Cerebral responses in anticipation of painful stimulation and while coping with it were investigated in a 'fakir' and 12 male volunteers. Experiment 1 consisted of 3 periods of 40 trials each. During period 1, subjects heard one of two acoustic warning stimuli of 6 sec duration signaling that either an aversive noise or a neutral tone would be presented at S1 offset. During period 2, subjects were asked to use any technique for coping with pain that they had ever found to be successful. During period 3, the neutral S2 was presented simultaneously with a weak electric shock and the aversive noise was presented simultaneously with a strong, painful shock, again under pain coping instructions. EEG activity within the theta band increased in anticipation of aversive events. Theta peak was most prominent in the fakir's EEG. A negative slow potential shift during the S1-S2 interval was generally more pronounced in anticipation of the aversive events than the neutral ones, even though no overt motor response was required. Negativity tended to increase across the three periods, opposite to the usually observed diminution. In Experiment 2, all subjects self-administered 21 strong shock-noise presentations. The fakir again showed more theta power and more pronounced EEG negativity after stimulus delivery compared with control subjects. Contrary to the controls, self-administration of shocks evoked a larger skin conductance response in the fakir than warned external application.

#### NOTES

A published case study by Pelletier (1977) reported EEG theta enhancement during pain control states, which were maintained by EEG feedback of alpha and theta bands. That author concluded that EEG theta was necessary for the control of pain psychologically.

The authors of this article measured slow brain potentials (SBPs) and vertical eye movements (VEMs). Principal components analysis of the EEG wave forms found

three components: theta (4-5.6 c/sec), alpha band (9-10 c/sec) and high frequencies (above 14.4 c/sec) plus harmonics loading in frequencies of 3.2-4.5 c/sec, 7.5-9, and above 15 c/sec.

Alpha "decreased over periods in the parietal record and was virtually absent in the fakir's EEG during period 3" (p. 301). The fakir had a lot of non-sinusoidal, especially square wave, activity.

"Very pronounced negativity was recorded preceding the aversive S2, greater than under neutral stimulus conditions .... This difference was most pronounced at the vertex ... The late negativity increased over periods in control subjects ... especially in anticipation of the aversive S2 ... . This contrasts with the usually observed decrease of SBP components over trials. As is shown in Figure 2, the PCA [principal components analysis] yielded two components for the 2.0 sec S2 interval, a positive deflection, which can be assigned to the P300 complex (here not reported), and a negative deflection, labeled post- imperative negative variation. ... This negative component increased over periods, being more pronounced in response to the aversive stimulation ... with increasing differentiation over period ..." (p. 302-303).

The fakir undertook an elaborate self hypnosis or trance induction to achieve analgesia that he had previously demonstrated in the laboratory (thrusting 4 unsterilized metal spikes into his abdomen, tongue, and neck without bleeding). This included "long- continued fixation on a point above the eye-brows. Blank facial expression, staring eyes, and a very low rate of eye-blinks indicated a trance-like state (periods without eye-blinks more than 30 min)" (p. 299). During the experiment itself, the fakir showed few ocular movements during the second and third periods. He also demonstrated large skin conductance responses, recorded from the second phalanges of the index and middle fingers of the left hand, to the aversive S1.

Experiment 2 was designed to emulate the self-administered aversive stimulation that the fakir routinely undertook, by having the volunteer Ss hold a switch that they pressed twice/minute, giving themselves a mild shock and an aversive noise. (These were the same aversive stimuli as were used in Experiment 1.) There were 21 self-paced button presses.

Three additional measures were taken: 1. Bereitschaftspotential (BP) - the mean negative shift during the 0.3 sec interval prior to the motor response of pressing the switch 2. Postimperative component (PINV) - the mean negative shift 0.9 to 1.9 sec after stimulus onset, i.e. elicited by closing the microswitch 3. Skin conductance response (SCR) - maximum change in skin conductance level during five second interval after the motor response of pressing the switch.

