidents, which occurred in the practice of a trained, licensed mental health professional, and university faculty member. Suggestions are provided for preventive practice, which may have reduced the risk of untoward aftereffects.

#### NOTES

In the Discussion section, the authors state, "A common thread throughout these three cases is that most occurred in the formal, controlled setting of a university, in a bona fide course on hypnosis given by a trained, experience [sic], and licensed mental health professional to a sophisticated, fully informed, and receptive class of students. That unwanted side effects occurred in such a setting points to the need for training and skill to avert complications and to properly intervene to correct and neutralize those complications as they arise" (pp. 6-7). They suggest ways of lowering risk of unwanted, unexpected side effects.

Moene, Franny C.; Hoogduin, Kees A. L. (1999). The creative use of unexpected responses in the hypnotherapy of patients with conversion disorders. International Journal of Clinical and Experimental Hypnosis, 47 (3), 209-226.

In a previously completed empirical study examining the use of hypnosis in a comprehensive treatment program with 85 patients who suffered motor conversion symptoms, 16 patients were reported by their therapists to have had unusual and unexpected responses during hypnosis. This article summarizes the literature on the occurrence of unintended phenomena during hypnosis and presents instances encountered in a study of conversion hysterics. The article illustrates these occurrences and their management with 7 clinical vignettes and concludes that surprising or unusual responses to hypnosis with these types of cases can be an opportunity for the patient to enhance understanding and gain control over his or her symptoms.

#### NOTES

The authors classify the problems into five groups: problems encountered during induction of hypnosis, problems encountered during treatment proper, untoward affect expression during treatment proper, exaggerated response to suggestions, and problems in terminating hypnosis. They offer a set of guidelines to therapists for managing these kinds of difficulties.

1998

Barber, Joseph (1998). When hypnosis causes trouble. International Journal of Clinical and Experimental Hypnosis, 46 (2), 157-170.

Like any other effective intervention, hypnotic treatment can occasionally cause harmful effects as well as beneficial ones. The first step in avoiding clinical complications is recognizing that they can occur. A review of the literature, however, suggests a long-standing inattention to the potential harmfulness of

hypnotic interventions, including patients' unexpected reactions, leading to clinical complications, including amnesia, catharsis, paralysis, disorientation, literalness of response, accelerated transference, and memory contamination. In addition to these unexpected reactions by patients, complications can also arise from a practitioner's need for power and by the inappropriately narrow focus on the hypnotic process itself, leading to distraction from the more fundamental clinical process.

**1996**

Lynn, Steven Jay; Martin, Daniel J.; Frauman, David C. (1996). Does hypnosis pose special risks for negative effects? A master class commentary. International Journal of Clinical and Experimental Hypnosis, 44 (1), 7-19.

**NOTES**

The authors review evidence in both experimental and clinical hypnosis situations. They conclude that "the available data do not justify the conclusion that hypnotherapy is any more dangerous, or ultimately less effective, than other psychotherapy and relaxation procedures" (p. 13). However, negative effects do sometimes occur in clinic or in laboratory. They indicate that the following situations and factors suggest need for particular care or vigilance:

Increased Psychopathology

Intensified Transference

Misconceptions About Hypnosis

Suggestions May Instigate or Reveal Unexpected Affect

Difficult or Inappropriate Suggestions

Direct Suggestions to Relinquish Symptoms

Countertransference Reactions

Suggestive Procedures and False Memory Creation

Inadequate Training in Psychology and Psychotherapy

**1995**

Barber, Joseph (1995, November). When hypnosis causes trouble. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

**NOTES**

Sexual acting out occurs, even with highly trained and responsible clinicians. But other problems occur, and it is the same qualities of hypnosis that make it useful that also make for problems. I found 20 publications that exhibited problems in therapy, and they all discussed only the mental illness of the patients.

Gravitz, Melvin A. (1995). Inability to dehypnotize: Implications for management. International Journal of Clinical and Experimental Hypnosis, 43, 369-374.

One of the possible complications of working with hypnosis, and a concern of some, is difficulty in alerting the patient from the hypnotic condition. Although such adverse reactions are rare and infrequently observed, they have been noted for many years. This article presents two cases of inability to dehypnotize and discusses the implications for clinical management of the dynamics that were found to be causally related to such behavior.

**NOTES**

The author presents two cases, and writes in conclusion, "It is clear that in both these cases, the individuals were in control of their situations and important personal needs of the moment. Practitioners who may encounter the infrequent problem of inability to dehypnotize their patients

should understand that the patient is thereby undertaking to control his or her own behavior for personally significant reasons. Understanding these reasons as defenses, and circumventing and even using such defenses, enable successful resolution of the problem" (p. 374). J. Holroyd

1994

Singh, Asha (1994, August). Positive and negative effects in hypnosis: Some contributing variables. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

Subjects (N = 155) were randomly assigned to hypnosis with the Harvard hypnotizability scale, hypnosis with neutral imagery instead of the test items in the Harvard scale, and a control condition of a taped chapter read from an Introductory Psychology text. All procedures were taped. Subjects' attitudes toward hypnosis and psychiatric symptoms were first measured. Using self-report measures, positive and negative effects were assessed at three time periods: (a) retrospective assessment of the experience during the intervention; (b) pre-post testing for assessing state immediately after the intervention; and (c) assessment 2 to 4 days later. Results showed a consistent trend at all three time periods. Hypnosis with imagery was more positive and less negative than the control condition. It was also more positive than the Harvard scale. Hypnosis with the Harvard scale was slightly less negative and slightly more positive than the control condition. Hypnotizability was not correlated with hypnosis effects; however, the intensity of hypnosis, or 'hypnoidal state', predicted positive effects (but not negative effects) at every time period in all three groups. Initial attitude was only slightly associated with effect; a positive attitude predicted an overall positive reaction to the experience for all groups, and negative attitude predicted reduced state anxiety 2 to 4 days later. Psychiatric symptomatology predicted a more negative experience during all conditions, but was associated with less negative feelings, more positive feelings, and reduced state anxiety afterward. In conclusion, hypnosis with a self-selected student population in an experimental setting is no more harmful than a control condition; in fact it is more enjoyable and more positive in its effects than the latter. Hypnosis has more positive and less negative effects when the Harvard test items are replaced by neutral imagery. Subject attributes play a more complex role than hypothesized in determining hypnosis effects. The implications of these findings are discussed. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall 1994, Vol. 3, No. 3.)

1993

Sivec, Harry; Lynn, Steven Jay (1993, October). Negative posthypnotic effects: The influence of prehypnotic experiences. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

Ss and Experimenters may mis-attribute negative experiential effects to hypnosis because of temporal contiguity. This study required Ss to complete the experiences scale before and after hypnosis and before and after a non-hypnotic control procedure. The PES is a 65 item scale and has a stable factor structure assessing pleasant, perceptual/kinesthetic, anger, and anxiety experiences.

49 Ss completed the test before and after the Harvard Group Scale, minus the word "hypnosis" in the induction, though it was presented as a study of hypnosis; 33 had the study presented as study of body awareness, and were to focus on body parts corresponding to the parts mentioned on the Harvard.

#### RESULTS.

Ss in both groups reported more perceptual/kinesthetic effects after than before the experience. Research failed to find hypnosis was associated with unique effects that were negative. The single

increase might be due to focusing on the body. The only difference between groups was that hypnosis Ss reported fewer anger experiences than those in the other group.

This data disconfirms the belief that hypnosis is associated with negative effects.

1992

Brentar, John P.; Lynn, Steven J. (1992, August). The Post-Hypnotic Experience Scale: Validity and reliability. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, DC.

This paper describes the development of the Posthypnotic Experiences Scale (PES), a 57-item scale comprised of four subscales labeled Pleasant, Somatic- Kinesthetic, Irritability/Anger, and Anxiety. It was derived by way of an initial factor analysis using 444 subjects and refined by a second factor analysis using 288 subjects. In three data collection phases, the subscales were found to be internally consistent and to exhibit low to moderate test-retest reliabilities. The PES was also found to evidence excellent content, convergent, and discriminant validity, as measured by indices of hypnotizability, positive affect, depression, anxiety, hostility, sensation seeking, dysphoria, social desirability, perceptual aberration, absorption, and physical symptomatology. Behavioral validity was demonstrated in so far as subjects who were willing to volunteer for a second experiment, without reimbursement, scored higher on the Pleasant subscale than did nonvolunteers. (ABSTRACT from the Bulletin of Division 30, Psychological Hypnosis, Fall, 1992, Vol. 1, No. 3.)

Crawford, Helen J.; Kitner-Triolo, Melissa; Clarke, Steven W.; Olesko, Brian (1992). Transient positive and negative experiences accompanying stage hypnosis. Journal of Abnormal Psychology, 101 (4), 663-667.

Frequency of positive and negative experiences accompanying stage hypnosis was assessed in follow-up interviews with 22 participants of university-sponsored performances. Most subjects described their experience positively (relaxing, interesting, exciting, satisfying, illuminating, and pleasurable), but some described it negatively (confusing, silly, annoying, and frightening). Five subjects (22.7%) reported partial or complete amnesia; all were highly responsive to the stage hypnosis suggestions. One subject was completely unable to breach amnesia and felt annoyed and frightened. Five subjects (22.7%) believed the hypnotist had control over their behavior. Participants (n=15) tested subsequently on the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & Hilgard, 1962) were mostly moderately to highly hypnotizable ( $M = 7.07$ ), and the scores correlated significantly ( $r = .68$ ) with the percentage of passed stage hypnosis suggestions.

NOTES: Echterling and Emmerling (1987, American Journal of Clinical Hypnosis) conducted a follow-up of 18 people who participated in stage hypnosis at a university, within a month after the experience. Referring back to the hypnosis itself, 39% reported positive experiences, 39% reported both positive and negative experiences, and 22% (four people) reported 'strongly negative' experiences. The present study contacted subjects immediately after the stage hypnosis experience, either in person or by telephone. They completed both objective questions and open-ended questions referring to three time periods: after the hypnotic induction, during the hypnotic suggestions, and after the stage hypnosis had been terminated. Subjects were invited to come to the laboratory to be tested for hypnotizability, and 15 of the 22 did return for testing.

Of the 22 Ss, 4 had previously participated in stage hypnosis, one in laboratory hypnosis, and one had been hypnotized by her father. Of the 15 tested with the Stanford Hypnotic Susceptibility Scale, Form C: 7 were high hypnotizables (scoring 9-12), 7 were medium hypnotizables (scoring 4-8), and one was a low hypnotizable (scoring 0-3). Several people reported that they 'went along with' the hypnotist's suggestions, role playing rather than actually experiencing the suggestions.

"Most of the subjects found the experience positive: 86.4%, relaxing; 86.4%, interesting; 77.3%, exciting; 59.0%, satisfying; 54.6% illuminating; and 54.6%, pleasurable. Negative experiences were also reported: 36.4%, confusing; 36.4%, silly; 9.1%, annoying; and 9.1%, frightening. Only 1 subject reported the stage hypnosis experience as entirely negative.

"The stage hypnotists told the participants about the suggestions at the end of the stage hypnosis performance and supposedly lifted amnesia. Despite this, some participants continued to experience partial or full amnesia for the suggestions. ...

"One participant reported complete amnesia even after the interview and was distraught, permitting only a telephone interview and not accepting an offer to be hypnotized at a later time to help recall what had been forgotten. ...

"... The interviewer told her what had been observed and attempted to breach the amnesia. The subject continued to report complete amnesia.

"Two other participants continued not to remember many of the suggestions but showed no major concern. Waking suggestions to breach amnesia were given, but no further information was obtained.

"Five participants reported feeling that the hypnotist had complete control over their behavior and that they could not resist the hypnotist's suggestions" (p. 664).

In their Discussion, the authors note that in general, when negative experiences occur, they tend to be mild and transient. None of the subjects in this investigation reported some of the negative sequelae reported in earlier literature (headaches, nausea, drowsiness). The few subjects who had strong cognitive distortions following hypnosis were highly hypnotizable, which also was observed in an earlier study published by the first author and her colleagues (Crawford, Hilgard, & Macdonald, 1982, *International Journal of Clinical and Experimental Hypnosis*).

Spontaneous post hypnotic amnesia is one example of cognitive distortion. The authors remarked on the rather high incidence of spontaneous amnesia for some specific suggestions (22.7%) , which was discovered when friends of the subjects described to them what they had done on stage. In an experimental study by Hilgard and Cooper (1965), only 7% of student subjects had spontaneous amnesia (though 35% had amnesia following suggestions for posthypnotic amnesia). Furthermore, in the Hilgard and Cooper study, hypnotizability correlated with suggested amnesia but not with spontaneous amnesia. Cooper (1972) reviewed the literature on posthypnotic amnesia and observed that spontaneous occurrence is less frequent than suggested amnesia.

Explanations of spontaneous amnesia include ideas that high hypnotizables who experience it are significantly different from those who do not (Chertok, 1981; Weitzenhoffer, 1989); or that it is due to expectancy (Kirsch, 1985); or that it is found in people with a tendency for dissociation in and out of hypnosis, or people who may be prone to repression or dissociative and post-traumatic stress disorders. For reviews of these issues, see Kihlstrom, 1987; Kihlstrom & Hoyt, 1990; Frankel, 1990; Nemiah, 1985; Spiegel, 1990; Spiegel & Cardena, 1991).

The authors note that stage hypnotists, while they may otherwise be ethical, do not provide information to subjects to correct misperceptions about hypnosis. For example, in this study 22.7% of the subjects believed, after the stage hypnosis experience, that the hypnotist had control over their behavior and they couldn't resist the suggestions. "Appropriate guidelines for stage hypnosis (see also Crawford et al., 1982) include screening out participants who are in therapy or counseling, correcting misperceptions about hypnosis among the participants before the hypnosis begins, screening subjects prior to hypnosis, avoiding embarrassing or upsetting suggestions, providing dehypnosis instructions to those who do not remain in hypnosis (or are asked to leave the performance), terminating fully the hypnotic experience, removing all amnesia suggestions and reviewing the events at the end of hypnotic experience, and remaining available afterward for further questions" (p. 666).

Peterson, Patricia; Coe, William C. (1991, April). Negative sequelae to hypnosis: A function of expectations?. [Paper] Presented at the annual meeting of the Western Psychological Association.

## NOTES

Researchers have theorized that the ways in which hypnotic subjects respond may result from their expectancies of the experience. If so, it seems likely that warning subjects of possible negative aftereffects before they are hypnotized could elicit subsequent reports of such effects.

Three groups of subjects were given varied expectancies prior to a hypnotic induction and scale: (A) a specific warning of a 50% chance of negative aftereffects, (B) a vague warning of negative aftereffects, and (C) no mention of aftereffects. Subjects later reported positive, negative, sleep related, and bodily change sequelae.

The findings were in the expected direction in that Group A reported more negative sequelae than Groups B or C. However, Group C (the controls) also reported more negative sequelae and bodily changes than Group B. The inadvertent addition of a positive expectancy administered in the Group B scenario may have acted as a confound and caused that group's lower level of negative sequelae.

## 1990

Gravitz, Melvin A. (1990). Adverse behavior associated with the eye-roll test of hypnotizability: Clinical and theoretical considerations. Psychotherapy: Theory, Research and Practice, 27, 267-270.

For 15 years, subjects' response to the eye-roll test has been used to measure susceptibility without adverse effects. A case is described of a hospitalized young man who displayed dissociative behavior when asked to do the eye-roll as part of a diagnostic evaluation. Etiological and theoretical considerations, and implications for therapeutic strategy are discussed.

Lazarus, A. A.; Mayne, T. J. (1990). Relaxation: Some limitations, side effects, and proposed solutions. Psychotherapy, 27, 261-266.

Deep-muscle relaxation has been widely regarded as anxiety inhibiting, and the relaxation response an antidote to tension and stress. However, some relaxation techniques have been shown to have negative effects. These include relaxation-induced anxiety and panic, paradoxical increases in tension, and parasympathetic rebound. Specific indications and contraindications are discussed

## NOTES

The following unpleasant side effects have been observed: "unpleasant sensations of heaviness, warmth, perspiration, tingling, numbness, dizziness, floating, coolness; paradoxical increases in tension; rapid heart rate; feelings of physical and psychological vulnerability; depression; fear of losing control; depersonalization; dissociation; myoclonic jerks; spasms; headache; akathisia; negative auditory, gustatory, and olfactory reactions; intrusive images and thoughts; anxiety; irritability; guilt; regressive urges; hallucinations; and panic" (p. 261).

People have been observed to have "negative or untoward reactions to meditation ([Lazarus, 1976]; French, Schmid & Ingalls, 1975; Kennedy, 1976), relaxation (Borkovec & Grayson, 1980; Carrington, 1977; Edinger & Jacobsen, 1982), and biofeedback (Miller & Dworkin, 1977). In his doctoral dissertation Heide (1981) found that more than half of his subjects under focused relaxation reported increased tension due to the relaxation session. Recently, the concept of RIA--relaxation-induced anxiety--has appeared in the literature (Heide & Borkovec, 1983; 1984). Clients suffering from generalized anxiety appear to be especially prone to RIA" (pp. 261-262).

Others have suggested that relaxation may be counterindicated for asthmatics, because the small airways dilate with sympathetic nervous system arousal. The specific instructions of autogenic training may be counterindicated for patients with gastrointestinal disease because focusing on a sense of warmth in the abdomen tends to produce more peristalsis, increased blood flow in the gastric mucosa,

and acidity in the gastric juice (Luthe & Schultz, 1979). Even the standard relaxation therapy for tension headache (as well as other pain problems) is being replaced with cognitive behavioral therapy, which may have relaxation as only one component. "The point again is that relaxation is not a panacea, and that an informed selection and administration of treatments is mandated, even in disorders where relaxation has traditionally been held second only to medication" (p. 264).

Interviews suggest people with relaxation induced anxiety (RIA) fear losing control. "Some are afraid of heightened arousal; others refer to helplessness, depression, some unidentified internal or external danger, a fear of going crazy, a negative association with anesthetics, a fear of falling from heights, plus any number of catastrophic expectations (Chambless & Goldstein, 1980)" (p. 264). Lazarus recommends that if someone displays RIA, the therapist may try alternative techniques, which might include for example tensing-relaxing muscles, passive receptivity, positive or pleasant imagery, focus on breathing, subvocal monotonous chant or mantra, or the Vipassana meditation practice of achieving awareness of spontaneous sensations and thoughts. The relationship with the therapist, differences in room illumination, amount of time per session, and sitting or reclining may be important.

"If a therapist deduces that a client is likely to derive benefit from relaxation training, three obvious questions arise: (1) Which of the many types of relaxation training programs is this particular client likely to respond to? (2) How frequently, and for what length of time, should the client practice the selected relaxation sequence? (3) Will treatment adherence be augmented or attenuated by the supplementary use of cassettes for home use?" (P. 262).

The authors describe their Structural Profile Inventory (SPI; Lazarus, 1989), a 35- item questionnaire, which may be used to predict the preferred sequences and forms of relaxation to employ with individual clients. "A predominantly imagery/sensory reactor, for example, may do well with visualization and autogenic training, whereas a highly active/cognitive client might be better advised first to engage in strenuous exercise followed by calming self-statements (Zilbergeld & Lazarus, 1988)" (p. 265). They suggest that for those patients who are perfectionistic and simply can't "just let go," they might simply fill a bathtub with warm water and sit in it for 10-20 minutes and rest with a magazine (rather than "relax") once or twice a day.

Page, Roger A.; Handley, George W. (1990). Psychogenic and physiological sequelae to hypnosis: Two case reports. American Journal of Clinical Hypnosis, 32 (4), 250-256.

Two cases of hypnotic sequelae occurring in a research context (with a non-clinical college population) are reported. Case 1 was a male who experienced retroactive amnesia following hypnosis: He was unable to recall familiar telephone numbers later that day. This was not a continuation of an earlier confusion or drowsiness (as is often found) since he indicated he was wide awake following hypnosis. Two parallels exist with previous reports: unpleasant childhood experiences with chemical anesthesia and a conflict involving a wish to experience hypnosis but a reluctance to relinquish control. Case 2 was a female who, while in hypnosis, experienced an apparent epileptic seizure that had characteristics of both petit mal and grand mal seizures. Although having a history of epilepsy, she had not had a seizure in 7 years. We suspect that the seizure was psychogenic and may have been triggered by wording used in the hypnotic scale or other similarities. Possible mechanisms are discussed and preventative recommendations are made.

1989

Brentar, J.; Lynn, Steven J. (1989). 'Negative' effects and hypnosis: A critical examination. British Journal of Experimental and Clinical Hypnosis, 6, 75-84.

Reviews evidence concerning if hypnosis is responsible for unwanted or negative posthypnotic effects, concluding that support for this hypothesis is lacking. Many such investigations are either anecdotal reports or are marred by methodological flaws that render the interpretation of posthypnotic experiences problematical. Controlled research has not provided support for the hypothesis that hypnosis per se is responsible for certain subjective changes which accompany it, or that hypnosis is more stressful or anxiety provoking than other common experiences encountered by subjects. Although a small percentage of subjects appear to experience posthypnotic reactions, they are typically fleeting, and the link between hypnotic procedures and negative effects has not been adequately substantiated. Indeed, routine hypnosis is typically harmless and is perceived by many subjects as a pleasant, positive experience.

Rickard, Henry C.; McCoy, Anthony D.; Collier, James B.; Weinberger, Martha B. (1989). Relaxation training side effects reported by seriously disturbed inpatients. Journal of Clinical Psychology, 45, 446-450.

Examined the extent to which 50 seriously disturbed inpatients (aged 24-74 years) reported side effects related to passive and progressive relaxation training. Questionnaire results show that most Subjects reported few side effects. When side effects were reported, intrusive thoughts were most frequent. There was no significant difference in side effects reported in response to the 2 training procedures.

1988

MacHovec, Frank J. (1988). Hypnosis complications, risk factors, and prevention. American Journal of Clinical Hypnosis, 31, 40-49.

There is a substantial body of clinical and experimental research data documenting the incidence of mild to severe after effects coincident with the use of hypnosis in persons with no prior history of similar medical or mental problems. This article provides an overview of relevant clinical and experimental research and a review of pertinent literature since 1887. Subject, hypnotist, and environmental risk factors are listed, a definition and classification system for hypnosis complications is suggested, and recommended preventive practices are described.

1986

Echterling, Lennis G.; Emmerling, David A. (1986, August). Contrasting response expectancies of stage and clinical hypnosis. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, DC.

Although both are labeled hypnosis, the experience, behaviors, and effects of hypnosis in stage and clinical settings differ dramatically. We explore these differences between stage and clinical hypnosis and conceptualize them within the framework of nonvolitional response expectancy. Two methods were used to gather information for this study. First, we observed the contrasting styles, strategies and situations in both stage and clinical hypnosis. Second, we identified and interviewed individuals who had experienced trance in both clinical and stage settings. We found significant differences in hypnotist style, subject attribution of causality, trance depth, trance behavior, and outcome. Our discussion contrasts the differing response expectancies of stage and clinical hypnosis in terms of situation, subject's role, and subject's perception of hypnotizability.

Hendler, Cobie S.; Redd, William H. (1986). Fear of hypnosis: The role of labeling in patients' acceptance of behavioral interventions. Behavior Therapy, 17, 2-13.

One hundred and five outpatient cancer chemotherapy patients were interviewed to assess their attitudes toward hypnosis and relaxation as well as to determine their beliefs in and willingness to try a behavioral procedure. Patients were randomly assigned to groups receiving identical descriptions labeled "hypnosis," "relaxation," or "passive relaxation with guided imagery." The description stressed the behavioral components of hypnosis and relaxation rather than the nonbehavioral techniques often associated with hypnosis such as age regression and posthypnotic suggestion. Patients believed hypnosis to be a powerful process that involved loss of control and altered states of consciousness. When compared with a group of college students, patients held significantly more fearful, conservative views about hypnosis. Patients who received a description of an intervention labeled "hypnosis" were significantly less likely to believe the procedure would effectively control their nausea and vomiting and were significantly less likely to state they would try the procedure than patients in the other two label conditions. This reaction to the label occurred independently of patients' degree of nausea, vomiting, and pain due to their chemotherapy treatments.

Judd, Fiona K.; Burrows, Graham D.; Dennerstein, Lorraine (1986). Clinicians' perceptions of the adverse effects of hypnosis: A preliminary study. Australian Journal of Clinical and Experimental Hypnosis, 14, 49-60.

Questionnaires were sent to all members of the Australian Society of Hypnosis and responses obtained from 202 members and associate members who used hypnosis clinically. Respondents' experience in the use of hypnosis and the frequency of use of hypnosis as a treatment modality varied. Overall 43.5% of respondents reported adverse effects with one or more patients over the preceding year. Most adverse effects attributed to hypnosis were transient and included development of panic or extreme anxiety, development of excessive dependence and difficulty in terminating hypnosis. Exacerbation or precipitation of significant depression was an infrequent but serious adverse effect attributed to hypnosis. Other infrequent adverse effects included symptom substitution, acting out behaviour, fantasied sexual seduction, precipitation or worsening of psychotic illness or difficulties in the management of organic conditions. The difficulties were acknowledged of differentiating between the effects of hypnosis itself and other components of the therapeutic transaction, but the results of this survey suggested both that hypnosis be employed clinically by properly trained professionals and that further sensitive clinical research is needed in the area.

LeBoeuf, Alan (1986). Relaxation-induced anxiety in an agoraphobic population. Perceptual and Motor Skills, 62, 910.

Two groups of 14 agoraphobic patients with anxiety attacks were randomly assigned to suggestion-imagery (like hypnosis) and progressive relaxation (with muscle tensing and release). The progressive relaxation group showed greater drop in subjective anxiety, but there was no difference between groups with regard to heart rate. Following the experience, the suggestion-imagery group had more negative responses to : Did you experience anxiety? Did you ever fear losing control? Did you experience any strange sensations during the session? Was the session aversive?

Milne, Gordon (1986). Hypnotic compliance and other hazards. Australian Journal of Clinical and Experimental Hypnosis, 14, 15-29.

Hypnosis is not an external 'force' or 'power' but a special kind of interaction between two persons. The outcome depends on the skill and intentions of the hypnotist and the responsiveness and compliance of the subject. Skill may be marred by procedural errors, 'sins of omission'; intentions by a

self-centred rather than a patient- centred approach, 'sins of commission'. A hazard peculiar to the use of hypnosis is a fallacious belief in the power it enables the operator to wield over the subject.

1985

Fellows, Brian J. (1985). Hypnosis teaching and research in British psychology departments: Current practice attitudes and concerns. British Journal of Experimental and Clinical Hypnosis, 2 (3), 151-156.

The author mailed a questionnaire to 58 departments of psychology to determine the extent/nature of hypnosis teaching and research, and attitudes toward teaching and research on hypnosis. The author noted a general anxiety about teaching students how to do hypnosis (as contrasted with learning about hypnosis). "Some of the anxieties which departments have about the teaching of hypnosis seem to stem from some rather ancient and invalid conceptions about the nature of hypnosis and what it can do" (p. 153). The author also relates his personal experience teaching undergraduates "something about the procedures and phenomena which have been traditionally associated with hypnosis" (p. 153). They may use one of the standard hypnotizability scales, study a particular hypnotic phenomenon such as ideomotor action or age regression, or study an empirical issue such as facilitation of recall. He reports not meeting with "any particular difficulties," but also that he has seen two problems: the student who is anxious about doing the procedure, and an occasional subject who reports the experience was unpleasant or disturbing--e.g. during age regression. He reports teaching students to handle these events in a normalizing manner. J. Holroyd

1984

Fewtrell, W. E. (1984). Relaxation and depersonalization. British Journal of Psychiatry, 145, 217.

#### NOTES

In 40 anxious patients treated with Jacobson's progressive relaxation, 7 reported distress (something like Heide's Relaxation Induced Anxiety). Looking retrospectively at the clinical notes, these seven usually reported symptoms of a depersonalization syndrome prior to treatment. The author administered Dixon's (1963) Self Alienation Questionnaire, which purports to measure depersonalization. The patients who had distress scored significantly higher on Self-Alienation than ten randomly selected control subjects who had responded to the relaxation procedures without problems (adverse effects patients' mean = 32; controls' mean = 22; P = .05).

This article presents evidence that the presence of relaxation may distress depersonalized patients, presumably exacerbating feelings of unreality.

Heide, F. J.; Borkovec, T. D. (1984). Relaxation-induced anxiety: Mechanisms and theoretical implications. Behaviour Research and Therapy, 22, 1-12.

Literature evidence documenting the occurrence of relaxation-induced anxiety is reviewed, and several hypothesized mechanisms to explain the phenomenon are discussed. Possible avenues for circumventing the problem in therapy are offered. Finally, a theoretical model is presented wherein the phenomenon is viewed with a broader framework designed to explain the development and maintenance of the more generalized anxiety disorders. That framework emphasizes the emergence of fear of somatic anxiety cues and fear of loss of control from more fundamental interpersonal anxieties.

Kleinhaus, Moris; Beran, Barbara (1984). Misuse of hypnosis: A factor in psychopathology. American Journal of Clinical Hypnosis, 26, 283-290.

Six cases of posthypnotic trauma are presented to illustrate possible psychopathologic symptoms that may be exhibited in Ss following the misuse of hypnosis, particularly for a stage performance. Medical professionals must be made aware of the possibility of immediate as well as long-term deleterious effects that may follow misuse of hypnosis so that those cases which come to the attention of the physician will be properly diagnosed and treated.

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott (1984). The direct hypnotic suggestion of altered mind/body perception. American Journal of Clinical Hypnosis, 27, 95-102.

Attentional and emotional shifts are examined following a hypnotically suggested out-of-body experience (OBE). Two hypotheses were tested: 1) that the OBE is maintained by blocking the perception of body-relevant stimulation at a sensory level; 2) that a hypnotically produced OBE is an emotionally neutral or even pleasant experience. Fourteen hypnotic subjects and 15 simulating Ss were administered a standardized induction followed by suggestions for an OBE. Geometric figures were then presented to the body but not to the "awareness." Although hypnotic Ss reported that they could not see the information, they still correctly "guess" the identity of the figures beyond chance levels. Thus, body-relevant information was obviously not blocked at a sensory level, but was kept out of awareness by some other mechanism. In addition, a significantly greater number of hypnotized than simulating Ss reported the OBE to be troubling and unpleasant, despite explicit suggestions for a positive experience. The potentially disturbing nature of OBEs and ways to minimize risk of negative affect are discussed.

Smith, Mark Scott; Kamitsuka, Michael (1984). Self-hypnosis misinterpreted as CNS deterioration in an adolescent with leukemia and Vincristine toxicity. American Journal of Clinical Hypnosis, 26 (4), 280-282.

A thirteen year-old girl with leukemia was taught self-hypnosis techniques for symptom control. She was hospitalized with probable vincristine toxicity and a superimposed hyperventilation syndrome. Her spontaneous use of the self-hypnosis technique was misinterpreted as central nervous system deterioration until her apparently comatose state resolved with suggestions from the therapist.

1983

Heide, F. J.; Borkovec, T. D. (1983). Relaxation-induced anxiety: Paradoxical anxiety enhancement due to relaxation training. Journal of Consulting and Clinical Psychology, 51, 171-182.

The present study was designed to document the occurrence of relaxation-induced anxiety. Fourteen subjects (7 male, 7 female) suffering from general tension and significant levels of anxiety were given one session of training in each of two relaxation methods, progressive relaxation and mantra meditation; order of presentation was counterbalanced. Four of the subjects plus one other who terminated prematurely displayed clinical evidence of an anxiety reaction during a preliminary practice period, while 30.8% of the total group under progressive relaxation and 53.8% under focused relaxation reported increased tension due to the relaxation session. Progressive relaxation produced greater reductions in subjective and physiological outcome measures and less evidence of relaxation-induced anxiety, and the phenomenon was not clearly evident from physiological measures and from subjective ratings even in this clinical population.

1982

Crawford, Helen J.; Hilgard, Josephine R.; MacDonald, Hugh (1982). Transient experiences following hypnotic testing and special termination procedures. International Journal of Clinical and Experimental Hypnosis, 30, 117-126.

For those who are responsive to hypnosis, the experiences can be unusual and involving. It is not surprising, therefore, that such experiences in response to tests of susceptibility may not be fully terminated when the hypnotic sessions end. In order to study the initial persistence of the effects, following administration of the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962) and the Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) of Weitzenhoffer and E. R. Hilgard (1962), 107 college Ss were interviewed about their hypnotic experiences and subsequent experiences related to hypnosis. 72% of Ss reported feelings of relaxation and being rested following SHSS:C. Only 5% reported minor transient posthypnotic experiences following HGSHS:A, while 29% of Ss reported these feelings following SHSS:C. Except in 1 case, cognitive distortions or confusion were reported only following the more cognitively oriented SHSS:C by Ss who scored significantly higher on cognitive items than those Ss who reported feeling drowsy. A special termination procedure involving exercise and conversation had no significant effect on the number of transient experiences. Such minor transient experiences are not a risk to Ss and any slight discomfort or uneasiness they cause can easily be dealt with by a well-trained hypnotist.

1981

leinhauz, Moris; Beran, B. (1981). Misuses of hypnosis: A medical emergency and its treatment. International Journal of Clinical and Experimental Hypnosis, 29 (2), 148-161.

Hypnosis is an intense interpersonal relationship requiring 2-way respect and involvement. Inadequate understanding of this dynamic relationship, and a consequent inability to cope with its potential dangers, may result in posthypnotic trauma. Unless treated carefully by a hypnotherapist who is experienced in both the techniques of dehypnotization and the utilization of psychotherapy, such traumas may persist for a very long time. In this paper, one striking case illustrates mishandling of the hypnotic event and immediate posthypnotic treatment and details the procedure by which successful treatment was eventually determined.

1979

Kleinhauz, Moris; Dreyfuss, Daniel A.; Beran, Barbara; Goldberg, Tova; Azikri, David (1979). Some after-effects of stage hypnosis: A case study of psychopathological manifestations. International Journal of Clinical and Experimental Hypnosis, 27, 219-226.

Some deleterious effects of stage hypnosis are described through a case report. A middle-aged respected member of a kibbutz who became the subject of an evening's entertainment by a stage hypnotist suffered a posttraumatic neurosis. The stage hypnotist, unaware of her traumatic childhood during World War II when she and her sister were hidden by Gentiles, requested her to regress to that age. This reactivated a former successfully repressed trauma and acted as a precipitating factor to the development of a traumatic neurosis which was left untreated. She was self-referred for adequate psychiatric treatment 11 years later. This treatment successfully restored her to an adequate level of functioning.

1978

Pettinati, Helen M.; Evans, Frederick J. (1978). Posthypnotic amnesia: Evaluation of selective recall of successful experiences. International Journal of Clinical and Experimental Hypnosis, 26 (4), 317-329.

Following suggestions of posthypnotic amnesia, Ss who are unresponsive to hypnosis tend to recall those suggestions that they passed rather than the ones that they failed; similar trends in hypnotizable Ss have been equivocal (Hilgard & Hommel, 1961; O'Connell, 1966). Modifications on the present selective recall index were developed to take into account the differences in the total recall pools available to hypnotizable and un hypnotizable individuals (who also differ in the total number of successful experiences), for the purpose of clarifying the amount of potential bias in the scoring procedure that may be accounting for previous ambiguous results. A sample of 88 volunteers were administered the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962). Both high and low hypnotizable Ss recalled more passed experiences during posthypnotic amnesia than would be expected by chance when alternative scoring procedures were used. This result is in accord with findings in other contexts in the normal memory literature. Although highly hypnotizable Ss were less likely to selectively recall successful experiences than were low hypnotizable Ss using 5 different scoring procedures, the differences between high and low Ss were not significant.

1977

Anderson, J. W. (1977). Defensive maneuvers in two incidents involving the Chevreul pendulum: A clinical note. International Journal of Clinical and Experimental Hypnosis, 25, 4-6.

#### NOTES

"Hypnosis frequently facilitates increased access to the unconscious. In both of these cases, the hypnotized subject gained contact with a thought which otherwise would likely have remained out of awareness. Then the ego quickly resorted to defensive maneuvers in order to deny the thought" (p. 6).

Duncan, B.; Perry, C. (1977). Uncancelled hypnotic suggestions: Initial studies. American Journal of Clinical Hypnosis, 19, 166-176.

Despite considerable anecdotal evidence of uncancelled hypnotic suggestions persisting posthypnotically, no laboratory investigation of the phenomenon's parameters has ever been attempted. From the literature on posthypnotic suggestion, one might expect uncancelled suggestions to have a quasi-automatic component and to be affected additionally by social, expectational and interactional variables. The report summarizes three initial investigations of parameters that may affect the carry over of uncancelled suggestions into the posthypnotic period. IN the first two, the incidence of uncancelled suggestions influencing behaviour following hypnosis was low. In a third experiment, there was a marked increase in the number of Ss manifesting the phenomenon. This appeared to be related to the hypnotist's instruction that Ss would experience all effects suggested for as long as the hypnotist asked them to. The finding is interpreted in the light of evidence indicating that highly hypnotizable Ss may imbue the hypnotist's communications with special meaning. The role of Ss motives, attitudes and sets, and of differences in specialized skills among highly hypnotizable Ss are also discussed as a basis for future investigation of other parameters affecting the phenomenon's occurrence.

Ryken, Klazina; Coe, William C. (1977, August). Sequelae to hypnosis in perspective. [Paper] Presented at the annual meeting of the American Psychological Association, San Francisco.

Sequelae associated with hypnosis are generally described in clinical contexts. The present study, however, examined the aftereffects of hypnosis in an experimental context, using appropriate control groups for comparison. A standard, self-report questionnaire was administered to six groups of subjects: two groups had been hypnotized and four groups had not been hypnotized. The results indicated that hypnosis created no more negative sequelae than most of the non-hypnotic conditions and actually resulted in more positive outcomes than some of the non-hypnotic conditions.

1976

Stewart, C. G.; Dunlap, W. P. (1976). Functional isolation of associations during suggested posthypnotic amnesia. International Journal of Clinical and Experimental Hypnosis, 24, 426-434.

A search was made for functional isolation effects of hypnotic amnesia that do not derive directly from either the explicit content or simple demand characteristics of amnesia instructions. The frequency of response repetition on a word association task was investigated as a function of posthypnotically suggested recall amnesia during the normal waking state. A trace of evidence for predicted amnesia effects occurred with only 1 out of 6 intensively trained, highly susceptible subjects. The results are compatible with the view that (a) suggested recall amnesia produces a disturbance of the retrieval process similar to source amnesia, and (b) indirect associational measures then merely serve to stimulate retrieval.

1974

Hilgard, Josephine R. (1974). Sequelae to hypnosis. International Journal of Clinical and Experimental Hypnosis, 22 (4), 281-298.

An interview sample of 120 university students yielded evidence that 15% had some kind of reaction to hypnosis that endured an hour or longer following an individual Form C session subsequent to group hypnosis. If those with short-term reactions lasting from 5 minutes to 1 hour are added, the number with some lingering effect rises to 31%. Although these symptoms following laboratory hypnosis were not found to be severe, their presence is of importance both for theoretical and practical reasons. Although as found in an earlier study, sequelae to hypnosis were more frequent among those with unpleasant reactions to earlier childhood anesthesia, the difference did not reach statistical significance.

1970

Fromm, Erika (1970). Age regression with unexpected reappearance of a repressed childhood language. International Journal of Clinical and Experimental Hypnosis, 18, 79-88.

Describes the case of a 26-yr-old, 3rd-generation Japanese-American who thought he knew no Japanese. When hypnotically age-regressed to levels below age 4, he spontaneously and unexpectedly spoke Japanese, while only English was spoken at the adult and age-regression levels above 4 yr. The psychodynamics of the S's repression of the childhood language and questions pertaining to the nature and theory of age regression are discussed. (Spanish & German summaries) (16 ref.) 1968

Faw, Volney; Sellers, David J.; Wilcox, Warren W. (1968). Psychopathological effects of hypnosis. International Journal of Clinical and Experimental Hypnosis, 16, 26-37.

The probability that hypnotic induction produces psychopathological effects has not been experimentally determined. The present study hypothesizes various negative effects following hypnosis such as increased signs of personality disturbances, increased need for medical attention, greater tendencies toward suicide, and negative effects among the more maladjusted persons of the population sample. 107 college students were assigned at random to experimental and control groups. The experimental group was hypnotized 3 times in successive weeks. A comparison between control and experimental groups in respect to pre- and post-MMPI score differences plus a follow-up with the college counseling center and infirmary for a 90-day period following induction led to the rejection of the hypotheses. A comparison of measures yielded some significant differences in favor of the

experimental group. It is concluded that there are nondetrimental effects when hypnosis is used with a normal college population.

Sakata, Kenneth I. (1968). Report on a case of failure to dehypnotize and subsequent reputed aftereffects. International Journal of Clinical and Experimental Hypnosis, 16 (4), 221-228.

The failure of a hypnotized S to execute a suggested task may have contributed to a failure to dehypnotize, the repression of the unsuccessful task after awakening, and a prolongation or reinstatement of hypnosis 3 days later. Some interview material and procedures utilized in handling the problems encountered are presented. (French & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1966

Cooper, L. M. (1966). Spontaneous and suggested posthypnotic source amnesia. International Journal of Clinical and Experimental Hypnosis, 14 (2), 180-193.

The occurrence of spontaneous and/or suggested posthypnotic source amnesia was investigated in a sample of 93 introductory psychology students. Ss were randomly assigned to 1 of 2 groups, served as Ss on 2 successive days, and were administered the Stanford Hypnotic Susceptibility Scale, Form C. For 1 group, source amnesia was suggested on 1 day and was not suggested on the 2nd day; this order was reversed for the 2nd group. 2 Ss (2%) showed spontaneous source amnesia on 1 of the 2 days and a significantly larger number, 8 (9%), showed suggested source amnesia. With a less rigid criterion of scoring source amnesia, the frequency of spontaneous source amnesia increased to 15% and suggested source amnesia to 11%. Spontaneous source amnesia correlated .57 with susceptibility, and suggested source amnesia, .34 with susceptibility. A correlation of .48 was found between recall amnesia and spontaneous source amnesia and .49 between recall amnesia and suggested source amnesia. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1965

Kost, Paul F. (1965). Dangers of hypnosis. International Journal of Clinical and Experimental Hypnosis, 13 (4), 220-225.

The various kinds of complications which have been associated with hypnosis are reviewed, and it is concluded that they have been greatly exaggerated. The dangers that are involved in hypnosis occur through ignorance, overzealousness, lack of understanding of the bases of interpersonal relationships, and the irresponsible acts of those who would use the technique for entertainment. [Author's Abstract]

Orne, Martin T. (1965). Undesirable effects of hypnosis: The determinants and management. International Journal of Clinical and Experimental Hypnosis, 226-237.