The fakir, but not the control Ss, showed a pronounced precentral PINV on each single trial of Experiment 2. He also showed pronounced SCRs (indicating autonomic arousal), which was even greater than the SCRs of control Ss. His subjective pain rating was 1 in Experiment 1 (compared with 6.4 for controls) but 8 during Experiment 2 (compared with 5.7 for controls), on a scale of 1 to 10 maximum. Thus the fakir's pain increased from Experiment 1 to 2, while for many volunteer Ss it decreased 2 or 3 points. When interviewed, he said that "intention and motor commands prevented the fakir from getting into 'trance' satisfactorily. Consequently, he reported to have experienced the aversive stimuli as more painful

than in experiment 1. Thus it might be that the observed PINV indicates the noncontingency between the demand for coping and the failure to cope or the discrepancy between expected control and presently experienced control" (p. 307). In their Discussion, the authors speculate that control of pain such as can be achieved by the fakir may involve dissociation of higher (possibly thalamic and cortical) and lower (reticular formation) arousal structures. Their observation of slow brain potentials (theta) recorded in anticipation of painful or aversive stimuli is in agreement with earlier published studies. However their observation of increasing negativity in anticipation of aversive stimuli is in contrast to previous research findings, in which diminution of negativity is generally observed. Both the fakir and subjects showed a post-stimulus negative shift in response to the S2; this has been "observed in normal subjects under conditions of change from controllable to uncontrollable aversive stimuli... and/or from obvious response-consequence contingencies to unpredictable control over the S2... PINVs were associated with an unexpected change in contingency or the inability to resolve ambiguity. Since a relationship was found between PINV amplitude and subjective ratings or experienced aversiveness of the painful stimulation, it may be speculated that obvious failure in coping with pain (i.e. more experienced pain) together with the requirement to cope (induced by instructions and experimental setting, giving rise to increased expectancy for control), produced a PINV (and probably feelings of uncontrollability together with a state of reactance and frustration) in the present experiments. In accordance with this point of view, it is of particular interest that only the fakir showed a more pronounced PINV in experiment 2, in which subjects delivered the painful stimuli to themselves. A postexperimental interview revealed that intention and motor commands prevented the fakir from getting into 'trance' satisfactorily" (p. 307).

1981

Blum, Gerald S.; Nash, John; Jansen, Robert D.; Barbour, John S. (1981, June). Posthypnotic attenuation of a visual illusion as reflected in perceptual reports and cortical event-related potentials. Academic Psychology Bulletin, 3, 251-271.

Highly selected and trained hypnotic subjects, capable of ablating portions of visual stimuli from conscious awareness, showed varying degrees of ability to attenuate the Titchener-Ebbinghaus circles illusion post-hypnotically under a negative visual hallucination instruction. The presence or absence of such inhibitory skill, inferred from perceptual reports, was differentially reflected in changes in cortical event-related potentials not typically associated with shifts in selective attention. These findings point to the cognitive operation of a distinctive mechanism of selective inattention.

#### NOTES

Blum et al. postulate an inhibitory mechanism of the central nervous system with stages of amplification and attenuation. They suggest that individual differences in inhibitory skill may be improved with practice even for very skilled Subjects. They studied this type of inhibition using a visual illusion (the Titchener-Ebbinghaus

circles) because the neural locus of such illusions is thought to be more central in the nervous system rather than at the level of the retina.

**Experiment 1.** Three Ss trained in using hypnosis viewed stimuli in waking and posthypnotic negative visual hallucination (NVH) conditions. All three had previously passed a negative hallucination item (not seeing a playing card of three such cards placed on a table). Training included practice sessions applying NVH to the experimental stimuli. S1 reported immediate success; S2 experienced some initial difficulty ("I have a feeling something's there") but then reported success; S3 required a couple of long practice sessions.

The classic Titchener-Ebbinghaus illusion stimuli were used. Stimuli were ten slides with drawings of a standard 17-mm-diameter black circle on the left and a comparison black circle on the right. The black circle on the right was either 14, 15, 16, 17, or 18 mm in diameter, skewed intentionally around 17, to compensate for the proportion of smaller and larger judgments applied to the comparison figure in relation to the standard. One black comparison figure was surrounded by seven 15-mm diameter white circles; the other by seven 10 mm diameter white circles. The key drawings were both black circles of 17 mm. The second set of five drawings, used as a control, contained the same black circles but lacked outer rings of white circles.