Various kinds of complications arising from the use of hypnosis are reviewed. The distinction is drawn between the induction of hypnosis when it is perceived as an episodic event, as in a laboratory context, versus the effect when it is perceived as leading to permanent changes, as in a therapeutic context. An attempt is made to draw these and other distinctions in order to understand better the possible sources of difficulties. [Author Abstract]

2001

Gibbons, Don E. (2001). Experience as an art form: Hypnosis, hyperempiria, and the Best Me technique. San Jose CA: Authors Choice Press. ([available online:] <http://www.iuniverse.com/bookstore/marketplace>))

#### NOTES

The Best Me Technique is a procedure for constructing suggestions which incorporates many different dimensions of experience -- beliefs, emotions, sensations, thoughts, motives, and expectations -- for maximum involvement and effectiveness. Best Me suggestions may be used with either hyperempiria, an alert induction based on suggestions of mind expansion and increased alertness and sensitivity, or with more traditional forms of hypnotic induction.

1999

Kirsch, Irving; Lynn, Steven Jay (1999). Automaticity in clinical psychology. American Psychologist, 54 (7), 504-515.

The authors provide an overview of the literature on the ability of response expectancies to elicit automatic responses in the form of self-fulfilling prophecies and link it to the broader psychological investigation of automatic processes. The authors review 3 areas of research in which response expectancies have been shown to affect experience, behavior, and physiology: placebo effects, the effects of false biofeedback on sexual arousal, and the alteration of perceptual and cognitive functions by hypnotic and nonhypnotic suggestion. Also reviewed are data suggesting that all behavior, including novel and intentional behavior, is initiated automatically. Following this review, the authors summarize some of the ways in which knowledge of response expectancy effects and other automatic processes that influence experience and behavior can enhance clinical practice.

#### NOTES

Although expectancy accounts for some variance in the development of classical hypnosis effects, it is also true that "experimental data suggest that faking accounts for relatively few of these effects" (p. 507). "The best predictors of hypnotic suggestibility are waking suggestibility and response expectancy, and expectancy remains a significant predictor of hypnotic response even with waking suggestibility controlled (Braffman & Kirsch, in press; Kirsch, 1997)" (p. 508). The authors theorize that automatisms (like Chevreul pendulum) are "responses that are primed for automatic activation by two response sets: an intention and an expectancy for their occurrence" (p. 508). They suggest that most behavior is routine, virtually automatic, because cognitive structures like schemas, scripts, or plans that are outside immediate awareness trigger the behavior. They cite research by Libet (1985) and hypotheses developed by Nisbett & Wilson (1977) and Dennett (1991), concluding that "the feeling of will is a judgment, rather than an introspected content" (p. 509). The authors discuss the Chevreul pendulum phenomenon in terms of expectancy theory and explore how their theory would apply to psychotherapy.

American Medical Association Council on Scientific Affairs (1995). Report on memories of childhood abuse. International Journal of Clinical and Experimental Hypnosis, 43 (2), 114-117.

#### NOTES

"The AMA considers the technique of 'memory enhancement' in the area of childhood sexual abuse to be fraught with problems of potential misapplication" (p. 114). "Most controversial are those 'memories' that surface only in therapy and those from either infancy or late childhood (including adolescence)" (p. 114)

Ganaway, George K. (1995). Hypnosis, childhood trauma, and dissociative identity disorder: Toward an integrative theory. International Journal of Clinical and Experimental Hypnosis, 43 (2), 127-144.

It is contended that prevailing exogenous trauma theory provides in most cases neither a sufficient nor a necessary explanation for the current large number of diagnosed cases of dissociative identity disorder (multiple personality disorder) and related dissociative syndromes purported to have arisen as a response to severe early childhood physical and sexual abuse. Relevant aspects of instinctual drive theory, ego psychology, object relations theory, self psychology, social psychological theory, sociocultural influences, and experimental hypnosis findings are drawn on to demonstrate the importance of adopting a more integrative theoretical perspective in the diagnosis and treatment of severe dissociative syndromes. Further cooperative experimental and clinical research on the etiology, prevalence, and clinical manifestations of the group of dissociative disorders is strongly encouraged.

Guyer, Charles G. II; Van Patten, Isaac T. (1995). The treatment of incest offenders -- a hypnotic approach: A brief communication. International Journal of Clinical and Experimental Hypnosis, 43 (3), 266-273.

Incest has become more prominent in public awareness over the past 15 years. The major focus of this interest has been on the incest survivor. The incest offender has received less attention. A hypnotic

approach to treating incest offenders is outlined that involves a seven-stage approach. A case example is presented and future research directions suggested.

Holroyd, Jean (1995). Handbook of clinical hypnosis, by Judith W. Rhue, Steven Jay Lynn, & Irving Kirsch (Eds.) [Review]. International Journal of Clinical and Experimental Hypnosis, 43 (4), 401-403.

#### NOTES

"This is a book for the thinking clinician" (p. 401). "The editors are to be congratulated for making this volume much more coherent than most edited books" (p. 402). "My impression is that the book is best suited for an intermediate or advanced course on hypnotherapy, or for people who are already using hypnosis in treatment. Although there is some material on the basics of hypnotic inductions and a few introductory sample scripts for inductions, a beginners" course should probably use a different book, or this book could be accompanied by an inductions manual. ... I recommend it very highly" (p. 403).

Levitt, Eugene E.; Pinnell, Cornelia Mare (1995). Some additional light on the childhood sexual abuse-  
psychopathology axis. International Journal of Clinical and Experimental Hypnosis, 43 (2), 145-162.

This exposition is an attempt to unravel the complexities of the relationship between childhood sexual abuse and adult psychopathology. Four facets of the relationship are examined in some detail: (a) the extent of childhood sexual abuse; (b) the probability that sexual abuse in childhood will result in psychopathology in the adult; (c) the reliability of early life memories in later life; and (d) the role of recovered memory of trauma in the healing process. The conclusions of this logico-empirical analysis are that first, government statistics tend to underestimate the extent of childhood sexual abuse, whereas independent surveys tend to overestimate it. Estimating prevalence is further complicated by variations in the definitions of key terms. Possibly the only safe conclusion is that true prevalence cannot be reliably determined. Second, empirical investigations of childhood sexual abuse conclude that not all victims are emotionally injured. A substantial number of these investigations find that a majority of victims suffer no extensive harm. Other variables such as family dynamics are involved; there may be only a few cases in which emotional harm results from sexual abuse as a single factor. Third, memory research suggests that memory in general is a dynamic, reconstructive process and that recall of childhood events is particularly vulnerable to distortion. Memory cannot dependably produce historical truth. Last, there is some clinical evidence that abreaction of a traumatic event in adulthood may have a remediative effect. Similar evidence for childhood trauma is lacking. The belief in the healing effect of recalling and reliving a childhood trauma depends on the therapist's orientation

Nagy, Thomas F. (1995). Incest memories recalled in hypnosis -- a case study: A brief communication. International Journal of Clinical and Experimental Hypnosis, 43 (2), 118-126.

Accuracy of repressed memories recovered in hypnosis cannot be reliably determined with any greater certainty than non-hypnotically recalled events. Therefore, the practice of therapists' accepting hypnotically enhanced memories as veridical, absent corroborating evidence, is not advocated. A 52-year-old woman with a 27-year history of panic attacks and sleep disorder inadvertently recovered incest memories in hypnosis. Photographs and remembered events by other family members were thought by the patient to provide general support although they did not constitute actual proof of abuse. Implications are discussed.

## NOTES

Author was asked to respond to two questions:

Is there a role for hypnosis in work with rape victims?

How does the therapist avoid the pitfalls of voyeurism and revictimization?

1994

Adrian, Cheri (1994, August). Sexual feelings in hypnosis: Managing therapeutic boundaries in hypnotic work. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

Therapist countertransference has been little addressed in discussions of hypnosis, particularly the sexual feelings that may be evoked in therapists in the hypnotic context. These are some of the most disturbing and problematic feelings therapists can experience toward patients, and they are little addressed in training. This issue is important both because of our increasing efforts to prevent sexual boundary violations in therapy and because therapist sexual feelings, like other countertransference feelings, can have important clinical meanings that are often avoided or ignored. This discussion defines the nature and purposes of patient-therapist boundaries. It describes the various dynamics which have been identified in therapists who become confused about sexual boundaries and proceed to mismanage them. It then elaborates the ways that using hypnosis may create special vulnerability for the therapist, not only to experiencing sexual feelings toward patients, but to becoming confused about their meaning and relevance to treatment. The discussion focuses attention on the origins and clinical significance of therapist sexual feelings, and acknowledges that such feelings may serve both awareness enhancing and defensive functions in the therapeutic process. A clinical case example illustrates various kinds of sexual feelings therapists may experience, the many meanings therapist sexual feelings may have, the various discomforts they typically generate, and the impulses to avoidance or acting out they may provoke. Further discussion addresses both clinically appropriate and inappropriate ways of managing boundaries in the presence of sexual arousal, and of utilizing sexual feelings as a means of deepening clinical understanding and of directing treatment. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall 1994, Vol. 3, No. 3.)

Bloom, Peter B. (1994). Clinical guidelines in using hypnosis in uncovering memories of sexual abuse: A master class commentary. International Journal of Clinical and Experimental Hypnosis, 42 (3), 173-178.

## NOTES

Gives case example and clinical guidelines for using hypnosis in uncovering memories of sexual abuse.

1. In medical practice, "Primum non nocere," i.e. "First do no harm."
2. "No therapist should ever, either directly or indirectly, suggest abuse outside of a specific therapeutic context--certainly not to a client who is on the phone making a first appointment!"
3. "A therapist must not jump quickly to the conclusion that abuse occurred simply because it is plausible."
4. "A therapist should never simply assume that a client who cannot remember much from childhood is repressing traumatic memories or is in denial."
5. "Remember 'a client is most vulnerable to suggestion and the untoward influence of leading questions when therapy begins to delve into painful life situations from the past, particularly from childhood.'"
6. "Therapists ... should be cautious about suggesting that clients cut off communication with their families."
7. "Therapists should reconsider the 'no pain, no gain' philosophy of treatment."
8. "The context of therapy is as important as the content."
9. "Tolerate ambiguity."

(Sincerity and conviction on the part of the patient reporting abuse are not in and of themselves reason

to believe the material.) 10. "Respect the current science of memory." 11. "Maintain responsibility for making the diagnosis and choosing the treatment." 12. "Pursue alternative diagnoses to account for the symptoms." 13. "Historical and narrative truth: Understand the difference."

#### COMMENT

The tenet that insight is necessary for change and growth is not true. Change can occur without insight, although insight may be helpful in maintaining change once it has occurred.

#### SUMMARY

These guidelines are presented to enhance safe practice, however, clinicians should use their own judgement to determine the best path to follow with each patient.

#### NOTE

Guidelines 1, 8, 9, 10, 11, 12, and 13 are those of Peter B. Bloom. Those labeled as Guidelines 2, 3, 4, 5, 6, and 7 were taken with permission from Yapko, M. (1993 September/October). "The seductions of memory. The false memory debate." *Family Therapy Networker*, 17, pp. 30-37. All discussions, however, are those of Peter B. Bloom.

Bowers, Kenneth S. (1994, October). Bringing balance to controversy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

Skeptics argue that concept of "repression" has no scientific merit, though even if a valid concept, it wouldn't validate all memories recovered. Skeptics regard laboratory evidence as essential, while clinicians are impressed by case reports. See Polonyi, Personal Knowledge.

It is not reasonable to say there is no evidence for fugue states, when seeing one, if it has not been demonstrated in the laboratory. But you can investigate some of the phenomena in the laboratory.

Most of the time it is an affectively loaded idea that is repressed; in contrast, trauma usually lead to intrusions into consciousness. So repression of a traumatic event may be a rare way to deal with the event.

Claims for repression and ESP differ in that there are probably observable mechanisms in the former (e.g. thought avoidance). If a person ejects thoughts about a topic frequently enough, the ejections become automatic. Freud's original description of repression used the word "intentional" and it was a footnote that took out that idea. (See Erdelyi's publications).

Recent research we conducted on intuition and on problem solving is relevant to this problem.

[The remainder of Bowers' presentation is not summarized here.]

Loftus, Elizabeth; Polonsky, Sara; Fullilove, Mindy Thompson (1994). Memories of childhood sexual abuse: Remembering and repressing. Psychology of Women Quarterly, 18, 67-84.

Women involved in out-patient treatment for substance abuse were interviewed to examine their recollections of childhood sexual abuse. Overall, 54% of the 105 women reported a history of childhood sexual abuse. Of these, the majority (81%) remembered all or part of the abuse their whole lives; 19% reported they forgot the abuse for a period of time, and later the memory returned. Women who remembered the abuse their whole lives reported a clearer memory, with a more detailed picture. They also reported greater intensity of feelings at the time the abuse happened. Women who remembered the abuse their whole lives did not differ from others in terms of the violence of the abuse or whether the violence was incestuous. These data bear on current discussions concerning the extent to which repression is a common way of coping with childhood sexual abuse trauma, and also bear on some widely held beliefs about the correlates of repression.

#### NOTES

In previous research, it was reported that violent or incestuous abuse is particularly susceptible to repression. This study differs from previous investigations in the definition of violence. In the present study, 'violence' is defined as any act involving vaginal, oral, or anal sex. Earlier research defined 'violence' as involving sexual assault with physical injury or fear of death.

Depending on the definition of repression, a sizeable minority (31% or almost 1/5) of this sample forgot their earlier abuse for a period of time. The authors state that this suggests there is little 'robust repression' in this sample. They cannot rule out the possibility that some women who were abused still, to this day, do not recall the experience; or that some who continue to have memory loss based on organic causes, including blackouts.

The authors suggest that future research in this area use more specific questions, including assessing whether Subjects respond to statements like: "There was a time when I would not have been able to remember the abuse, even if I had been directly asked about it," or "There was a time when I would not have been able to report the abuse because I had no idea that it had even happened to me." Also, when Subjects report that a memory had emerged after a period in which they had no recall, the Experimenter should enquire about how and when the recovered memory occurred.

The authors conclude that remembering abuse is more common than forgetting it.

Mulhern, Sherrill (1994). Satanism, ritual abuse, and multiple personality disorder: A sociohistorical perspective. International Journal of Clinical and Experimental Hypnosis, 42 (4), 265-288.

During the past decade in North America, a growing number of mental health professionals have reported that between 25% and 50% of their patients in treatment for multiple personality disorder (MPD) have recovered early childhood traumatic memories of ritual torture, incestuous rape, sexual debauchery, sacrificial murder, infanticide, and cannibalism perpetrated by members of clandestine satanic cults. Although hundreds of local and federal police investigations have failed to corroborate patients' therapeutically constructed accounts, because the satanic etiology of MPD is logically coherent with the neodissociative, traumatic theory of psychopathology, conspiracy theory has emerged as the nucleus of a consistent pattern of contemporary clinical interpretation. Resolutely logical and thoroughly operational, ultrascientific psychodemonology remains paradoxically oblivious to its own irrational premises. When the hermetic logic of conspiracy theory is stripped away by historical and socio/psychological analysis, however, the hypothetical perpetrators of satanic ritual abuse simply disappear, leaving in their wake the very real human suffering of all those who have been caught up in the social delusion.

Nash, Michael R. (1994). Memory distortion and sexual trauma: The problem of false negatives and false positives. International Journal of Clinical and Experimental Hypnosis, 42 (4), 346-362.

Logically, two broad types of mnemonic errors are possible when adult psychotherapy or hypnosis patients reflect on whether they were sexually abused or not as a child. They may believe that they were not abused when in fact they were (false negative error), or they may believe they were abused when in fact they were not (false positive error). The author briefly reviews the empirical evidence for the occurrence of each of these types of errors, and illustrates each with a clinical case. Further, in considering the incidence, importance, and clinical implications of these errors, the author contends that clinical efficacy in no way assures that a false negative or a false positive has been avoided. A plea is made for theorists and researchers to acknowledge that both categories of errors can occur and to conduct future clinical and laboratory research accordingly.

Nash, Michael R. (1994, October). Reports of early sexual trauma: The problem of false negatives and false positives. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

The problem of false positives and problem of false negatives are distinct and should be treated differently. The question involves pseudomemories vs repression.

Evidence for false positives: 1. Memory research 2. Developmental psychopathology 3. Contemporary psychoanalytic theory 4. Clinical field studies

No laboratory researcher has produced false memories that are as vivid, or as emotionally loaded as early abuse.

Evidence for repression: 1. "Repressor Personality" research (Weinberger & Schwartz, who view it as a trait rather than a state). 2. Implicit memory research 3. Hypnosis research on memory (see Nash chapter in Fromm & Nash book on research in hypnosis) 4. Clinical field studies

Spanos, Nicholas P.; Burgess, Cheryl A.; Burgess, Melissa Faith (1994). Past-life identities, UFO abductions, and satanic ritual abuse: The social construction of memories. International Journal of Clinical and Experimental Hypnosis, 42 (4), 433-446.

People sometimes fantasize entire complex scenarios and later define these experiences as memories of actual events rather than as imaginings.

This article examines research associated with three such phenomena: past-life experiences, UFO alien contact and abduction, and memory reports of childhood ritual satanic abuse. In each case, elicitation of the fantasy events is frequently associated with hypnotic procedures and structured interviews which provide strong and repeated demands for the requisite experiences, and which then legitimize the experiences as "real memories." Research associated with these phenomena supports the hypothesis that recall is reconstructive and organized in terms of current expectations and beliefs.

#### 1993

Hawkins, Russell (1993). An analysis of hypnotherapist-client sexual intimacy. International Journal of Clinical and Experimental Hypnosis, 41, 272-286.

While sexual interaction between psychologists, physicians, and other health therapists of all kinds and their clients is typically condemned by professional bodies as unethical, the controversy regarding the potential for hypnosis to produce compliant behavior in unwilling or nonconsenting subjects suggests that hypnotherapist-client sex may warrant special attention. Because the experiments required to clarify the potential for hypnosis to potentiate nontrivial compliance are themselves unethical and/or inconclusive, experimental methods cannot be adequately used to clarify this issue. Instead, the matter can be addressed by reference to other forms of evidence, such as the responses of therapists and clients to anonymous surveys and the analysis of cases, that have reached the courts. Consideration of this qualitatively deficient evidence suggests that even if the use of hypnotic suggestion can lead to compliance to sexual demands, overt coercion is seldom used in practice. Social psychological and situational factors are particularly salient in understanding therapist-client sex. The question of whether there are special properties of the dynamics of the hypnotic experience, other than specific coercive suggestion and beyond those typically found in other forms of therapy, is considered. Comparisons are drawn with other examples of socially condemned sex, such as teacher-student sex, sexual harassment in the workplace, incest, and extramarital sex.

London, Ray William (1993, October). Refreshed adult memories: Abuse survivor or therapeutic victim?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

The author addresses four areas: 1. public policy 2. psychological issues 3. legal issues (evidence) 4. how to properly deal with it

A definition of sexual abuse is being applied to behaviors that for years were not considered out of bounds (e.g. entering a bathroom where someone else is). Furthermore, using the word "survivor" for abused people equates patients with survivors of concentration camps, who do not present with repressed memories typically. National incidence of child abuse remains unclear estimates are 6 to 60% of females. In Florida, only 13% of cases reported are confirmed.

Some therapists who specialize in this area in surveys indicate that they have false beliefs regarding memory and effects of trauma.

[These represent only partial notes on a lengthy and substantial paper.]

Perry, Campbell (1993, October). A case of multiple allegations of masturbation by a psychiatrist during hypnotic and/or sodium amytal therapy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

This is a case study of a Canadian psychiatrist accused by 5 women of masturbating during therapy.

Rhue, Judith W.; Lynn, Steven Jay (1993, October). Dissociation, childhood sexual abuse, and fantasy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

We are reporting on part of an ongoing study, with results still being analyzed. We are looking at imagination, fantasy, and dissociation in abused and non-abused children. This focuses on the relationship between dissociation and fantasy and imagination.

For Janet, dissociation was the primary defense against trauma. [Quotes D. Spiegel also.] There is a body of research on trauma associated with the development of dissociation. 1. NIH found 97% of multiple personality patients reported trauma in childhood; 83% were sexually abused; 75% were repeatedly physically abused; 68% had both types of abuse. 2. Bliss - studied 70 MPDs and found same results. 3. Ross, Norton, and Noosney [?name] - found same results 4. Coombs & Milstein - same

The incidence of retrospective reports of abuse is much lower in other types of patients.

So, what is going on during child abuse? We wanted to look at children experiencing or who recently experienced abuse. Also looked at a children's scale of dissociation symptoms and validated other studies.

We studied 39 children referred to Ohio University College of Osteopathic Medicine; 12 had primary problem as sexual abuse (8 of whom were female). Non-abused Ss were either behavioral or adjustment disorders. 8 reported severe physical abuse. Parents concurred in presence of abuse. Physical abuse consisted of broken bones, burns, etc. Average age 9-10.

Ss were given the Beck Depression Scale, Children's Fantasy Inventory, Meyers' Children's Creative Imagination Scale, Children's Perception Alteration Scale, Figure Drawings, WISC-R, and 2-3 other measures. Research assistants administering the scales didn't know the children's diagnoses.

We found no support for the hypothesis that sexual abuse in childhood is associated with imagination, fantasy, or dissociative tendencies--not surprising considering that only 4 Ss were abused by their

father or stepfather, 2/3 of Ss had fondling as the most severe abuse they had experienced; only 2 had intercourse; 2/3 were abused only 1-3 times. Sexual abuse that is not violent, severe, prolonged, or perpetrated by a parent may not lead to the same problems.