The Subject was to state whether the black circle on the right appeared larger, smaller, or the same as the standard black circle on the left. Slides were shown for 4 seconds each, with 6 seconds in between slides.

Alternating blocks of trials were given under baseline (B) condition and a posthypnotically programmed negative hallucination condition (NVH). In the NVH condition, "the rings of white circles surrounding the standard and comparison black inner circles were 'ablated' from consciousness. The observers were amnesic in the waking state for their prior hypnotic instructions and were cued in advance of a block of trials simply by the phrases 'This will be a mixed series' (referring to B, in which the stimuli appeared as they really were, some with outer rings of white circles present and others not), or 'This will be a black only series' (referring to NVH, in which all stimuli appeared to the observer as black circles only, whether the outer rings were physically present or not)" (pp. 254- 255). Sessions were spread out over 8-12 months for each observer, interspersed with a variety of other experiments.

In one session the Experimenters used a selective attention instruction, with Ss given posthypnotic suggestions to regulate their cognitive arousal to a peak of mental alertness and concentration (+AA) and focus on the inner black circles but not to negatively hallucinate the outer white circles.

Although all three Ss showed the illusion effect, they varied in ability to attenuate the illusion when negative visual hallucination suggestions were given. "S1 showed a very greatly reduced frequency of reports in the illusory direction under the NVH condition, a less marked reduction under +AA concentration, and no reduction at all under a waking instruction to ignore the outer circles; S2 revealed a moderate but significant reduction under NVH but not under +AA; S3 gave no evidence of attenuation in either condition" (p. 258). The response times for the two more

successful Ss (1 and 2) with the 17 mm stimuli under NVH conditions were not different when the outer circles were either present or absent.

**Experiment 2.** The next year S1 and S2 returned but S3 was no longer available as a Subject; S4 and S5 were added and trained in hypnosis skills. EEG evoked response potentials (ERPs) were recorded while Ss made size judgments as in Experiment 1. Averaged ERPs for each block of 100 stimulus presentations were obtained for the first 500 milliseconds following stimulus onset. Judges blind to the experimental conditions evaluated the ERP records.

All Subjects experienced the Titchener-Ebbinghaus illusion, but again there were individual differences in ability to attenuate the illusion: S1 was the most successful; S2 gave significantly fewer responses in the larger category under NVH than B conditions; and both S1 and S2 improved attenuation performance over the previous year. S4 fell between S1 and S2 in ability; S5 was unable to attenuate the illusion in the NVH condition.

**Results.** "All three observers whose perceptual reports indicated some attenuation of the visual illusion during the NVH condition also showed a consistent reduction of the P2-N2 amplitude during NVH" (p. 262) at the Occipital sites. Median amplitude reduction was 36%, 40%, and 36% for S1, S2, and S4; only 7% for S5. There were no similar reductions for the other electrode sites, though "enhancement of P2-N2 amplitudes occurred in the lateral prefrontal and frontal areas in the two most successful individuals, S1 and S4" (p. 263). There was also a lag in N2 peak latencies for the three best subjects. The Experimenters noted that the N2 peak occurred 50 msec later in the frontal and prefrontal areas than in the occipital area.

In their Discussion, the authors express the view that it is not likely that faking could have occurred, for several reasons: 1. The Subjects were trained to report honestly, and they often had reported failures to experience hypnotic phenomena suggested during training sessions. 2. The task elicited rapid responses, usually in less than 2 seconds, to 10 different slides in randomized blocks of 100 trials, which would make self monitoring of responses extremely difficult. 3. Subjects exhibited a consistency of responses over experimental sessions that were widely separated in time, making conscious or unconscious deception unlikely. 4. The finding of no difference in latency between 17 mm stimuli with and without outer rings of white circles supports an interpretation of reliable reporting. 5. Differences in ERP data between the B and NVH conditions were obtained only for those Ss who successfully attenuated the illusion.