In a sample of women whose assaults were rape, only 25% reported it as rape.

On other hand, physical punishment was more reliably associated with dissociation (.47), imagination and fantasy in absorption scale (.41-.51 with question about using imagination to block awareness of punishment). Physical punishment was associated with increased dissociation.

Sample size is small and the trend is in the predicted direction, so later results may be significant.

Conclusion: measures of fantasy, dissociation, and imagination were correlated. Children's Perception Alteration Scale and the measures of fantasy and imagination were validated. Diverse measures of fantasy were highly correlated with one another.

We need a non-abused sample to add to this research.

The clinical sample had a higher dissociation score than Evers, Sanders, and Shostick's cutting score.

We use 60 as a cutting score (for an abused sample) while they used 55.

#### COMMENTS FROM THE AUDIENCE:

Jack Watkins: the sexual abuse for the most part was not painful. Answer by Rhue: The group of sexual abuse cases includes very wide varieties of experiences; we need to examine that in our research. Also, trauma and the perception of trauma is an individual matter.

Etzel Cardena: We presented a paper at APA in which sexual abuse was a predictor of psychogenic seizures, and most important, the duration of the abuse.

Phyllis Alden: In a recent study in Germany, it was length of time for the abuse that predicted [dissociative symptoms?].

Sivec, Harry; Lynn, Steven Jay (1993, October). Hypnosis and early memories. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

The investigators hypnotized people and asked that they recall their earliest memories. Gorham & Hafner tested highs and lows in 2 sessions, one with a hypnotic induction. Ss in hypnosis reported more themes, whether high hypnotizables or not. Ss might have held back in non hypnosis condition however.

Hypothesized that early memories would have affect-laden materials.

20 Ss in hypnosis group, 20 Ss in relaxation condition, all highs (scored minimum of 9 of 12 on the Harvard Scale). Ss were told they were randomly selected from a pool and that it was a study of personality. Ss were administered a number of questionnaires and tests.

The two groups received either a Stanford Form C Scale induction or a relaxation procedure.

We used the procedure of Bloom [spelling?] for recall of two memories, and to probe the earliest memory. Also to recall two recent memories. Counterbalanced for order of presentation.

Positive affect, negative affect, affect intensity, and primary process were rated; 12 themes were rated. ANOVA was used.

Earliest memory at 3.8 yrs. Next earliest is 7.5 for hypnosis and 5.2 for relaxation groups. 4.3 is earliest for hypnosis group; there may be a basement effect. Negative affect varied by condition and by order of administration and recency of memory assessed. When early memories were elicited first, no differences were found in groups; when elicited second, negative affect was greater for [missed words]. Affect was more abundant and intense in the hypnosis group, but only when recent memories were elicited before early memories and only in the [missed words].

Early recollections were slightly more primary process (bizarre) than later, which should alert clinicians.

Themes didn't differ between groups. Early memories involved more trauma than later memories. Negative affect correlated with psychopathology measures for earliest memory but not later memory. Used posthypnotic experiences scales. There is a decrease in unpleasant experiences, suggesting the benefit of catharsis when recalling early memories.

1992

Darken, Rachel (1992). Hypnosis in the treatment of survivors of sexual abuse. Australian Journal of Clinical and Experimental Hypnosis, 20, 105-110.

This paper outlines the problems of child sexual abuse and its long-term sequelae, often reaching down generations. In psychotherapy with survivors of childhood sexual abuse, hypnosis offers a flexible treatment modality and the paper focuses particularly on the use of hypnosis and self-hypnosis for the "reparenting" element of psychotherapy.

Herbert, James D.; Mueser, Kim T. (1992). Eye movement desensitization: A critique of the evidence. Journal of Behavior Therapy and Experimental Psychiatry.

The scientific evidence supporting the efficacy of eye movement desensitization (EMD), a novel intervention for traumatic memories and related conditions, is reviewed. The sparse research conducted in this area has serious methodological flaws, precluding definite conclusions regarding the effectiveness of the procedure. Clinicians are cautioned against uncritically accepting the clinical efficacy of EMD.

Sexual abuse and the abuse of hypnosis in the therapeutic relationship. International Journal of Clinical and Experimental Hypnosis, 28, 283-297.

Hollander, Ellen L.; Baw, Saul D. (1992, October). Improving outcomes in sex therapy through the use of hypnotic methods. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

NOTES

This is a report on the Cornell University Medical College Human Sexuality Program and Behavior Therapy Program. Cognitive-behavioral treatment is the principal approach in sex therapy these days (in contrast to insight treatment before 1954).

The authors find hypnosis to be useful in cases that were previously thought to be treatment refractory. Insensuality, inability to be absorbed, seems at the root of these problems. Hypnosis is useful for diagnosis and for developing task relevant immersion.

Three types of disorders: Desire phase Excitement phase Orgasm phase

Each phase has specific obstacles that can be elicited with a detailed interview: 1. Desire: anti-fantasy or the person focuses on unpleasant images 2. Excitement: performance anxiety or rumination about sexual potency (especially in men) 3. Orgasm: spectating or self-observation

Basic treatment strategy is to promote maintenance of absorption while dealing with the material that had been eliciting anxiety. In past we traditionally assumed absorption was present. Often this isn't the case. It can be addressed with hypnotic methods. Conceptualized as a skill, hypnosis can improve the patient's ability to shift from peripheral to focal awareness.

Reports in the literature address sexual dysfunction as one unitary phenomenon, using direct suggestions, anxiety/stress reduction techniques, metaphorical suggestions, ego strengthening devices, hypnoanalytic procedures to uncover the unconscious determinants of dysfunction.

Lohr, Jeffrey M.; Kleinknecht, Ronald A.; Conley, Althea T.; Dal Cerro, Steven; Schmidt, Joel; Sonntag, Michael E. (1992). A methodological critique of the current status of eye movement desensitization (EMD). Journal of Behavior Therapy and Experimental Psychiatry.

Eye Movement Desensitization (EMD) has been recently advocated as a rapid treatment for the elimination of traumatic memories responsible for the maintenance of a number of anxiety disorders and their clinical correlates. Despite a limited conceptual framework, EMD has attracted considerable interest among clinicians and researchers. The popularity and interest generated by EMD will likely result in wide usage. We present a methodological critique of it with reference to assessment, treatment outcome, and treatment process. We also provide guidelines for judging the methodological adequacy of research on EMD and suggest intensive research to assess effectiveness, treatment components, and comparisons with other procedures.

Mottahedin, I. (1992). Was hypnosis involved in the Nelson case?. Contemporary Hypnosis, 9 (3), 158-163.

#### NOTES

This is a comment on a case described by Gibson in the same issue of this journal. The case involved a man accused of raping women after hypnotizing them.

Murrey, Gregory J.; Cross, Herb J.; Whipple, Jim (1992). Hypnotically created pseudomemories: Further investigation into the 'memory distortion or response bias' question. Journal of Abnormal Psychology, 101 (1), 75-77.

I

In order to study whether pseudomemories represent actual memory distortions or are a result of response bias, 60 highly hypnotizable subjects and subjects from the general population were divided into 4 experimental groups and were tested for pseudomemory manifestation after receiving a false suggestion. Of the 4 groups of subjects, 3 were offered a monetary reward as a motivation to distinguish false suggestion from the actual occurrence. Pseudomemory manifestation was found to be significantly higher among subjects not offered a reward than among subjects who were offered such a reward. The implications of these findings are discussed.

NOTES: The article contains a review of the literature through 1989. The study tested the hypothesis that when it is important to distinguish fantasy from reality in a hypnosis experiment, subjects can do so--a position presented by Spanos and McLean (1986). They used a verifiable event to test for pseudomemory production, as in research published by McCann and Sheehan (1988). Subjects were 30 high hypnotizable and 30 unselected students.

Subjects were shown a videotape of a mock robbery scene. The next week, Groups A, B, and C heard audiotapes "to enhance memory," but in addition to motivating statements about "trying to remember" certain details, the tapes included misleading information (e.g. "Remember the color of the hat the robber was wearing" when in fact there was no hat on the robber). Subjects in these groups were 'influenced.'

"Both highly hypnotizable subject groups (Groups A and B) listened to the audiotape after being administered a 10-min hypnotic induction procedure (modified from that of Barber, 1969). Subject Group C listened to the audiotape without hypnosis. The control group, Group D, did not listen to the audiotape and was, therefore, classified as 'uninfluenced.'"

A week later subjects responded to multiple-choice and yes-no or true-false questions about the robbery scene. The yes-no question about whether the robber was wearing a hat served as the

dependent variable, a measure of pseudomemory. "To motivate subjects to report the truth rather than to follow any perceived expectations of the experimental of social context, we offered subjects in Groups B, C, and D a monetary reward if they achieved the most correct answers on the quiz (according to the videotape). The reward was offered just before administration of the quiz to ensure that no collusion between the subjects could occur. Group A was not offered any such reward" (p. 76). "The number of subjects in Group A (hypnotized, influenced, no reward) who reported the false information at posttest (12) was significantly greater than that of Group B (hypnotized, influenced, offered reward.... However, the difference in incidence of pseudomemory between Group B and the control group, Group D (not hypnotized, uninfluenced, offered reward), was nonsignificant" (p. 76).

**Table 1 Incidence of Pseudomemory Per Group** -----

	False suggestion	Group A	Group B	Group C	Group D
result (n=15)	(n=15)	(n=15)	(n=15)	(n=15)	(n=15)

Accepted 12 6 7 3

Rejected 3 9 8 12 ----- Note. Group

A = hypnotized, influenced, not offered reward.

Group B = hypnotized, influenced, offered reward.

Group C = not hypnotized, influenced, offered reward.

Group D = not hypnotized, not influenced, offered reward.

In the Discussion, the authors wrote, "Because the only variable among these groups was the reward, a reasonable conclusion from the findings is that pseudomemories manifested by the subjects were (for the most part) not actual memory distortions. Presumably, the reward provided the subjects in Group B an incentive to 'report the truth' and a disincentive to give biased reports on the basis of the perceived expectations of the social or experimental context. Thus these data suggest that pseudomemory effects or the occurrence of the pseudomemory phenomenon among highly hypnotizable subjects can be minimized by providing a motivation to subjects to give unbiased reports. "A major implication of these findings is that researchers should control for response bias resulting from perceived social demands or from leading test designs when they conduct pseudomemory research. Of further concern is the fact that a number of researchers contend that hypnotic interrogation of eye-witnesses can greatly facilitate the creation of pseudomemories (Levitt, 1990; Loftus, 1979; Orne, 1979; Putnam, 1979), and therefore hypnosis either should not be allowed in the courtroom or should be strictly controlled. Yet in light of our findings, response bias may be a confound in pseudomemory research, and thus researchers need to be cautious when making inferences to specific situations from data obtained in an experimental setting.

"Despite the existence of a confound of (unmeasured) differences in hypnotizability between the two groups, there was no significant difference between Group B and the control group (Group D). This suggests that if response bias is controlled for, there may not be significant differences in manifestation of pseudomemories between highly hypnotizable subjects and subjects representative of the general population. However, further research is needed in order to address this question" (pp. 76-77).

1991

Chu, James A.; Dill, Diana L. (1991). Dissociation, borderline personality disorder, and childhood trauma. American Journal of Psychiatry, 148 (6), 812.

Comments on the article by S. N. Ogata et al (see PA, vol 78:4681) on the high prevalence of childhood physical and sexual abuse in inpatients with borderline personality disorder. It is suggested that dissociative symptoms in borderline patients may simply be a less severe form of intrapsychic fragmentation than multiple personalities.

Cornell, William F.; Olio, Karen A. (1991). Integrating affect in treatment with adult survivors of physical and sexual abuse. American Journal of Orthopsychiatry, 61 (1), 59-69.

Presents a theoretical and technical model for affectively centered treatment of adults abused as children, focusing on the function of denial and dissociation as central defense mechanisms. The concept is introduced of working at an "affective edge." At this experiential point, a client can maintain both cognitive understanding and emotional and bodily awareness without triggering denial and dissociation. This approach fosters careful monitoring of the client's functioning both during and between therapeutic sessions. The proposed therapeutic approach uses noninvasive touch and body-centered techniques. Focus is on integrating affect and on the importance of the therapeutic relationship.

Friedrich, William N. (1991). Hypnotherapy with traumatized children. International Journal of Clinical and Experimental Hypnosis, 39 (2), 67-81.

The psychological impact of trauma can include cognitive, affective, and behavioral components. The degree to which a child is either overwhelmed by or unable to access the traumatic event can make the working through of the event in therapy difficult. Hypnotherapy is a useful modality not only for alleviating symptoms but also for uncovering the traumatic event(s) with associated affects, integrating and making sense of the experience. 4 case studies are reported to illustrate the utility of hypnotherapy with young, traumatized children.

Gibson, H. B. (1991). Can hypnosis compel people to commit harmful, immoral and criminal acts?: A review of the literature. Contemporary Hypnosis, 8, 129-140.

The literature relating to whether hypnosis can be used to compel people to perform acts that are dangerous, immoral or criminal is reviewed, some evidence over the past 200 years being discussed. Relevant real-life instances are cited as well as the laboratory studies of the twentieth century. Detailed criticisms of the latter are made, and it is shown that although no really conclusive findings have emerged, such research has strongly implied that hypnosis does not increase compliance. Four past criminal trials concerned with alleged rape and sexual assault are cited. It is concluded that whilst hypnosis may be one among a number of techniques used in sexual seduction, it is not reasonable to claim that rape has ever been effected by means of hypnosis alone.

NOTES: Review of literature that concludes that while hypnosis may be one among a number of techniques used in sexual seduction, it is not reasonable to claim that rape has ever been effected by means of hypnosis alone.

Rhue, Judith W.; Lynn, Steven Jay (1991). Storytelling, hypnosis and the treatment of sexually abused children. International Journal of Clinical and Experimental Hypnosis, 39 (4), 198-214.

The present article describes an assessment and therapy program for sexually abused children using hypnotherapeutic techniques which center on storytelling. Storytelling presents the therapist with an opportunity to use comforting suggestions, symbolism, and metaphor to provide the emotional distance necessary to deal with the trauma of abuse. Hypnotherapy proceeds in a stepwise fashion from the building of a sense of safety and security; to imaginativge sharing; to the introduction of reality events; to the final step of addressing complex emotional issues of loss, trust, love, and guilt brought about by the abuse.

Smith, William H. (1991). Antecedents of posttraumatic stress disorder: Wasn't being raped enough? A brief communication. International Journal of Clinical and Experimental Hypnosis, 39, 129-133.

Many rape victims, like those traumatized by war, accidents, and natural disasters, are able to recover from their ordeal with supportive, crisis-oriented treatment. For others, however, symptoms may persist and require more intensive treatment. Hypnosis allows a modulated re-experiencing and abreaction of the traumatic event that can help to provide the victim with a relieving sense of mastery, and it fosters a receptive context for reassurance and interpretation regarding the irrational or exaggerated thoughts and feelings involved. 2 case examples are presented in which earlier conflicts appeared to play a role in perpetuating the patients' symptoms. Detecting and addressing these antecedents resulted in complete alleviation of long-standing problems through relatively brief treatment using hypnosis.

1990

Levitt, Eugene E. (1990). A reversal of hypnotically "refreshed" testimony: A brief communication. International Journal of Clinical and Experimental Hypnosis, 38 (1), 6-9.

A case is briefly presented in which questioning under hypnosis led to a positive identification of an accused rapist when the victim had previously been uncertain. During the trial, the victim was first certain, then reverted to her pre-hypnotic uncertainty. An appeal from the conviction of the defendant was denied on the grounds that the witness' uncertainty meant that the hypnotic intervention was harmless error. It is possible that this decision may not be entirely justified.

Perry, Campbell (1990). Coercion by hypnosis? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 242-243.

## NOTES

"A postexperimental inquiry (following Orne, 1959) might have informed the reader of the degree to which operationalization of the coercion in terms of disobedience was successful. Without this additional step, it is difficult to determine whether what was found in the laboratory by these investigators applies to what has been reported in clinical and field settings for almost 200 years" (p. 242).

"In particular, elsewhere, the authors equate coercion with involuntariness and appear to view involition as a euphemism for coercion. While I agree that perceiving involition of one's own behavior may contribute to the commission of unconsenting acts in hypnosis, the two are easily distinguished at the conceptual level. Laboratory subjects ordinarily report much behavior in hypnosis that is experienced involuntarily, without the issue of it being coerced ever being broached" (p. 242).

Author describes cases in which patients claimed they participated in sex with hypnotist against their wills because they were hypnotized. "What may be happening in both of these reports is that the hypnotized subjects found themselves responding involuntarily; from this, they appear to have adduced that they could not resist the hypnotist's suggestion. That is, they were coerced not by hypnosis but by their belief, which was a direct function of the experience of involuntariness, that they could not resist" (p. 243). "In short, if a hypnotized person equates involuntary behavior with powerlessness, "coercion" may occur in this limited sense. Conceptually, this appears to be a far cry from equating involition with coercion" (p. 243).

Somer, E. (1990). Brief simultaneous couple hypnotherapy with a rape victim and her spouse: A brief communication. International Journal of Clinical and Experimental Hypnosis, 38 (1), 1-5.

This paper presents a case involving a rape victim and her emotionally affected spouse. Although the assault occurred before the couple met, the husband was too upset to concentrate when the victim wanted to share her rape-related feelings, nor could he provide the much needed empathy and support. This, apparently, was due to his difficulties in handling his own rage. Simultaneous couple hypnotherapy was used to allow the victim to share her experience under conditions safe for both her and her spouse. As he imagined in trance the rape account described by his age-regressed wife, he learned to identify his emotions and experience them in a controlled manner. During subsequent sessions, the husband was encouraged to include himself in his wife's abreaction and reshape the traumatic scene for both of them. The husband's rescuing behavior and the expressions of violent anger towards the perpetrator had several positive consequences. Not only did they change the abandonment component of the victim's traumatic memory, but they also helped the husband deal in better ways with his own feelings of anger. It also provided the couple with a helpful coping mechanism they later effectively applied under different circumstances.

1988

Borgeat, Francois; Rezanowicz, Thaddeus; Chaloult, Louis (1988). La stimulation preconsciente et consciente de l'imaginaire erotique. Revue Canadienne de Psychiatrie, 33, 394-398.

The stimulation of erotic fantasies through the association of relaxation and erotic conscious or preconscious suggestions has been evaluated. This study was attempted following positive results in the stimulation of fantasmatic activity in alexithymic subjects with a similar procedure. Thirty female subjects, allocated into three groups practiced relaxation daily for two weeks including three sessions with psychological measures. During the second week, erotic suggestions, preconscious for one group and conscious for another one were added. The third group (control) received only relaxation throughout. Results have shown an increase of sexual arousal and erotic imagery during the sessions with erotic suggestions. Sexual activities and desire increased in the two experimental groups. There was no difference between the effects of the preconscious and conscious suggestions. Possible clinical applications of such a procedure are discussed.

Venn, J. (1988). Misuse of hypnosis in sexual contexts: Two case reports. International Journal of Clinical and Experimental Hypnosis, 36 (1), 12-18.

A military officer was accused by 2 young men of having used hypnosis to attempt homosexual relations. The officer denied the charges and claimed that the young men had imagined these events while they were in altered states of consciousness. The officer did admit to questionable practices such as consuming alcoholic beverages with the 2 young men and then using relaxation techniques with them in bedrooms. Subject motivation and nonhypnotic coercive tactics such as abuse of authority and alcohol seem important in understanding alleged cases of hypnotic coercion

1986

Herman, Judith; Russell, Diana; Trocki, Karen (1986). Long-term effects of incestuous abuse in childhood. American Journal of Psychiatry, 143, 1293-1296.

Studied 2 groups of adult women with histories of incest, a nonclinical sample (n - 152) and an outpatient sample (n - 53) to investigate long-term outcomes of sexual abuse. Results indicate that Ss in the community sample reported a range of long-term effects from the incest. Most said they had recovered well from their trauma. Most Ss who had suffered forceful, prolonged, or highly intrusive sexual abuse, or who had been abused by their father or stepfather, reported long-lasting negative

effects. The patient sample reported histories comparable to the most severe traumatic histories in the community sample.

Miller, Arnold (1986). Hypnotherapy in a case of dissociated incest. International Journal of Clinical and Experimental Hypnosis, 34 (1), 13-28.

This case study describes hypnotherapy with a young woman who, in the course of treatment, began to remember her incestuous relationship with her alcoholic father. Her presenting symptoms included self-assaultive masturbation, suicidal fantasies, depression, impaired sexual functioning, and inability to resume her education. Different phases of treatment entailed uncovering work, mastering the incest experience with the help of emotionally corrective experiences, the use of part-selves to assist coping, and the integration of several part-selves into a more effective personality. After 4 years of treatment she has successfully resumed her education, has normal sexual functioning, and is no longer incapacitated by depression.

1985

Bliss, Eugene L.; Larson, Esther M. (1985). Sexual criminality and hypnotizability. Journal of Nervous and Mental Disease, 173, 522-526.