The authors also state, "In terms of our conceptual model of the mind, inhibitory skill is attributable to the capacity for invoking inhibitory action earlier in the sequence as signals are processed through stages of amplification and attenuation en route to consciousness (Blum & Barbour, 1979). In the NVH condition of the present task, first- stage attenuation ... [Subject 1] ... occurs in time to negate the illusion as well as preventing conscious awareness of the outer white circles, second-stage attenuation takes place too late to disrupt the illusion but still in time to keep the outer circles from consciousness" (p. 265). Note that the unsuccessful Subject 5 had the highest score on the screening hypnotizability tests. The variation among very high hypnotizables casts doubt on the practice of grouping Ss who score between 9 and 12 on the SHSS. "It is perhaps not surprising that many previous

hypnotic studies involving alterations in such subtle phenomena as visual illusions have yielded negative results." p. 266.

N.B. None of the Ss was able to eliminate the illusion under a strong waking instruction to ignore the outer circles while judging the inner black ones. "These different results for AA and NVH instructions pinpoint the contrast between selective attention (+AA) and selective inattention (NVH)" (p. 266).

The ERP changes seen in occipital and frontal areas were in opposite directions. Thus "the data suggest an effect which seems to parallel both investment of attention (increases in late components over frontal cortex) and withdrawal of attention (relative decreases in late components over occipital cortex). This parallel leads us to speculate that our occipital decreases may have been due to active inhibition of information-processing in the occipital regions, and that the late component enhancement over frontal areas may have been due to the mobilization of resources in these areas necessary to accomplish the tonic inhibition of visual input. ... Activity in the frontal cortex apparently 'programs' inhibition on the specific sensory nuclei of the thalamus, in a modality specific and topographical way, accomplishing gating of sensory information to primary sensory cortex" (p. 268).

Chen, Andrew C.; Dworkin, Samuel F.; Bloomquist, Dale S. (1981). Cortical power spectrum analysis of hypnotic pain control in surgery. International Journal of Neuroscience, 13, 127-136.

Cortical power spectrum (CPS) of brain potentials was recorded from the scalp between prefrontal and parietal regions in both right hemisphere (RH) and left hemisphere (LH). A pattern of laterality shift in CPS occurred at different stages during an extensive oral surgery, performed under hypnosis, in a young female patient. Video and audio recordings as well as psychophysiological recordings were obtained through the following 6 stages: Baseline, Hypnosis, Surgery (1 hr, no cortical recording), Immediate Postsurgery Procedure, Hypnotic Re-experience, Hypnotic Rest, and Posthypnotic Baseline. Indications of anxiety and pain scores were reported in writing by the patient through verbal command by the hypnotist. In each stage, 10 min of CPS (10 spectrum/stage, 8 epochs/spectrum, 6 seconds/epoch) were analyzed by a PDP-11 computer. The results of CPS analysis demonstrated significant large total power reduction at different stages. There was significant correlation between both hemispheres at baseline, but dissociation of hemispheric power output occurred during hypnosis stages. LH was more dominant than RH during baseline and presurgery hypnosis, but both were leveled-off immediately following the surgery procedure. However, RH became more dominant during all postsurgery hypnosis stages. Interestingly, this pattern shifted back to the original relationship during the posthypnotic baseline stage. Specific changes of spectral power in theta and alpha of EEG activities in both hemispheres also occurred in conjunction with hypnosis.

NOTES

Subject was a 25 year old woman, described as only medium in hypnotizability. She scored 3 on the 5-point Stanford Hypnotic Clinical Scale, 7 on the 12-point Stanford Hypnotic Susceptibility Scale, and 3 on up-gaze, between 2 and 3 on eye roll, on the Spiegel eye roll test.

The principal hypnotic approach was a suggestion of dissociation, i.e. that the patient "experience herself swimming freely and powerfully, in a deep cold mountain lake, pre-occupied with the intensity of the blue-black color of the water, the shimmering of light from above, and the possibilities of exploration of rock formations, caves, etc. It was suggested that while she was experiencing the exhilaration and strenuous stimulation of the cold water and the vigorous exercise, an 'observing-self' would remain on the shore, watching and ensuring that no harm would come to the person. The suggestion was reinforced that any stimulation experienced was experienced in the body, not in the person" (p. 129).