Investigated 33 17-35 yr old sexual offenders, 18 of whom had been convicted of rape, 9 of pedophilia, and 6 of incest. Ss completed a questionnaire containing a list of 15 factors that might have contributed to their crime, a self-report containing 305 items that are symptoms characteristic of 11 major psychiatric syndromes, and the Stanford Hypnotic Susceptibility Scale. Controls for the self-report were 48 individuals taken from a church group, nurses, technicians, and graduate students. Controls for the hypnotizability scale were cigarette smokers who smoked 1 1/2 pack/day and S data taken from the literature. Results show that two-thirds of the Ss had histories of spontaneous self-hypnotic experiences (dissociations); 7 of these were DSM-III multiples and 6 were probable multiples. This group had very high hypnotizability scores. The other one-third without histories of spontaneous self-hypnosis had normal scores. It is concluded that spontaneous self-hypnosis contributed to the perpetration of the crimes in many of these cases, although other factors also directed the antisocial behaviors. (22 ref).

1984

Matthews, William J. Jr.; Kirsch, Irving; Allen, George J. (1984). Posthypnotic conflict and psychopathology -- controlling for the effects of posthypnotic suggestions: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32 (4), 362-365.

Hypnotically implanted paramnesias (false memories) designed to arouse Oedipal and non-Oedipal sexual conflicts were implanted in 2 groups of male undergraduate Ss. Ss in a third condition were hypnotized but no paramnesia was implanted. In a fourth condition, the Oedipal paramnesia was presented to Ss who had been instructed by coexperimenters to simulate hypnosis. All Ss had achieved a score of 7 or higher on the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. C. Orne, 1962). Following implantation of the paramnesia, Ss were given conflict activating instructions consisting of posthypnotic suggestions to express strong sexual feelings in response to cue words contained in the paramnesias. Ss in all conditions produced significantly more symptoms of discomfort to cue words than to neutral words. No significant between-group differences were found. These results question the contention that discomfort following the implantation of an Oedipal paramnesia constitutes empirical support for psychoanalytic theory.

Nash, Michael R.; Lynn, Steven Jay; Givens, Deborah L. (1984). Adult hypnotic susceptibility, childhood punishment, and child abuse: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32, 6-11.

Earlier empirical and theoretical work has suggested that there is a relationship between higher hypnotic susceptibility and severity of childhood punishment. Experiment 1 surveyed the parents of 14 extremely high and 11 extremely low susceptible Ss concerning punishment. Low susceptible Ss were found to be more frequently punished than highs; no significant differences were found on the severity measure. Experiment 2 assessed the hypnotizability of 16 adult Ss who reported being physically abused before the age of 10 and compared these scores to those of 300 adult Ss who had not reported being abused. The mean hypnotizability of abused Ss was greater than that of controls, and the distribution of their scores appeared bimodal. Limitations of both experiments are discussed and suggestions are made for future investigations.

Stava, L. (1984). The use of hypnotic uncovering techniques in the treatment of pedophilia: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32 (4), 350-355.

This case study describes the use of the hypnotic uncovering techniques of induced dreams (Sacerdote, 1967) and the affect bridge (Watkins, 1971) in reducing inappropriate sexual arousal in a male pedophile. Treatment effects were examined through the use of both psychophysiological measures of penile tumescence and psychological tests. The hypnotherapeutic treatment regime consisted of 25 sessions over approximately 9 months. At the end of treatment, psychophysiological measures revealed a definite reduction of sexual excitation to slides of prepubescent children. Psychological testing indicated reduced defensiveness as well as reduced sexual anxiety to adult women. Various hypnotherapeutic experiences which may have contributed to the treatment effects are discussed.

Watkins, John G. (1984). The Bianchi (L.A. hillside strangler) Case: Sociopath or multiple personality?. International Journal of Clinical and Experimental Hypnosis, 32 (2), 67-101.

The case of Kenneth Bianchi (the Los Angeles "Hillside Strangler") has been controversial ever since he was first arrested in January, 1979. This contributor saw Bianchi as a consultant on March 21st and 22nd, 1979. Under hypnosis, he manifested what appeared to be a multiple personality. An underlying personality, "Steve," whose existence was apparently unknown to Bianchi, claimed responsibility for the 2 murders in Bellingham and those in Los Angeles. As a consequence, the court appointed 5 other consultants to examine the defendant. On April 20, 1979, I activated the Steve personality without a hypnotic induction. It described many murders in Los Angeles, indicating which ones he (Steve) had done and which ones Bianchi's cousin (Angelo Buono) did. The major personality (Ken) appeared to be amnesic to all this. 2 additional "personalities" were elicited by Martin Orne, another consultant. However, Orne would not accept the diagnosis of multiple personality. He diagnosed Bianchi as an "Antisocial Personality" (Sociopath) and claimed that he was a clever malingerer. He also asserted that Bianchi had never been hypnotized. The evidence, Rorschach tests, intelligence tests, handwriting samples, art creations, plus recorded sessions by Watkins, Orne and others, are analyzed. This writer concludes that the diagnosis of multiple personality is strongly supported.

1983

Epstein, S. J.; Deyoub, P. L. (1983). Hypnotherapeutic control of exhibitionism: A brief communication. International Journal of Clinical and Experimental Hypnosis, 31 (2), 63-66.

Hypnotherapy was used to treat a 30-year-old exhibitionist in 8 sessions. Under hypnosis, he explored causes for his behavior, developed tension reducing techniques, and learned a posthypnotic emergency response. If he felt exposure imminent, his fists would clench, precluding the possibility of exposure. At 2-year follow-up, there were no known exposures.

**Karlin, Robert (1983). Forensic hypnosis--two case reports: A brief communication. International Journal of Clinical and Experimental Hypnosis, 31 (4), 227-234.**

Two criminal cases are briefly described. In these cases, hypnosis was used to "refresh the recollection" of the victim. In each case, the victim's unsupported identification of a perpetrator, produced through hypnosis, was the sole evidentiary basis of the prosecution. There was considerable evidence that both identifications were based on confabulation.

**Polk, W. M. (1983). Treatment of exhibitionism in a 38-year-old male by hypnotically assisted covert sensitization. International Journal of Clinical and Experimental Hypnosis, 31 (3), 132-138.**

This case study reports the successful treatment of a 38-year-old male with a 14 year history of exhibitionism. A multifaceted treatment program was used, involving hypnotically assisted covert sensitization and brief marital therapy. Hypnosis was used to develop psychic aversive and reinforcing stimuli from the patient's past experience. The value of hypnosis in enhancing imagery in cognitive treatment approaches and the need for only experienced clinicians to utilize the present intervention strategy is discussed.

Araoz, Daniel (1978, August). Hypnosis in treating sexual abulia. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.

Sexual abulia is described as a pathological condition where normal sexual desire is absent, following Kaplan's recent conceptualization of hypoactive sexual desire. Reasons for preferring the current descriptive label are proposed. The clinical use of hypnosis in its treatment is outlined with emphasis on constructive and guided fantasy production. A detailed case illustrates the procedure of hypnotherapy in treating an extreme case of sexual abulia. General conclusions on the effectiveness of hypnosis for this sexual dysfunction are drawn and two hypotheses are suggested to explain its cure. The need for further research is stressed.

Brown, Jude M.; Chaves, John F., Ph.D (1978, August). Hypnosis in the treatment of sexual dysfunction. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.

Recent reports suggest that hypnosis may be a useful technique for the treatment of sexual dysfunction. Five distinct strategies for the utilization of hypnosis in sex therapy can be identified: (1) as a diagnostic tool, (2) to improve self-confidence, (3) as an adjunct to behavior therapy, (4) for the direct removal of symptoms, and (5) to facilitate the resolution of neurotic conflicts. Case reports documenting these applications of hypnotic procedures typically fail to include significant information regarding patient variables, symptomatology, the nature of the therapeutic intervention, and criteria for improvement. Although the conclusions provided by these case studies are encouraging, it is essential that the efficacy of hypnotic techniques in sex therapy be evaluated by controlled studies.

1977

Wijesinghe, B. (1977). A case of frigidity treated by short-term hypnotherapy. International Journal of Clinical and Experimental Hypnosis, 25, 63-67.

The case is presented of a patient with longstanding frigidity who was resistant to treatment by widely used behavioral techniques. Following the training in hypnosis, a free-association procedure enabled her to integrate past experiences, unconscious fantasies, and her sexual difficulty. The patient made a dramatic recovery and the treatment gains were seen to be maintained at follow-up after 1 year.

1966

Roper, P. (1966). The use of hypnosis in the treatment of exhibitionism. Canadian Medical Association Journal, 94, 72-77. (Abstracted in American Journal of Clinical Hypnosis, 1966, 9, p. 83)

The use of hypnosis in the treatment of exhibitionism is described in three patients in whom the condition has been present for more than five years. In each patient there was no subsequent recurrence of the exhibitionism once therapeutic suggestions had been made in a deep hypnotic trance, the follow-up period being respectively five years, four and a half years, and one year. The method of treatment and the results are discussed in terms of the concepts of behaviour therapy. It is concluded that with certain patients suffering from exhibitionism the use of hypnosis may well be one of the best methods of treatment, but considerable care should be exercised to exclude those patients with an

underlying psychosis, mental defect or psychopathic condition. It is also noted that the efficacy of the treatment would appear to depend on achieving a satisfactory depth of hypnotic trance. If this is not reached, the results are less likely to be successful. (Author's abstract, from AJCH pp. 83-84).

1965

Beigel, Hugo G. (1965). Three transvestites under hypnosis. International Journal of Clinical and Experimental Hypnosis, 13 (2), 71-82.

The literature on transvestism is reviewed. Most authorities agree that it is rarely, if ever, treated successfully. A therapeutic approach is outlined which combines conventional analytically-oriented psychotherapy with appropriate hypnotherapeutic techniques. 3 illustrative cases are presented. Clinical study in the manner described has been proved effective in less than 50 sessions in 10 of the 24 cases seen. It has helped to clarify the etiology of this condition. The widely accepted belief that transvestism cannot be treated successfully appears unwarranted in the light of the findings presented. (18 ref.) Schneck, Jerome M. (1965). Hypnotherapy for vaginismus. International Journal of Clinical and Experimental Hypnosis, 13 (2), 92-95.

The literature on hypnotherapy contains few comments, usually generalizations, on vaginismus. 2 patients with this problem are presented here. Methods used and degrees of success are described. Major stress was on hypnotic relaxation with supporting, persuading, and graded, encouraging measures. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Dittborn, Julio (1957). Hypnotherapy of sexual impotence. Journal of Clinical and Experimental Hypnosis, 5 (4), 181-192. (Abstracted in Psychological Abstracts 62: 3 II 81D)

#### NOTES

"Summary

"An attempt is made to classify sexual impotence using several criteria, namely; the performance of coitus, the duration of the symptom and the nature of the sexual object which causes it.

"A method of muscular relaxation and preanesthetic hypnosis is described, which, when associated to where visual filmlike images may lead through training, in certain cases, to the progressive disappearance of the symptom.

"The evolution of nine cases variously classified is narrated.

"The possible mode of action of the therapeutic method hereby described is discussed from a theoretical standpoint" (pp. 191-192).

Merrill, George G. (1957). Sexual complications of hypnosis. Journal of Clinical and Experimental Hypnosis, 5 (3), 138-146.

#### NOTES

"Summary: Sexual complications of hypnosis can occur, consisting of either positive or negative erotic manifestations, of either a heterosexual [sic] or homosexual sort, to a more intense degree than is seen in most other forms of psychotherapy. These complications can result in a real threat to the hypnotist himself as well as to the success of his treatment, unless he is emotionally prepared to deal with them competently" (p. 145).

1956

Guze, Henry (1956). The involvement of the hypnotist in the hypnotic session. Journal of Clinical and Experimental Hypnosis, 4 (2), 61-68.

#### NOTES

"In summary, in the actual hypnotic relationship, the attitudes of the operator may influence his behavior markedly and are probably even more important than those of the subject in carrying through a successful relationship. It has been indicated in another paper that the subject's impulse handling is more important than his attitude toward hypnosis in actual hypnotizability. This view is a re-interpretation of that of Sarason and Rosenzweig (16) with regard to the same problem. The way the operator handles his own impulses seems in itself a most significant problem, and is expressed in his reactions to the induction and later the trance state of the subject. It is indicated that to some workers, the hypnotic response of the subject offers a rare feeling of power which may have psychosexual implications of a heterosexual or homosexual kind depending on the sex of the patient and the emotional needs of the operator. Child-parent relationship attitudes may also be elicited as well as conflicts about dominance-submission related to earlier experience of the worker.\*\* As suggested by Bruno-Bettelheim (1) for children who cannot participate in relations with others as a result of a fear of their own hostility, it appears that some persons might find the hypnotic situation difficult because of a similar factor. Thus some therapists or research workers might be impelled to reject the use of this measure or to fail in using it, because of a non-verbalized fear of their own impulses toward a 'helpless' subject in their power. This same situational response may be a problem that arises in the psychotherapeutic or even ordinary medical relationship. Its effect may be to limit full exploration and exploitation of therapeutic possibilities, and to hamper treatment of numerous disorders.

"It is perhaps appropriate to point out in conclusion that Freud left hypnosis, it would seem, because of some unresolved problems. Wolstein (23) says because he could not hypnotize all his patients and because of the magical connotations of hypnosis. The hypnosis in transference is still an open field. Are the two phenomena over-lapping or on a continuum? Are the problems of the therapist really the same in both areas? Is transference an aspect of hypnosis" (pp. 66-67).

"\*\* Data on male-female differences in success as hypnotists with members of the opposite sex might be very illuminating" (p. 66).

1953

Beigel, Hugo G. (1953). Prevarication under hypnosis. Journal of Clinical and Experimental Hypnosis, 1 (3), 32-40.

#### NOTES

Author describes three cases in which hypnosis was used to confirm or disconfirm information provided in the waking state. All three cases involved marital relationships and mistrust. "It is interesting that, awakened from the hypnotic state, none of the subjects made the slightest attempt to deny any of the admissions made" (p. 39).

Kroger, William S. (1953). Hypnotherapy in obstetrics and gynecology. Journal of Clinical and Experimental Hypnosis, 1 (2), 61-70.

Author's Summary - "A high percentage of gynecologic complains [sic] are due to psychic factors. Therapeutic efforts, therefore, must be directed primarily toward the psychologic component. Until recently, the principal weapon of the dynamically oriented physician was orthodox psychoanalysis. However, the increased interest for a relatively rapid approach has demonstrated the diagnostic and therapeutic value of hypnoanalysis. This development has been concomitant with the psychoanalyst's [sic] interest in 'brief psychotherapy' and narcosynthesis.

"In many functional gynecologic disorders, hypnoanalysis has supplanted the parent therapy even though this form of treatment utilizes the concepts of dynamic psychiatry.

"The relevant literature on the use of hypnotherapy in functional obstetrical and gynecological disorders has been reviewed.

"Significant areas for research have been pointed out.

"This review emphasizes that hypnosis *per se* is only of value in obtaining symptomatic relief. On the other hand, hypnoanalysis elicits the responsible dynamics behind the symptom, and is effective in reaching all aspects of the personality.

"Hypnoanalysis will be more applicable in obstetrics and gynecology when there is a wider acceptance of its techniques" (p. 68).

## **SIMULATOR**

**1999**

**Bryant, Richard A.; Barnier, Amanda J.; Mallard, David; Tibbits, Rachel (1999). Posthypnotic amnesia for material learned before hypnosis. International Journal of Clinical and Experimental Hypnosis, 47 (1), 46-64.**

The impact of a suggestion for posthypnotic amnesia on material learned either before or during hypnosis was investigated across 2 experiments. In Experiment 1, very high, high, and low hypnotizable participants learned a word list either before or immediately after a hypnotic induction. During hypnosis, participants were given a suggestion for posthypnotic amnesia for the word list. After hypnosis, they were tested on recall, word-fragment, and word-recognition tasks. Experiment 2 replicated and extended Experiment 1 through application of the real-simulating paradigm. Across the 2 experiments, there was no difference in the performance of participants who learned the word list either before or during hypnosis. Although amnesia on direct memory measures was associated with high hypnotizability (Experiment 1), an explanation based on demand characteristics could not be excluded (Experiment 2). The implications of these findings for the use of post-hypnotic amnesia as a laboratory analog of disorders of autobiographical memory are discussed.

**Kirsch, Irving; Burgess, Cheryl A.; Braffman, Wayne (1999). Attentional resources in hypnotic responding. International Journal of Clinical and Experimental Hypnosis, 47 (3), 175-191.**

Theories of hypnotic responding differ regarding attentional processes. Predictions derived from neodissociation, dissociation control, response set, and ironic process theory were tested by administering suggestions with and without cognitive load to high suggestible participants and low suggestible simulators. Cognitive load interfered with responses to ideomotor and cognitive suggestions but not with responses to challenge suggestions. The effect of cognitive load on suggested amnesia depended on the assessment of that response. Although cognitive load decreased recall on the amnesia trial, it did so even more on recall trials before the amnesia suggestion was given and after it was canceled. These data indicate that attentional effort is required for both recall and memory suppression. Under conditions of low cognitive load, simulators displayed less recall than did nonsimulating participants during suggested amnesia, and they reported smaller subjective responses to ideomotor and challenge suggestions.

**1998**

**Barnier, Amanda J.; McConkey, Kevin M. (1998). Posthypnotic responding: Knowing when to stop helps to keep it going. International Journal of Clinical and Experimental Hypnosis, 46 (2), 204-219.**

The authors examined the effect of specifying (cue) or not specifying (no cue) the cancellation cue for posthypnotic suggestion. Responding was indexed on formal, embedded, informal, and postexperimental tests. Thirty-six real, hypnotized participants and 20 simulating participants took part in an application of the real-simulating paradigm. Responding declined across the four tests. Real participants in the cue condition maintained responding longer than simulators in the cue condition, and they also maintained responding longer than reals and simulators in the no cue condition. The findings highlight the interactional influence of individual, interpersonal, and situational factors in posthypnotic responding and underscore the active involvement of individuals in hypnotically initiated events.

Perugini, Eve Marie; Kirsch, Irving; Allen, Sarah T.; Coldwell, Eleanor; Meredith, Janelle M.; Montgomery, Guy H.; Sheehan, Julia (1998). Surreptitious observation of responses to hypnotically suggested hallucinations: A test of the compliance hypothesis. International Journal of Clinical and Experimental Hypnosis, 46 (2), 191-203.

Suggestions for arm levitation and for visual, auditory, tactile, and taste hallucinations were administered twice via audiotape to a group of high suggestible students and low suggestible simulators. During one of the administrations, participants were led to believe they were alone, but their behavior was surreptitiously recorded on videotape and observed on a video monitor. During the other administration, they were observed openly by an experimenter who had not been informed about group assignment. When unaware that they were being observed, simulators were significantly less responsive to suggestion and engaged in substantially more role-inappropriate behavior. In contrast, the responsiveness of nonsimulating students was not affected by the presence of an experimenter, and they exhibited little role-inappropriate behavior even when alone. These data indicate that the responses of suggestible individuals reflect internally generated changes in experience and are not due to simple intentional compliance (i.e., faking).

1997

Green, Joseph P. (1997). Hypnotizability, the dissociative experiences scale, HGSHS: A amnesia, and automatic writing: Is there an association?. International Journal of Clinical and Experimental Hypnosis, 45 (1), 69-80.

The present study examined whether participants (N = 112) selected on the basis of high and low dissociative ability (Dissociative Experiences Scale [DES]; Bernstein & Putnam, 1986), high and low/simulating hypnotizability (Harvard Group Scale of Hypnotic Susceptibility, Form A [HGSHS:A]; Shor & Orne, 1962), and past performance on the HGSHS:A amnesia item differentially passed an automatic writing suggestion administered during a follow-up experiment. Results from a loglinear analysis supported a single main effect for hypnotizability. Low hypnotizable, simulating participants were more than six times as likely to pass the automatic writing suggestion than high hypnotizable participants. Results found dissociation status and past performance on an ostensibly dissociative suggestion (i.e., amnesia) to be independent of passing the automatic writing suggestion. Findings are discussed in light of other research regarding the relation between the DES and hypnotizability.

1996

Martin, Daniel J.; Lynn, Steven Jay (1996). The Hypnotic Simulation Index: Successful discrimination of real versus simulating participants. International Journal of Clinical and Experimental Hypnosis, 44 (4), 338-353.

Researchers have attempted to find a method that accurately and reliably discriminates hypnotized individuals from those who are simulating hypnosis. Although an extensive literature exists in this area, researchers have failed to identify a discriminator that is consistently successful with a majority of the individuals who are tested. In the current study, 43 hypnotized and 37 simulating participants were categorized on the basis of their scores on the newly created Hypnotic Simulation Index (HSI). Using all 31 items of the HSI as predictors, 94% of the participants were correctly classified. In addition, a reduced set of only 15 items correctly classified 96% of the participants. These results suggest that the HSI is effective in discriminating hypnotized and simulating participants. -- Journal Abstract

Reed, Steven B.; Kirsch, Irving; Wickless, Cynthia; Moffitt, Kathie H.; Taren, Paul (1996). Reporting biases in hypnosis: Suggestion or compliance?. Journal of Abnormal Psychology, 105 (1), 142-145.

The tendency of highly hypnotizable participants to bias their retrospective perceptual reports in response to instructional demands was reexamined with the addition of low-hypnotizable control participants instructed to simulate hypnosis. Mean scores of high-hypnotizable participants and simulators did not differ, but the responses of simulators to the demand instruction was less variable than those of high-hypnotizable participants, and the shape of the response distribution was different. Unlike simulators, some high-hypnotizable participants who had reported changes in perception that were consistent with a hypnotic suggestion subsequently reported changes opposite to those suggested by a demand instruction. These data were interpreted as suggesting that the responses of high-hypnotizable participants to both the demand instruction and the preceding hypnotic suggestion were not entirely due to compliance.

1995

Barnier, Amanda J.; McConkey, Kevin M. (1995, November). Posthypnotic suggestion: Knowing when to stop helps to keep it going. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

Posthypnotic suggestion sometimes leads to compulsive and involuntary responding, but we have little information about the parameters of such a response. In some research in our laboratory, we found that subjects who were given a posthypnotic suggestion that encouraged them to experience a desire to respond, showed a different pattern of response from those simply told to make a specific behavioral response. In another study, we gave subjects a posthypnotic suggestion to mail a postcard every day to the experimenter; some subjects were told to respond until they saw the hypnotist again (termination), others were given no specific information about how long they should respond (no termination). Those expecting a termination to the suggestion showed a different pattern of response across 16 weeks of testing. Thus, the information included in the suggestion about how or when to respond influences posthypnotic responding.

Present Experiment: Laboratory test of including specific information in the posthypnotic suggestion about how long to respond - cancellation cue vs. no cancellation cue. Responding indexed on four different tests: formal, embedded, informal, postexperimental. Also used real/simulating methodology. We expected that responding would decline across the four tests, but that the decline would be slowest for those expecting a cancellation cue.

Methodology: High hypnotizable subjects scored 8-10 on SHSS:C, lows scored 0- 3 on SHSS:C. Given real/simulating instructions (Orne, 1959). Formal test was given immediately after deinduction; embedded test was given during an inquiry question; informal test was given as the hypnotist appeared to terminate the experiment and leave the room; postexperimental test was given by another

experimenter during a postexperimental inquiry. The suggestion was to cough when Ss heard a particular response cue.

**Results:** On the formal test, there was no difference between reals or simulators in either the cue or no cue condition, although simulators in the cue condition tended to overplay their response. Across the tests, responding declined. In particular, the majority of reals and simulators in the no cue condition stopped responding after the formal test. In the cue condition, reals and simulators responded similarly on the embedded test, but differently on the informal test; more reals than simulators continued to respond across the tests. Few subjects responded on the postexperimental test. Subjects' postexperimental comments indicated that reals and simulators in the no cue condition believed that one response was sufficient; simulators in the cue condition were confused about whether to keep responding, and reals in the cue condition responded compulsively across the test.

**Conclusions:**

The inclusion of a cancellation cue in a posthypnotic suggestions maintains responding for a longer period. Responding posthypnotically is not explained solely by demand characteristics. Rather, individuals respond on the basis of their interpretation of the implied intent of the hypnotist's message (c.f., Sheehan, 1971). Responding changes across test types. These findings contribute to a model of posthypnotic responding. They point to the active responding of hypnotized individuals (c.f., Kihlstrom: experimental subjects try to make sense of the message of the suggestions and instructions they receive).

**Green, J. P.; Lynn, Steven J. (1995, August). Dissociation, hypnotic amnesia and automatic writing: Is there an association?. [Paper] Presented at the annual meeting of the American Psychological Association, New York.**

This study examined whether differences in self-reported dissociative experiences (DES, Bernstein & Putnam, 1986) and past performance on hypnotic amnesia (HGSHS: A, Shor & Orne, 1962) influence the frequency of passing an automatic writing suggestion. Participants (N = 112) were divided into high hypnotizable ('real') and simulating groups. Results from a log linear analysis indicated that automatic writing was independent of both dissociation status and past performance on an ostensibly dissociative hypnotic suggestion (i.e., amnesia). Simulators were more than six times as likely to pass the automatic writing suggestion than reals. Findings were discussed in light of other research regarding the relation between the DES and hypnotizability. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1995, Vol. 4, No. 3.)

**Schnyer, David M.; Allen, John J. (1995). Attention-related electroencephalographic and event-related potential predictors of responsiveness to suggested posthypnotic amnesia. International Journal of Clinical and Experimental Hypnosis, 43 (3), 295-315.**

Higher frequency electroencephalographic (EEG) activity around 40 Hz has been shown to play a role in cognitive functions such as attention. Furthermore, event-related brain potential (ERP) components such as N1 and P1 are sensitive to selective attention. In the present study, 40-Hz EEG measures and early ERP components were employed to relate selective attention to hypnotic response. Participants were 20 low hypnotizable individuals, half assigned as simulators, and 21 high hypnotizable individuals. Each of these groups was subsequently divided into two groups based on recognition amnesia scores. The four groups differed in 40-Hz (36-44 Hz) EEG spectral amplitude recorded during preinduction resting conditions but not in EEG amplitude postinduction. The groups also differed in N1 amplitudes recorded during hypnosis. Regression analysis revealed that these effects only distinguish the high hypnotizable participants who experienced recognition amnesia from all other

groups. The findings support the role of selective attention in hypnotic responsiveness, and the utility of subdividing high hypnotizable individuals is discussed.

1994

Kennedy, James; Coe, William C. (1994). Nonverbal signs of deception during posthypnotic amnesia: A brief communication. International Journal of Clinical and Experimental Hypnosis, 42 (1), 13-19.

The question of hypnotic subjects complying with instructions, perhaps even purposely deceiving the hypnotist or deceiving themselves, has arisen from the state-nonstate (skeptical-credulous) theoretical controversy. However, experimental testing of competing hypotheses has been difficult. The current report offers methodological procedures that may prove useful. Subjects who were given posthypnotic amnesia instructions were tested on free recall and implicit recall of a 20-word list. To detect the possibility of deception, videotapes of real subjects and simulating subjects during and after posthypnotic amnesia were rated for nonverbal signs of deception, signs taken from the works of Ekman, Ekman and Friesen, and Zuckerman et al. Preliminary results were gathered on a small pilot sample, and recommendations for procedural improvements are proposed.

Kinnunen, Taru; Zamansky, Harold S.; Block, Martin L. (1994). Is the hypnotized subject lying?. Journal of Abnormal Psychology, 103, 184-191.

Do the verbal reports of deeply hypnotized Subjects truthfully reflect their subjective experiences of hypnotic suggestions? Exp 1 established that the electrodermal skin conductance response (SCR) provides an effective method for detecting deception in the laboratory equally well in hypnotized and nonhypnotized Subjects. In Exp 2, deeply hypnotized and simulating Subjects were administered a number of hypnotic suggestions in a typical hypnotic session, without mention of deception, and were questioned about their experiences while SCR measures were recorded concurrently. Results indicate that 89% of the hypnotized Subjects' reports met the criterion for truthfulness, whereas only 35% of the simulators' reports met this criterion. Implications for the theory of hypnosis are discussed.

Lynn, Steven Jay; Pezzo, Mark (1994, August). Close encounters with aliens? Simulated accounts following a hypnotic interview. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

## NOTES

A survey of 5900 adults regarding unusual experiences concluded that 1 of 50 Americans may have had UFO experiences.

This study resembles that of Lawson (1977), in which Ss were asked to imagine UFO experiences; their descriptions were difficult to distinguish from real reports. One problem with Lawson's research is that he provided the Ss with information (e.g. to imagine they were abducted by aliens).

Our study differs from Lawson's in that we didn't actually hypnotize subjects. Our Ss' task was to 'simulate hypnosis, in recovered memory research.' We manipulated cues provided to the Ss. Ss were told their purpose was to role play an excellent hypnotic subject. Standard simulation instructions were given. Then they were told that hypnosis frequently is used to recover experiences that the Ss cannot remember.

Ss were given a description of a Scene: driving on a road in the country, no traffic, etc. They were told that they couldn't remember 2 hours of what happened. Then a second Experimenter used a pseudo hypnotic induction, and told them they were going to recall material regarding events that had happened.

Ss completed an Omni Magazine questionnaire developed by Hopkins, who is an advocate of UFO sitings. They received the questionnaire either after the experiment, before the experiment, or with specific cues.

4 of 21 (19%) of the minimal cue condition Ss identified lights in the sky as a UFO; at the end, 52% saw a UFO. Thus, even with minimal information, subjects report interactive behavior. Almost all medium cue Ss reported the UFO. 17% felt a loss of control, being floated or transported to the spaceship. Only one S said the aliens were cruel. Only one of the role players picked up the word "trondant," a word used by Hopkins to pick up simulators who are hypnotized.

Our findings present a conservative picture. When Ss thought they would be thrown out of the experiment if detected as simulators, they avoided talking about bizarre events. 15% who were told to role play a close encounter failed to do so!

Our findings do not imply that persons who report contacts are simulating; but the basis for such reports are widely available to college students.

Lynn, Steven. Jay; Rhue, Judith W.; Myers, Bryan P.; Weekes, John R. (1994). Pseudmemory in hypnotized and simulating subjects. International Journal of Clinical and Experimental Hypnosis, 42 (2), 118-129.

High hypnotizable (n = 23) and low hypnotizable simulating (n = 13) subjects received pseudomemory suggestions. High hypnotizable and low hypnotizable simulating subjects were equally likely to pass the target noise suggestion during hypnosis and were also equally likely (high hypnotizables, 47.83%; low hypnotizable simulators, 64.29%) to report pseudomemories when tested for pseudomemory after instructions to awaken. As in previous research with task-motivated subjects, pseudomemory rate (high hypnotizables, 47.48%; low hypnotizable simulators, 46.25%) was not reduced by informing subjects that they could distinguish fantasy and reality in a nonhypnotic state of deep concentration. At final inquiry, after deep concentration, high hypnotizable and low hypnotizable simulating subjects' pseudomemories remained comparable (43.48% and 38.46%, respectively). Unlike previous research, high hypnotizable subjects did not report more unsuggested noises and more pseudomemories of novel sounds than did awake low hypnotizable simulating subjects. Pseudo-memory reports were generally consistent with subjects' ratings of whether the hypnotist expected them to believe the sounds were real or imagined.

Martin, D.; Tomak, J.; Lynn, S. J. (1994, October). Detecting simulation with the hypnosis simulation index. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

## NOTES

Orne described demand characteristics of the hypnotic situation, such that some Ss want to either deceive the hypnotist or to please the hypnotist or to help the experiment work. To separate essence of hypnosis he devised an experimental technique, which informs S to role-play, and tells them intelligent Ss will be able to do this. Sheehan & McConkey note that though the model specifies subjective experience, it lacks a way of determining if people are truthful.

We developed a scale assuming hypnotized Ss would be truthful and wouldn't say they had experiences they didn't, but that simulators would exaggerate. The scale included events plausibly reported by highs but not widely reported.

The scale has 31 items, and is titled the Hypnotic Experience Scale. It has 24 items for experiences during hypnosis, 5 for experiences after hypnosis, and 2 for how deeply hypnotized they felt and what kind of hypnotic subject they thought they were.

Ss participated in 2 sessions. They had the Harvard group scale in the first, and simulation instructions in second session. Simulation instructions were read to Low and Medium subjects. To encourage Ss to keep eyes closed, they were told it was essential to keep their eyes closed. We had scores on:

Hypnosis Simulation Index

**SCL 90**

**DES**

**Tellegen Absorption Scale**

**Highs did not receive any simulation suggestions. Then the Stanford Scale was administered. Highs and Simulators had to pass at least 9 Harvard items.**

**Of the predictors, only the Hypnosis Simulation Index discriminated. It correctly classified 94% of the Ss. To eliminate non-useful items, a stepwise discriminate analysis was performed. 15 items remained. These 15 items were used in a series of analyses. They discriminated between the 2 groups from 100% to 70% of the time.**

**This study is the first to successfully discriminate hypnotized from dissimulating subjects. Simulators' performance indicate they tend to respond in stereotypic ways that exaggerate how hypnotized Ss respond. Hypnotized Ss who passed more than 10 items only rated themselves as average on hypnotizability.**

**This has potential applications in forensic situations.**

**Spiegel, David; Schefflin, Alan W. (1994). Dissociated or fabricated? Psychiatric aspects of repressed memory in criminal and civil cases. International Journal of Clinical and Experimental Hypnosis, 42 (4), 411-432.**

**During the last decade, clinicians, courts, and researchers have been faced with exceedingly difficult questions involving the crossroads where memory, traumatic memory, dissociation, repression, childhood sexual abuse, and suggestion all meet. In one criminal case, repressed memories served as the basis for a conviction of murder. In approximately 50 civil cases, courts have ruled on the issue of whether repressed memory for childhood sexual abuse may form the basis of a suit against the alleged perpetrators. Rulings that have upheld such use underscore the importance of the reliability of memory retrieval techniques. Hypnosis and other methodologies employed in psychotherapy may be beneficial in working through memories of trauma, but they may also distort memories or alter a subject's evaluation of their veracity. Because of the reconstructive nature of memory, caution must be taken to treat each case on its own merits and avoid global statements essentially proclaiming either that repressed memory is always right or that it is always wrong.**

**Mare, Cornelia; Lynn, Steven Jay; Segal, David; Sivec, Harry; Marsden, Kim; Myers, Bryan (1992, October). The 'dream hidden observer': A real-simulator comparison. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.**

**NOTES**

**In previous research, after the Stanford Scale Form C dream suggestion, the authors gave the suggestion to the Ss that "in hypnosis you can discover part of the unconscious mind that is aware of new thoughts, images, that might be related or might not be related to your dream; let your index finger lift when that happens." There were strong demand effects observed in those Ss.**

**94% of highs and 78% of mediums passed the hidden observer test, with more personal and more primary process material produced in the hidden observer condition. All Ss recalled their suggested dreams after awakening, but only 1/3 recalled their hidden observer. The authors think it was because Ss thought the hidden observer was "unconscious."**

**Authors compared highs with low simulators in the present study. Michael Nash says two things differentiate highs: more primary process thinking, and more affect availability in hypnosis. In this study, if high hypnotizables' dreams have more of these, it would support the psychoanalytic model.**

**N = 18 Highs who passed 9 Harvard Scale suggestions; 18 lows passed 3 or fewer suggestions.**

**Simulating instructions were from Orne, 1977.**

**Hypnotists were blind to the hypotheses and to the hypnotizability of Ss. This differs from the first study in two ways: (1) instructions to Ss (here they were more like Hilgard's original suggestions), and (2) more probing about dream content before receiving the hidden observer instructions.**

**We did a 5-point scale on bizarre content, on different thoughts after the experience, and on additional content. Primary process was measured by Bizarre Content and by Shifts in Time or Location. Did ANOVA on 2 primary process and 3 affect measures. Many other analyses also were used. Even under multiple probes, most Ss passed hidden observer test. (In both groups only 1 didn't pass the hidden observer test.) So it is a very reliable suggestion, suggesting that hidden observer instructions are a very credible metaphor (for clinical practice).**

**The 2 groups were comparable on rates of reporting more personally revealing information in the hidden observer condition: so this suggestion could be useful to get additional information from patients.**

**The results supported one hypothesis: dream reports were associated with more primary process thinking. This was more true of highs than lows. Results supported the view that primary process is not attributed to role playing because the blending of dream and hidden observer responses occurred in the high hypnotizables; more novel content was found in the highs.**

**No support was found for the hypothesis that more affect is produced under these conditions.**

**Though simulators were unable to role-play the primary process thinking of highs, they may have been vigilant and may have suppressed primary process thinking.**

**Mozenter, Randi H.; Kurtz, Richard M. (1992). Prospective time estimation and hypnotizability in a simulator design. International Journal of Clinical and Experimental Hypnosis, 40, 169-179.**

**The present study of prospective time estimation examined the effects of hypnosis on short time intervals using a real-simulator design. The major hypothesis predicted a 2-way interaction between group (high hypnotizability, low hypnotizability, and simulator) and condition (waking and hypnotic) across all 4 time intervals (30, 60, 120, and 240 seconds). It was further hypothesized that on a "suggested" task (a measure of hypnotic depth), high hypnotizability subjects and simulators would not differ from each other but would differ from low hypnotizability subjects. 42 undergraduates were screened on both the Creative Imagination Scale (Wilson & Barber, 1977) and the Stanford Hypnotic Clinical Scale for Adults (Morgan & J. R. Hilgard, 1975, 1979) and assigned to 1 of 3 groups (high hypnotizability, low hypnotizability, simulator) based on combined hypnotizability scores. Subjects verbally estimated time intervals of 30, 60, 120, and 240 seconds, 3 times each, both while in a waking and a hypnotic condition. Hypnotic depth was assessed once following each time interval. Partial support was found for the first hypothesis where, for both the 60- and 120-second intervals, high hypnotizability subjects increased their overestimation in the hypnotic condition. Low hypnotizability and simulator Subjects showed no such increase. The second hypothesis, that high hypnotizability and simulator Subjects would differ from low hypnotizables on the "suggested" task, was confirmed. The partial replication of previous research was examined in the context of choice of hypnotizability measure and reliability of time estimation.**

## **NOTES**

**[Perhaps the increase in time estimation shown by highs is evidence of inhibition of cortical response--the time keeper. It is the opposite of the shortened experience of time that often has been found in hypnosis when retrospective technique was used (Bowers, 1979; Jasinski, 1986), though St. Jean did not find time shortening in 3 studies (p. 170).]**

Berrigan, Lee P.; Kurtz, Richard M.; Stabile, Joseph P.; Strube, Michael J. (1991). Durability of 'posthypnotic suggestions' as a function of type of suggestion and trance depth. International Journal of Clinical and Experimental Hypnosis, 39, 24-38.

3 types of 'posthypnotic suggestion,' based upon factor analytic studies, were administered to high hypnotizability Ss (reals) and to low hypnotizable Ss instructed to simulate hypnosis (simulators) (N = 12 high and 6 low hypnotizable Ss per suggestion). The 'posthypnotic suggestions' consisted of instructions given to Ss following a hypnotic induction that, when the posthypnotic cue was later given, they would re-enter the hypnotic state and perform a certain task at that time. Ss were then tested 6 times for durability of 'posthypnotic response' during an 8-week period. Responses to the 'suggestions' were rated by research assistants (objective scores) and by Ss themselves (subjective scores). There was a significant Trials x Type of 'Suggestion' interaction for both types of scores for the reals but not for the simulators, indicating different rates of decline with time for the different 'suggestions' for the hypnotic Ss. Depth of reported hypnotic trance during the assessment sessions was found to be strongly related to performance of the 'posthypnotic suggestion' for both real and simulating Ss.

#### NOTES

The suggestion was either arm lowering, verbal inhibition for the name of S's hometown when asked, and suggestion of imagined or hallucinated smell of ammonia odor in response to the sound of a substance-free aerosol can being sprayed.

Kinnunen, Taru; Zamansky, Harold S.; Block, Martin L. (1991, August). Is the hypnotized subject lying?. [Paper] Presented at the annual meeting of the American Psychological Association, San Francisco.

To determine whether or not hypnotized subjects misrepresent or lie about their hypnotic experiences, electrodermal skin conductance responses were measured while groups of deeply hypnotized subjects and simulators responded to questions about their experiences to a series of suggestion. 89% of the responses of the hypnotic subjects met the criteria for truthfulness, while 65% of the responses of the simulators indicated deception. Differences between "reals" and simulators were highly significant. The relevance of the results for the nature and theory of hypnosis is discussed. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Provided by former Editor, James Council.)

Spanos, Nicholas P.; DuBreuil, Susan C.; Gwynn, Maxwell I. (1991). The effects of expert testimony concerning rape on the verdicts and beliefs of mock jurors. Imagination, Cognition and Personality, 11, 37-51.

Mock jurors heard one of 4 versions of a 'date rape' case and deliberated in small groups, to a verdict. Exposure to the direct examination of an expert who testified about rape myths undermined belief in the defendant's testimony that sex with the complainant had been consensual, and increased the frequency of guilty votes. However, exposure to the expert's cross-examination reversed the effects of the direct examination on the frequency of guilty votes. Women jurors disbelieved the defendant and voted him guilty to a greater extent than male jurors, while in both sexes profeminist attitudes correlated with disbelief in the defendant's testimony but failed to correlate significantly with final verdicts. Implications are discussed

Bates, Brad L. (1990). Compliance and the Carleton Skill Training Program. British Journal of Experimental and Clinical Hypnosis, 7, 159-164.

## NOTES

He presents examples of how the Carleton training program for increasing hypnotizability encourages compliance, which suggests that the results are not truly an increase in suggestibility or hypnotizability.

Spanos, Nicholas P.; James, Barbara; de Groot, Hans P. (1990). Detection of simulated hypnotic amnesia. Journal of Abnormal Psychology, 99, 179-182.

Highly hypnotizability nonsimulators and high- and low-hypnotizable simulators of hypnosis were administered a hypnotic amnesia suggestion and tested for recall and recognition of a previously learned word list. Simulators exhibited higher levels of recall and recognition amnesia than non-simulators. Most important, simulators recognized 'forgotten' words at lower levels than expected by chance significantly more often than did nonsimulators. Implications for the detection of simulated amnesia in clinical samples are discussed.

Bryant, Richard A.; McConkey, Kevin M. (1989). Hypnotic blindness: A behavioral and experiential analysis. Journal of Abnormal Psychology, 98, 71-77.

## NOTES

"This research examined the influence of visual information on a decision task that subjects were administered during hypnotically suggested blindness. Real, hypnotizable subjects and simulating, un hypnotizable subjects were tested in two experiments. Experiment 1 focused on behavioral responses, and Exper. 2 focused on experiential reactions. In both experiments, the findings indicated that the behavioral responses of reals were influenced by visual info. despite their reported blindness. The behavioral responses of reals and simulators were essentially similar. The experiential data in Experiment 2 provided information about the phenomenal nature of subjects' reported blindness. The experiential reactions of reals and simulators were essentially different. The research is discussed in terms of the issues that need to be considered in the development of a model of hypnotic blindness" (p. 71).

Bryant, Richard A.; McConkey, Kevin M. (1989). Hypnotic emotions and physical sensations: A real-simulating analysis. International Journal of Clinical and Experimental Hypnosis, 37, 305-319.

Real hypnotizable Ss and simulating un hypnotizable Ss were administered a suggestion for either happiness, emotional neutrality, or sadness. The emotion was assessed through subjective and behavioral measures taken once before, twice during, and once after the emotion. Findings indicated that emotionally congruent changes occurred in both self-report and performance measures. Ss' physical sensations during the emotion were assessed on a 34-item self-report scale. It was demonstrated that Ss in the happy versus sad conditions reported different physical sensations; in particular, they reported different facial sensations. The responses of real hypnotizable subjects, however, were essentially paralleled by those of simulating un hypnotizable subjects. Therefore, the possibility exists that hypnotized subjects may have been responding on the basis of social demands. The findings are discussed in terms of the effects of the emotion suggestions, and the implications of real and simulating Ss displaying similar affective responses.

## NOTES

Used the real-simulating model in an attempt to eliminate the possibility that hypnotized Subjects in previous studies may have been responding to the demand characteristics of the situation. Used both subjective and behavioral measures. Self-report happiness and sadness, of emotion intensity; behavioral performance measure of speech rate, indexed by counting speed (which has been shown to distinguish between happiness and sadness). Used 34-item self-report Physical Sensations Scale based on Pennebaker, J. W. *The psychology of physical symptoms*. New York: Springer-Verlag,

1982.

They cite Weiss, et al (1987) who focused on the onset latency, and the fluctuation of muscular contraction associated with facial expression indicated a difference between posthypnotically cued and simulated emotions of anxiety and pleasure.

Marks, David F.; Baird, John McR.; McKellar, Peter (1989). Replication of trance logic using a modified experimental design: Highly hypnotizable subjects in both real and simulator groups. *International Journal of Clinical and Experimental Hypnosis*, 37, 232-248.

A potentially useful method for diagnosing the presence of hypnosis has been the comparison of hypnotic Ss and simulators. The present study attempted to replicate the hypnotic-simulator differentiation in regard to trance logic, as originally described by Orne (1959), using a modified design in which Ss in the 2 conditions were matched for hypnotizability scores. Orne's doubled person hallucination (DPH) suggestion was presented, and the results showed significant differences between the two treatment conditions in both DPHs and spontaneous transparency reports. One interesting case of DPH occurred in the simulator group with one S in whom a hypnotic-like state was self-induced. In contrast to the placid acceptance of DPH among Subjects in the hypnotic condition, the experience was a confusing and mildly disturbing one for this S, who was not expecting any unusual perceptual experiences. Trance logic results from the 'metasuggestion,' experienced through participation in a formal induction procedure, that hypnosis entails new rules of experience and behavior.

## NOTES

Demonstrates changes in perception as a function of suggestion. This experimental design should show what the essential characteristics of hypnosis would be. They compared hypnotized Subjects with simulating Subjects, but modified the original simulator design so that the Subjects in the two conditions were matched for hypnotizability scores. In this design, hypnotizability can be eliminated as a causal factor if any differences are found between groups. The design has the disadvantage of not being able to assure that the simulating Subjects do not inadvertently enter hypnosis.

"The results indicate that the distribution of hypnotized and simulator Subjects reporting DPH has a 1-in-20 probability of occurring by chance. These results confirm Orne's (1959) original claim that hypnotized Subjects who report the hallucination will tend to acknowledge the real target person behind. In contrast with most of the previous research, the present study has replicated Orne's finding that 100% of reals who acknowledge the hallucination also report DPH. Orne also claimed that simulators who report the hallucination will seldom report DPH. In the present experiment 58% of the simulators produced DPH responses, a greater number than would be expected on the basis of Orne's original data. In the 25 year period between the two studies, however, the sophistication of the university student population in regard to hypnotic effects could well have increased and, therefore, a better level of hypnotic simulation might well be expected. Additionally, and perhaps more importantly, highly hypnotizable simulators can be expected to be more successful at accurately playing the role of hypnotized Ss, because they are more likely to have had direct access to relevant fantasy-oriented experiences than low hypnotizables" (p. 242).

"The claim by Orne (1959) that a spontaneous transparency response is 'absolutely diagnostic' of the hypnotized S therefore appears to be correct" (p. 242).

"Hypnosis is a condition in which suggestions bring about alterations in imagery, memory, mood, motor control, or perception. These alterations are subjectively real, and while the circumstances under which these alterations occur most reliably entail co-operative, highly hypnotizable Ss participating in a hypnotic induction procedure, highly hypnotizable Ss may experience hypnotic phenomena in their everyday life (Shor, 1959; Shor, Orne, & O'Connell, 1962). The results of the present investigation correspond well to the description of 'trance logic' given originally by Orne (1959). The Ss were selected from the high end of a continuum which has variously been characterized as 'tranceability' or suspension of usual 'generalized reality-orientation' (Shor et al., 1962), 'absorption' (Tellegen & Atkinson, 1974), 'fantasy-proneness' (Wilson & Barber, 1983), and in the general literature, 'hypnotizability' or 'hypnotic susceptibility.' The Subjects who experienced DPH would likely have been characterized by high scores on other measures of hypnotizability, and they were found to have significantly higher scores on the measure of hypnotizability used in the present study (CIS plus BSS)" (p. 244).

Spanos, Nicholas P.; Flynn, Deborah M. (1989). Simulation, compliance and skill training in the enhancement of hypnotizability. British Journal of Experimental and Clinical Hypnosis, 6, 1-8.

Subjects who underwent cognitive skill training were compared to no treatment controls and to subjects in two simulation treatments on the behavioural and subjective dimensions of two hypnotizability post-tests. Ss in a trained simulation treatment received skill training but were instructed to fake the responses of someone who had been transformed by training into an excellent hypnotic subject. Standard simulators did not receive skill training, but were instructed to fake their responses to the two post-tests. A final group of untrained Ss (i.e. naturals) who attained the same behavioural scores on a hypnotizability index as did post-tested skill-trained Ss, was also compared to the treated groups. Ss in the two simulation treatments performed similarly on all hypnotizability indexes. Simulators out-performed both skill-trained and natural subjects (who failed to differ from one another) on all indexes, and skill-trained and natural subjects, in turn, out-performed the no treatment controls. These findings suggest that sustained faking cannot account adequately for the enhancements in hypnotizability produced by skill training.

Van Denberg, Eric J.; Kurtz, Richard M. (1989). Changes in body attitude as a function of posthypnotic suggestions. International Journal of Clinical and Experimental Hypnosis, 37, 15-30.

Hypothesized that highly hypnotizable subjects who remained amnesic for posthypnotic suggestions to improve body attitude would show greater changes than subjects who were not amnesic. Subjects given simulating instructions were used as a comparison group to assess experimental demands. 48 females were screened with the Harvard and assigned to one of 4 conditions: (a) high hypnotizable with amnesia suggestions, (b) high hypnotizable without suggested amnesia, (c) low hypnotizable simulator with amnesia, and (d) low hypnotizable simulator without suggested amnesia. A fifth group was formed of those high hypnotizable subjects who remembered the suggestion despite instructions to the contrary. The Body Attitude Scale (Kurtz, 1966) was administered prior to and 3 days after the experimental suggestions. Results generally demonstrated that high hypnotizable amnesic subjects manifested the greatest attitudinal and phenomenological changes as a result of the posthypnotic suggestion, although conclusions were tempered by performance of simulating subjects. The implications for hypnosis research and clinical practice are discussed.

NOTES

"The hypothesis that hypnotized subjects would report greater positive changes in affect, self-esteem, and social functioning than simulators was tested using a brief structured questionnaire. An analysis of Subjects responses to the questionnaire while with the 'blind' research assistant (simulators in role) revealed number significant differences between groups (N = 48) on six of the seven questions. ... An analysis of Subjects' responses to the questionnaire while being debriefed by the primary investigator (simulators out of role) revealed significant differences among groups (N = 48) on three of the seven questions. ... High hypnotizable subjects with maintained amnesia demonstrated a strong tendency to be the most responsive of all groups of subjects on the first and second assessment. In contrast, the high hypnotizable Ss for whom amnesia 'broke down' reported the fewest phenomenological changes of any of the five groups during the first assessment, and comparatively few during the second assessment. Also of note is that once out of their role, simulators in both conditions dramatically reduced their reporting of positive change" (pp. 23-24).

"Moreover, a closer examination of the data demonstrated that phenomenological and behavioral differences in the groups did appear at several points during the experiment. For example, the 10 high hypnotizable subjects told to explicitly remember the suggestion did so, while 3 of the 10 simulators in this condition claimed to have forgotten it. On debriefing, these Subjects reported they did this because they believed 'really hypnotized subjects wouldn't be able to remember anything, even if they were told they could.' Further, no simulator in the amnesia condition reported they could recall the suggestion, in contrast to the high hypnotizable subjects, 44% of whom said they did remember it. With regard to phenomenological differences, simulators stated during debriefing with the primary investigator that they intentionally faked changes on BAS, and that they experienced no true effects from the suggestion for positive body attitude change. In contrast, high hypnotizability amnesic subjects reported global, pervasive changes in their mood and self-esteem that went beyond specific alterations in attitudes toward their appearance. By comparison, high hypnotizable subjects told to remember the suggestion reported greatly increased self-absorption and acute awareness of the suggestion, 'sort of like a broken record in my head'" (pp. 25-26).

"As shown by the present study, amnesia maintenance can be quite problematic. Of 18 high hypnotizable subjects for whom amnesia was suggested, only 10 remained fully amnesic for the suggestion after 3 days. In addition, those 8 subjects for whom amnesia 'broke down' showed minimal shifts on BAS, or in reports of phenomenological changes. Such frequent amnesia failure has been reported by other researchers, although the effectiveness of the suggestion is not always so compromised" (p. 26).

1988

Gruzelier, John; Allison, James; Conway, Ashley (1988). A psychophysiological differentiation between hypnotic behaviour and simulation. International Journal of Psychophysiology, 6, 331-338.

Psychophysiological differentiation between conditions of hypnosis and simulation were examined with markers evolved from a series of experiments charting neuropsychophysiological accompaniments of hypnotic behaviour. Eighteen subjects participated in two sessions in which bilateral electrodermal activity was monitored to moderate intensity tones. Measurement in Session I, a Baseline-Control, of individual variation in rates of habituation of orienting responses, non-specific responses and tonic levels of skin conductance, enabled allocation of matched groups to Session II in which the same auditory stimuli were mixed with a taped hypnotic induction. Half the subjects were instructed to fake hypnosis and the others to comply. In session II the groups were differentiated as follows: (1) rate of habituation to the tones was retarded in the simulation condition and facilitated in the hypnosis condition compared with baseline; (2) the incidence of non-specific electrodermal responses was elevated in simulators after instructions to 'fake hypnosis'; (3) right-hand levels of skin conductance

were elevated in simulators; (4) all but one subject in the hypnosis condition admitted to hearing the tones whereas all but one in the simulation condition claimed not to have heard them

Spanos, Nicholas P.; Gwynn, Maxwell I.; Della Malva, C. Lori; Bertrand Lorne D. (1988). Social psychological factors in the genesis of posthypnotic source amnesia. Journal of Abnormal Psychology, 97 (3), 322-329.

Three experiments assessed the role of social psychological variables in source amnesia. Experiment 1 found that low-hypnotizable subjects instructed to simulate partial amnesia were more likely to exhibit source amnesia than high-hypnotizable hypnotic or task-motivated subjects. Experiment 2 found equivalent rates of source amnesia in low-hypnotizable simulators and high-hypnotizable hypnotic subjects. In addition, the findings of Experiment 2 failed to support the idea that the instructions for partial amnesia given to simulators cued for the occurrence of source of amnesia as well as for the occurrence of partial amnesia. In Experiment 3, preliminary instructions that legitimated source amnesia as a role-appropriate response produced significantly more posthypnotic source amnesia than did neutral or no instructions. Together, the findings of the 3 experiments support the relation of source amnesia to experimental demands and subjects' expectations.

1987

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott; Carlson, Victor (1987). Subjectively complete hypnotic deafness and auditory priming. International Journal of Clinical and Experimental Hypnosis, 35 (1), 32-40.

The present study examined the cognitive and attentional mechanisms by which auditory information is maintained out of awareness during complete hypnotic deafness. Adopting a methodology from recent work on subliminally presented pattern- masked words and dichotic listening, the study tested whether spoken words presented during complete hypnotic deafness affect lexical decisions concerning subsequently presented word choices. The response of 9 hypnotized and 15 simulating Ss to spoken stimulus words presented following hypnotic deafness instructions was compared to the response of 20 baseline control Ss who never were exposed to the stimulus words. While the response pattern of hypnosis Ss appeared different from that of baseline control Ss, hypnotic Ss showed no evidence of the priming effect found in subliminal perception and dichotic listening studies. Simulator response deviated significantly from hypnotized and baseline control responses.

## NOTES

10 highs capable of hypnotic deafness, screened by Harvard Group and Stanford Profile Scales (Means 11.0 and 24.7, respectively) and 15 lows (means 1.7 and 1.7, respectively) participated in the study; the low hypnotizables being in the simulation group. For the experimental session, a different E administered a standard hypnotic induction and the deafness suggestion, testing for deafness by snapping fingers near S's ear and making loud requests for motor responses.

An experimental trial consisted of tapping an S on the hand, saying the stimulus word out loud, and visually presenting four words for the S to read out loud and circle one. "Of the 18 main experimental trials, the four-word array consisted of two words which were related to the stimulus (one word which was semantically related to the spoken stimulus word and one word which was phonetically related), and two neutral unrelated words" (p. 34). For example, if the spoken word were 'dream,' the word array might include 'cream, tennis, sell, sleep.' There also were "3 phonetically unrelated trials (whose arrays consisted of one phonetically related choice and 3 unrelated choices) and 2 stimulus word-unrelated trials (whose arrays consisted of the stimulus word and 3 unrelated choices) ... [and] 7

dummy trials with 4 unrelated choices only" (p. 34). Ss rated their degree of deafness on a 10-point scale after hypnosis was terminated.

Possible sources of bias were examined by having 20 control Ss respond to blank tachistoscopic slides with the instructions that they were participating in a study of 'subliminal perception.' Another 22 Ss were asked to identify the semantically and phonetically related words from the word array, which for the most part they did successfully.

All Ss rated themselves as '10' on the deafness scale, indicating total deafness. The principal results are seen in Tables 1 and 2.

Table 1 Mean Number of Related and Unrelated Responses (Percentage of Responses) for all S Groups on the 18 Mean Experimental Trials

Response Category S Group N Related Unrelated Total

Hypnotized 9 7.22 10.78 18

(40.13%) (59.88%) (100%)

Simulating 15 12.13 5.87 18

(67.43%) (32.61%) (100%)

Baseline 19 8.79 9.21 18 Controls (48.82%) (51.17%) (100%)

Table 2 Mean Number of Phonetic and Semantic Responses within the Related Response Category on the 18 Main Experimental Trials

Related Responses S Group Phonetic Semantic Hypnotized 1.78 5.44

(9.89%) (30.24%) Simulating 7.07 5.07

(39.27%) (28.16%) Baseline 4.21 4.58 Controls (23.38%) (25.44%)

Hypnotized Ss were significantly different from simulators (Table 1) in number of related responses. Simulators gave significantly more related responses than baseline controls. Simulators also gave more phonetically related words than either the hypnotized or baseline Ss (Table 2); there was no difference between groups on semantically related words. (Authors performed other useful and detailed analyses.)

In their Discussion section, the authors note that they did not obtain the expected results of hypnotized Ss producing more related responses than baseline Ss. "In fact, internal analyses of hypnotized and baseline responses revealed that the pattern of choices for hypnotic deaf Ss was opposite to the direction predicted by subception. Hypnotic Ss appeared to avoid phonetically related word choices, even for items on which baseline control Ss scored above chance. ...

"This kind of non-baseline performance by hypnotic Ss can be accounted for by either a strategic enactment conceptualization of hypnosis (Spanos, 1982; Wagstaff, 1981) or Hilgard's (1979) neo-dissociation theory. Spanos might emphasize the hypnotic S's active strivings to meet the hypnotist's perceived expectations. ... Neo-dissociation theory might stress the mechanisms by which processing of auditory inputs are maintained outside of awareness via a dissociative barrier.

" ... Given the tendency for simulating Ss to 'overplay' hypnotic phenomena (Levitt & Chapman, 1979), one might have expected simulators to pointedly avoid related responses, thus producing a lower frequency of related words than either the hypnotic Ss or the baseline controls (in effect being more deaf than the deaf). Just the opposite occurred. One possible explanation for this behavior presents itself: In their work with posthypnotic suggestion and the 'disappearing hypnotist' ... M. T. Orne and others found that simulating Ss may be more alert and responsive to demand cues than are hypnotic Ss. In the present study, the authors' original hypothesis was that hypnotic Ss might reveal a subception effect by above-chance responding on related word choices. If we assume that this expectation was somehow communicated to Ss by some subtle aspect of the experimental procedure, then it is conceivable that simulating Ss were able to detect and act upon these cues, while hypnotized Ss remained relatively unattuned to such subtleties.

"In sum, the priming effect noted in the subliminal perception research does not appear to be a feature of complete hypnotic deafness, at least as measured in this study. The behavior of simulating Ss in the

present study should be another caution to researchers that differences between hypnotized and simulating Ss may reflect simulation effects in addition to, or instead of, hypnotic effects" (pp. 37-38).

#### NOTES

Cited by Bryant R. A. & McConkey, K. M. (1989) Hypnotic emotions and physical sensations: A real-simulating analysis, IJCEH, 37, 305-319, who state, "Finally, future research could usefully focus on aspects of experiencing emotions that are not obvious to simulators. Recent research by Weiss et al. (1987), for instance, that focused on the onset latency and the fluctuation of muscular contraction associated with facial expression indicated a difference between posthypnotically cued and simulated emotions of anxiety and pleasure, and this points to the potential value of investigating specific aspects of emotional experience. Thus, future investigations of real and simulated emotions and physical sensations could usefully employ more subtle and unobtrusive measures of the specific emotional responses of subjects" (p. 316).

Schacter, Daniel L. (1986). Amnesia and crime: How much do we really know?. American Psychologist, 41, 286-295.

Claims of amnesia occur frequently after the commission of violent crimes and can have a significant bearing on the outcome of criminal trials. This article considers the relation between amnesia and crime within the broader context of research on memory and amnesia and provides a critical evaluation of current knowledge concerning the issue. Particular attention is paid to the problem of distinguishing between genuine and simulated claims of amnesia. It is suggested that reliable data concerning the nature of amnesic episodes that occur after the commission of a crime are sparse, and that there is as yet little evidence that genuine and simulated amnesia can be distinguished in criminal cases. The results of several laboratory studies are summarized that indicate that feeling-of-knowing ratings distinguished between genuine and simulated amnesia under conditions in which psychologists and psychiatrists did not.

Silverman, Paul S.; Retzlaff, Paul D. (1986). Cognitive state regression through hypnosis: Are earlier cognitive stages retrievable?. International Journal of Clinical and Experimental Hypnosis, 34, 192-204.

Piagetian theory maintains that stage sequence is invariant due to irreversible transformations of cognitive structure which characterize development. The present study aimed to test this claim by attempting to stage-regress hypnotized and hypnosis-simulating adults. A prediction discrepancy technique was used whereby 3 tasks (conservation of volume, horizontality, and seriation) and target ages (8, 7, and 5 years) were selected based on evidence of failure by actual children, but adult predictions of success by children. Under both regressed and simulating conditions, adult task scores were substantially higher than those of actual children, though slightly lower than scores obtained during the normal adult state. The modest partial regression obtained suggests superficial performance adjustments attributable to procedure demand characteristics or to enhancement of role playing rather than temporary modifications of cognitive structure.

Spanos, Nicholas P.; Robertson, Lynda A.; Menary, Evelyn P.; Brett, Pamela J. (1986). Component analysis of cognitive skill training for the enhancement of hypnotic susceptibility. Journal of Abnormal Psychology, 95, 350-357.

Four treatments to enhance the hypnotic responsiveness of subjects who pretested as low in hypnotic susceptibility were compared. Complete skill training included information aimed at encouraging (a) positive attitudes, (b) the use of imagery strategies, and (c) an interpretation of hypnotic behavior as active responding. Partial training included only components (a) and (b). Both training packages enhanced attitudes toward hypnosis to an equivalent degree. However, complete training was much more effective than either partial training or no treatment at enhancing behavioral and subjective responding on two different posttest scales of hypnotic susceptibility. More than half of the subjects who received complete training, but none of the partial training or control subjects, scored in the high-susceptibility range on both posttests. Subjects explicitly instructed to fake hypnosis and those in the complete skill-training treatment exhibited significantly different patterns of posttest responding. Findings support social psychological perspectives that emphasize the importance of contextual factors in hypnotic responding.

Spanos, Nicholas P.; Weekes, John R.; Menary, Evelyn; Bertrand, Lorne D. (1986). Hypnotic interview and age regression procedures in the elicitation of multiple personality symptoms: A simulation study. Psychiatry, 49, 298-311.

Patients diagnosed as suffering from multiple personality (i.e., multiples) behave as though they possess two or more distinct personal identities. When behaving as one identity, these patients often display signs of amnesia for events that occurred while they were behaving as a different identity (Sutcliffe and Jones 1962; Taylor and Martin 1944). In most theoretical accounts multiples are conceptualized as the passive victims of unconscious psychological processes that are beyond their sphere of control. For instance, patients' secondary identities are typically described as "dissociated" mental entities, as "taking over" behavioral control, as behaving independently of (and often in opposition to) patients' wishes and intentions, and so on (Allison and Schwarz 1980; Gruenewald 1984; Prince 1930; Watkins and Johnson 1982). Our paper criticizes this traditional account and suggests instead that multiple personality may be more usefully conceptualized as a social role enactment. Along these lines we present a study using college student role players as subjects to test the hypothesis that the kinds of clinical interview procedures employed routinely to diagnose multiple personality may instead encourage and legitimate enactments of this syndrome.

1985

Ashton, M.A.; McDonald, R.D. (1985). Effects of hypnosis on verbal and non-verbal creativity. International Journal of Clinical and Experimental Hypnosis, 33 (1), 15-26.

60 female volunteers, 30 hypnotizable and 30 un hypnotizable, screened on 2 measures of hypnotizability, were assigned to a hypnosis, simulation, or waking motivated treatment condition to assess whether hypnosis has a differentially enhancing effect upon verbal and non-verbal creativity test performance. Verbal and figural components of the Torrance Tests of Creative Thinking (Torrance, 1974) and the Sounds and Images Test (Cunnington & Torrance, 1965) were the principal dependent variables. Postexperimental measures of absorption and effortless experiencing were also obtained. A 2 x 3 independent groups ANOVA did not sustain the prediction of an interaction effect between S hypnotizability and the presence of hypnosis on 3 composite measures of verbal and nonverbal creativity. Although there was an absence of treatment effects, hypnotizable Ss consistently achieved higher scores on the Torrance scoring categories, and their performance was statistically

superior on a composite index of overall creativity. Absorption and effortless experiencing measures were also significantly higher for hypnotizable Ss than for unhypnotizable Ss.

Lundy, R. M.; Geselowitz, L.; Shertzer, C. L. (1985). Role-played and hypnotically induced simulation of psychopathology on the MMPI: A partial replication. International Journal of Clinical and Experimental Hypnosis, 33 (4), 302-309.

In Wilcox and Dawson (1977) hypnotized Ss who were simulating paranoia while taking the MMPI (Dahlstrom & Welsh, 1960) were not detected as simulators by 2 MMPI validity measures, the F scale and the Gough F minus K index (Gough, 1950). The present study found that hypnotized Ss were detected by the same measures, thus failing to replicate Wilcox and Dawson (1977). Hypnotized Ss in the present study, however, were different from a comparison group in not appearing to overlay psychopathology to the same degree.

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott; Frauman, David; Rhue, Judith (1985). Hypnotic age regression and the importance of assessing interpersonally relevant affect. International Journal of Clinical and Experimental Hypnosis, 33, 224-235.

The present study was undertaken to replicate an earlier experiment and to clarify which factors in this previous experiment (Nash, Johnson, & Tipton, 1979) were responsible for the obtained child-like behaviors of hypnotically regressed Ss. As in the previous study, 3 characteristics of the transitional object relationship (spontaneity, specificity, and intensity) were used as the primary criteria to investigate the effects of hypnotic age regression when Ss were regressed to age 3 and placed in 3 home situations. While in the previous study E suggested separation anxiety and isolation during the 3 home situations (mother-absent condition), the present study deleted all references to anxiety and isolation, and replaced them with suggestions of security and maternal proximity (mother-present condition). As expected, the mother-present versus mother-absent conditions led to similar hypnotized- simulating differences. In further accord with predictions, hypnotized Ss and simulating Ss requested a transitional object infrequently in the presence of mother. The importance of using dependent measures which index affective processes germane to interpersonal affect-laden experience is discussed.

Spanos, Nicholas P.; Weekes, John R.; Bertrand, Lorne D. (1985). Multiple personality: A social psychological perspective. Journal of Abnormal Psychology, 94, 362-376.

The part of an accused murderer remanded for pretrial psychiatric evaluation was role played by 48 college students. Role players were assigned to interview treatments that varied in how extensively they cued for symptoms of multiple personality. The most explicit treatment (i.e., Bianchi treatment, n = 16) included a hypnotic interview that was used in diagnosing a suspect in the "Hillside strangler" rape- murder cases as suffering from multiple personality. A less explicit hypnotic treatment (n = 16) and a nonhypnotic treatment (n = 16) were administered to the remaining role players. Most subjects in the Bianchi treatment displayed the major signs of multiple personality (e.g., adoption of a different name, spontaneous posthypnotic amnesia). In a later session subjects who role played as multiple personalities performed very differently on psychological tests administered separately to each role-played identity. Those who failed to enact the multiple personality role performed similarly when tested twice. Findings are discussed in terms of a social psychological formulation that emphasizes the roles of active cognizing, contextual cueing, and social legitimization in the genesis of multiple personality.

Spanos, Nicholas P.; de Groot, Hans P.; Tiller, Dale K.; Weekes, John R.; Bertrand, Lorne D. (1985). 'Trance logic,' duality, and hidden observer responding in hypnotic, imagination control, and simulating subjects: A social psychological analysis. Journal of Abnormal Psychology, 94 (4), 611-623.

Tested the hypothesis that a tolerance for logical incongruity characterizes hypnotic responding and is related to reports of duality experiences during age regression and hidden-observer responding during suggested analgesia. 30 undergraduates (the "reals") with high scores on a responsiveness-to-suggestion scale were randomly assigned to hypnotic or imagination control treatments, while 15 undergraduates with low scores were assigned to a simulation treatment in which they were instructed to fake hypnosis. Ss were assessed on 6 indicators of logical incongruity, given age-regression suggestions and perception tasks, administered a suggestion for analgesia and hidden observer instructions, and interviewed. Results do not support the hypothesis. The differences in responding that did emerge between reals and simulators were accounted for by the different task demands to which Ss were exposed. These behavioral differences, which have been previously interpreted in terms of intrinsic characteristics of hypnosis, may instead reflect a combination of between-treatments differences in demands and between- Ss differences in the interpretation of those demands and in the ability to fulfill them.

1984

Lynn, Steven Jay; Nash, Michael R.; Rhue, Judith W., Frauman, David C.; Sweeney, Carol A. (1984). Nonvolition, expectancies, and hypnotic rapport. Journal of Abnormal Psychology, 93 (3), 295-303.

Prior to hypnosis, subjects were informed either that hypnotizable subjects can resist motoric suggestions or that such control does not characterize good hypnotic subjects. During hypnosis, susceptible and simulating subjects received countering suggestions involving inhibiting suggestion-related movements. Susceptible subjects' responses were found to be sensitive to prehypnotic normative information. There was a corresponding tendency for reports of involuntariness to be sensitive to the expectancy manipulation. Furthermore, subjects were able to feel deeply hypnotized and to rate themselves as good subjects yet concomitantly experience themselves as in control over their actions when normative information supported this attribution. Reports of suggestion-related sensations but not imaginative involvement were associated with movements in response to countersuggestion. Simulators were unable to fake susceptibles' reports of sensations and involuntariness. However, for all subjects, movements paralleled expectancies about appropriate response, supporting the hypothesis that involuntary experiences are sensitive to the broad expectational context and are mediated by active cognitive processes. Also, rapport with the hypnotist was found to be a factor. Susceptible subjects with highly positive rapport resolved hypnotic conflict, in part, by achieving a compromise between meeting normative expectations and complying with the hypnotist's counterdemand.

Matthews, William J. Jr.; Kirsch, Irving; Allen, George J. (1984). Posthypnotic conflict and psychopathology -- controlling for the effects of posthypnotic suggestions: A brief communication. International Journal of Clinical and Experimental Hypnosis, 32 (4), 362-365.

Hypnotically implanted paramnesias (false memories) designed to arouse Oedipal and non-Oedipal sexual conflicts were implanted in 2 groups of male undergraduate Ss. Ss in a third condition were hypnotized but no paramnesia was implanted. In a fourth condition, the Oedipal paramnesia was presented to Ss who had been instructed by coexperimenters to simulate hypnosis. All Ss had achieved a score of 7 or higher on the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. C. Orne, 1962). Following implantation of the paramnesia, Ss were given conflict activating instructions

consisting of posthypnotic suggestions to express strong sexual feelings in response to cue words contained in the paramnesias. Ss in all conditions produced significantly more symptoms of discomfort to cue words than to neutral words. No significant between-group differences were found. These results question the contention that discomfort following the implantation of an Oedipal paramnesia constitutes empirical support for psychoanalytic theory.

Orne, Martin T.; Dinges, David F.; Orne, Emily Carota (1984). On the differential diagnosis of multiple personality in the forensic context. International Journal of Clinical and Experimental Hypnosis, 32 (2), 118-169.

The problems of diagnosing multiple personality disorder in a forensic context are discussed, and illustrated by the case of State v. Kenneth Bianchi (1979), a defendant who was both charged with first degree murder and suspected of having the disorder. Because of the secondary gain (e.g., avoiding the death penalty) associated with the diagnosis of multiplicity in such a case, hypotheses had to be developed to permit an informed differential diagnosis between multiple personality and malingering. If a true multiple personality disorder existed, then (a) the structure and content of the various personalities should have been consistent over time, (b) the boundaries between different personalities should have been stable and not readily altered by social cues, (c) the response to hypnosis should have been similar to that of other deeply hypnotized subjects, and (d) those who had known him over a period of years should have been able to provide examples of sudden, inexplicable changes in behavior and identity, and evidence to be the case. Rather, the content, boundaries, and number of personalities changed in response to cues about how to make the condition more believable, and his response to hypnosis appeared to reflect conscious role playing. Further, the life history indicated a persistent pattern of conning and deliberate deception. It is concluded that Mr. Bianchi was simulating a multiple personality and the diagnosis of Antisocial Personality Disorder with Sexual Sadism was made. Differential diagnoses and the clinical aspects that appeared to account for his behavior are discussed.

Sheehan, Peter W.; Tilden, Jan (1984). Real and simulated occurrences of memory distortion in hypnosis. Journal of Abnormal Psychology, 93 (1), 47-57.

79 undergraduates were prescreened for high or low susceptibility to hypnosis (Harvard Group Scale of Hypnotic Susceptibility--Form A) and tested individually to examine memory distortion in hypnosis. Independent groups of Ss were allocated to a 2 x 2 factorial design in which s grouping (hypnotic or simulating) was crossed with an information condition that either misled or did not mislead Ss about a series of scenes depicting an apparent robbery. It was hypothesized that memory distortion would characterize the performance of hypnotic Ss when memory was examined in unstructured, narrative recall. Results show that real Ss were differentiated appreciably from simulating Ss in the extent to which they incorrectly intruded uncued errors (i.e., errors not arising from misleading information) into their memories but not in their intrusion of cued errors (i.e., errors arising from misleading information). Real Ss remembered correctly more detail of a peripheral kind but also distorted more with respect to the same kind of detail. Results overall negate the view that earlier memory traces are revived in hypnosis, thereby leading to more accurate retrieval, and suggest that hypnotic Ss bring distinctive styles of information processing to bear on their recollections of complex, socially meaningful events

Sheehan, Peter W.; Grigg, Lyn; McCann, Terry (1984). Memory distortion following exposure to false information in hypnosis. Journal of Abnormal Psychology, 93 (3), 259-265.

92 Ss preselected for hypnotic responsiveness on the Harvard Group Scale of Hypnotic Susceptibility--Form A were tested in strict application of the real-simulating model of hypnosis to examine the hypothesis that hypnotic Ss distinctively incorporate false material into their memories when that material is introduced after, rather than before, hypnotic induction. Both real (n = 46) and simulating (n = 46) Ss were either exposed or not exposed to misleading information after receiving induction instruction. Procedures for testing were otherwise identical to those adopted in an earlier study by the 1st author and J. Tilden (see PA, vol 71:14147) in which false information was presented prior to hypnosis. Results confirm the hypothesis and show that hypnotic Ss differed appreciably from simulating Ss by incorporating more misleading material into their memory. Findings highlight the possibility of distinctive processing in hypnosis and implicate lowered critical assessment by hypnotic Ss of information they confidently accepted in the hypnotic context (20 ref)

1983

Nogrady, Heather; McConkey, Kevin M.; Laurence, Jean-Roch; Perry, Campbell (1983). Dissociation, duality, and demand characteristics in hypnosis. Journal of Abnormal Psychology

Examined hypnotic dissociation (as indexed by the "hidden-observer" method), duality in age regression, and the potential impact of situational cues on these phenomena. 12 high- and 9 low-susceptible undergraduates (as determined by the Stanford Hypnotic Susceptibility Scale) were tested in an application of the real-simulating paradigm of hypnosis; 10 high- to medium-susceptible Ss were also employed. Inquiry into Ss' experiences was conducted through the experiential analysis technique, which involves Ss viewing and commenting on a videotape playback of their hypnotic session. Results demonstrate that neither the hidden-observer effect nor duality could be explained solely in terms of the demand characteristics of the test situation. The hidden-observer effect was observed in high-susceptible Ss only; all Ss who displayed the hidden-observer effect also displayed duality in age regression. High-susceptible Ss were distinctive in their reports of multiple levels of awareness during hypnosis. Findings are discussed in terms of the cognitive skills that Ss bring to hypnosis and the degree to which the hypnotic setting encourages the use of dissociative cognitive processes. (43 ref).

Wagstaff, Graham F. (1983). Comment on McConkey's "Challenging hypnotic effects: The impact of conflicting influences on response to hypnotic suggestion". [Comment/Discussion] .

## NOTES

"Probably the most consistent finding to emerge from McConkey's review is that hypnotic subjects tend to respond in accordance with what they feel the hypnotist really wants, regardless of conflicting experimental demands" (p. 13).

1982

Raikov, V. L. (1982). Hypnotic age regression to the neonatal period: Comparisons with role playing. International Journal of Clinical and Experimental Hypnosis, 30 (2), 108-116

The present study explored differences in behavior and reflexes following instructions to age regress to infancy or to portray infancy while high hypnotizable Ss were in an actor's role. Additional role enactment controls were provided by professional actors and low hypnotizable Ss. High hypnotizable Ss while hypnotized reproduced realistic newborn reactions, both behavior and reflexes, which were strikingly like new-born infants during actual age regression, but were unable to produce as many during role enactment. Similarly, the low hypnotizable Ss and professional actors were unconvincing.

Negating the theory of age ablation, results are discussed in the light of reactivation of lost memories through the breaking of amnesic barriers during hypnotic age regression.

Spanos, Nicholas P.; Bridgeman, M.; Stam, H. J.; Gwynn, M. I.; Saad, C. I. (1982-83). When seeing is not believing: The effects of contextual variables on the reports of hypnotic hallucinations. Imagination, Cognition and Personality, 2, 195-209.

When administered a hallucination suggestion most high susceptible hypnotic and task-motivated subjects reported that they "saw" the suggested object. When asked what they meant by "saw," however, almost all indicated that they had imagined the object but did not believe that it had actually been present. On the other hand, simulating subjects maintained that the suggested object had been "really there." Simulators were also more likely than non-simulators to provide "life-like" descriptions of the suggested object (e.g., solid rather than transparent, colored, highly vivid). These findings are consistent with the view that hypnotic hallucinations are context-generated imaginings. They also indicate that unique or unusual psychological processes like "trance logic" need not be posited to account for the descriptions of "hallucinatory" experiences proffered by hypnotic subjects.

#### NOTES

It was observed that hypnotized Ss reported more vivid (and longer sustained) imagery than task motivated Subjects. Hypnotized Ss did not differ from high susceptible simulators on vividness of imagery or how long they experienced the imagery, but did report shorter and less vivid imagery than simulators who were low hypnotizables.

#### 1981

McConkey, Kevin M.; Sheehan, Peter W. (1981). The impact of videotape playback of hypnotic events on posthypnotic amnesia. Journal of Abnormal Psychology, 90 (1), 46-54.

Examined the breakdown of amnesia by showing 48 hypnotic and nonhypnotic undergraduates (Harvard Group Scale of Hypnotic Susceptibility) a videotape of the hypnotic events they had experienced. The extent of the amnesia for these events was defined precisely, and simulating procedures were employed to analyze the cues in the overall test situation. Videotape display of the hypnotic events was presented via the Experiential Analysis Technique and served to optimize conditions for breakdown. Some hypnotic Ss' amnesia could not be broken down even though they were exposed via videotape playback to the events to be recalled and when suggestions for the period of amnesia were quite explicit. Simulators showed breaching of amnesia but attributed their recall to the videotape rather than to the hypnotic session. Hypnotic Ss were distinctive in their inability to recall experiential aspects of their performance even though they could recall behavioral aspects. The data are discussed in relation to the hypothesis that dissociative cognitive mechanisms underlie posthypnotic amnesia. (22 ref).

#### 1980

Bauer, K. E.; McCanne, T. R. (1980). Autonomic and central nervous system responding during hypnosis and simulation of hypnosis. International Journal of Clinical and Experimental Hypnosis, 28 (2), 148-163.

Heart rate, electrodermal responding, respiratory rate, frontalis muscle tension, and occipital electroencephalographic activity were monitored while 6 female Ss were experiencing hypnosis and while 6 other female Ss simulated the experience of hypnosis. Physiological data were collected during 7 sessions on 7 consecutive days. The results indicated no differences in physiological responding

between hypnotized and simulating Ss. Both groups of Ss exhibited significant decreases in heart rate and amount of electroencephalographic alpha activity during their experiences, relative to pre- and posthypnotic or simulating levels. In addition, both groups of Ss exhibited significant increases in electroencephalographic beta activity during their experiences. Both groups of Ss also displayed lowered levels of electrodermal activity, skin conductance, and respiratory rate during their experiences. The changes in these modalities, however, were significant for hypnotized Ss, but were generally not significant for simulating Ss. Both groups of Ss also manifested lowered levels of muscle responding during their experiences, but these changes in responding were not significant for either group of Ss. The results are discussed in terms of several current theories of the nature of the hypnotic experience.

McConkey, Kevin M.; Sheehan, Peter W. (1980). Inconsistency in hypnotic age regression and cue structure as supplied by the hypnotist. International Journal of Clinical and Experimental Hypnosis, 28 (4), 394-408.

Inconsistency in hypnotic age regression was elicited by asking Ss to write a complex sentence, in contexts that varied appreciably in the extent to which they cued Ss that illogical response was appropriate. Hypnotically responsive and unresponsive Ss were assigned to a real or simulating group in application of the real-simulating model of hypnosis and tested in 1 of 3 distinct cue conditions. Cue conditions either followed those of previous studies and communicated that no particular response was appropriate, or communicated that an illogical response was appropriate, or inappropriate. It was hypothesized that cue structure would have a significant impact. Data indicated that cues for logical response had a greater influence on the behavior of Ss than did cues for illogical response when compared with the base response condition; at times, real Ss behaved appreciably more illogically than simulating Ss. Also, detailed analysis of the reports of both groups of Ss indicated distinctive properties of experience that point to the importance of recognizing the complexities of consciousness underlying the experiences of highly susceptible Ss.

## NOTES

Susceptible Subjects are more likely to follow the hypnotist's nonverbalized suggestion when it is counter to their expectation. But not consistently. His article in April 1979 *Journal of Abnormal Psychology* reports 10 studies of this. Such individual differences that exist relate to styles of performance, parameters which have nothing to do with hypnotizability.

1970

Gray, Arne L.; Bowers, Kenneth S.; Fenz, Walter D. (1970). Heart rate in anticipation of and during a negative visual hallucination. International Journal of Clinical and Experimental Hypnosis, 18 (1), 41-51.

Gave 10 stimulating control and 10 hypnotic undergraduates a suggestion to negatively hallucinate. Heart rate responses recorded prior to and including the hallucination period indicated consistent differences between groups. Hypnotic Ss responded with heart rate acceleration in anticipation of the hallucination, while controls responded with heart rate deceleration during the same period. It is suggested that these differences reflect differences in the subjective experiences of hypnotic and simulating Ss. 1969

Graham, Kenneth (1969). Brightness contrast by hypnotic hallucination. International Journal of Clinical and Experimental Hypnosis, 17, 62-73.

Tested the veridicality of a hypnotic hallucination elicited by a buzzer through a conditioning procedure. The stimulus to be hallucinated consisted of 2 gray circles, 3 in. in diameter, mounted on a white card. 11 highly susceptible Ss were able to produce this hallucination upon hearing the buzzer during a series of test trials following the training. Following a 2nd training series, a black and white background was provided for the hallucination and Ss tended to report the hallucinated circles as a brightness contrast. A 2nd group of highly susceptible Ss was not hypnotized, but was asked to respond as if hypnotized. These Ss tended not to report the contrast. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Greenleaf, Eric (1969). Developmental-stage regression through hypnosis. American Journal of Clinical Hypnosis, 12, 20-36.

Twenty subjects serving as their own controls were given four developmental tasks under conditions of hypnotic regression (R) and hypnotic simulation (S). Scored interview data were correlated with performances under R and S. Findings: (a) The Ss' pattern of responses is best conceptualized as a 'mixed' regression rather than 'true' developmental regression. (b) Even when Ss are used as their own controls, the R condition is productive of a greater mean number of childlike responses than is the S condition, disregarding response patterns. (c) The S condition scores provide measures of a set of relatively independent, the R condition of a set of relatively unitary performance variables; this in the same Ss. (d) Factor analysis yielded three orthogonal factors: 'outcome by test performance,' a personality constellation and a factor describing interpersonal actions. The specific situational variable with greatest impact on test performance was the subject's ability to pretend.