The patient was trained in inductions and dissociation first in the therapist's office, then with two sessions in the research laboratory (where tooth pulp stimulation pain thresholds were measured), and then two sessions in the hospital dental operatory. The results of the computerized CPS were analyzed by hemispheres. "Large reductions in total power occurred at different stages associated with hypnosis and these reductions in power output of the CPS showed significant left-right differences" (p. 130).

"The total energy output of LH [left hemisphere] continued to diminish as hypnosis continued by as much as 80% of baseline value, while RH [right hemisphere] power output tended to be stabilized from the initial hypnosis recording stage until the awake baseline stage" (p. 130).

"Those stages involving hypnosis were characterized by dominant RH energy output in the alpha spectrum. ...

"Alpha output for the LH decreased an average of 65% between awake baseline levels and postsurgery hypnosis stages, while RH alpha only decreased approximately 50% of resting levels. This resulted in a relative shift of alpha output which was approximately equal in both hemispheres prior to surgery, to a 2:1 shift in favor of RH alpha output as hypnosis progressed. This differential shift in laterality of alpha was reversed when the subject awakened from hypnosis.

"Of interest was the observation that total power reductions and laterality shifts associated with hypnosis were not altered by the profound instrumentation of surgery and postoperative pain, nor were observed laterality shifts affected by hypnotic suggestions aimed at recreating the surgical experience (see Stage 5)" (p. 130).

During the experiment when the investigators used hypnotic suggestion to recreate the surgical experience, LH output continued to diminish while RH output did not change, making the LH-RH contrast highly significant. "This suggests that the RH is active during deep stages of hypnosis and can remain so despite hypnotic suggestions which are presumed to be intensely aversive" (p. 131).

In their Discussion, the authors reinforced the conclusion that overall cortical functioning is reduced during hypnosis, and that the left cerebral hemisphere shows a greater reduction than the right. They discuss the increased theta density in RH and LH during the postsurgery hypnosis stage in terms of reports that theta is

associated with altered states of consciousness (Tebeis et al., 1975; Ulett et al., 1972; Anad, China, & Singh, 1961; Banquet, 1973; Kasamatsu & Hirai, 1966; Wallace, 1970) and with cognitive tasks like mental arithmetic (Dolce et al., 1974).

The authors note that their results are congruent with Hilgard's neodissociation theory of hypnosis, and add that since their suggestions were dissociative in nature rather than of local anesthesia, the EEG may reflect the brain physiology of dissociation.

Finally, they comment on the implications for pain neurophysiology. "The total power changes and shifting patterns in laterality of cortical functioning observed more closely tracked the hypnosis experience than the pain experience; this is, in fact, a very puzzling issue. It appears on the face of it that the EEG measurements recorded are not reflective of EEG-related pain phenomenology despite the strenuous and invasive surgical procedures used. The observations that overall power output continued to decrease during the several hypnosis stages after strenuous surgery and then increased as the patient came out of hypnosis makes reasonable the possibility that hypnosis has some functional brain correlates; we cannot conclude from the present cortical power spectrum analysis that any brain correlates of surgical pain were revealed. We are well aware that EEG recordings were not available during actual surgery itself, because of artifacts resulting from head movements, etc. Nevertheless, it can be fairly claimed that recordings obtained immediately after such oral surgery of one hour duration, could reasonably be expected to be associated with a person in pain. But, both by verbal report and available objective data, any surgically induced traumatic pain was of brief duration under hypnosis" (p. 135).

Karlin, Robert; Goldstein, Leonide; Cohen, Allen (1981, October). A shift to the right: EEG during hypnotic induction. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Portland, OR.

Bilateral electroencephalographic activity was recorded from temporal and occipital sites during a resting baseline and hypnotic induction periods. Results indicated that highly hypnotizable subjects showed a shift to greater right hemisphere activation when the hypnotic induction period was compared to the resting baseline period. This was not the case for the less hypnotizable subjects. This study replicates the recent findings of MacLeod-Morgan (1982).

1980

Barabasz, Arreed F. (1980). EEG alpha, skin conductance and hypnotizability in Antarctica. International Journal of Clinical and Experimental Hypnosis, 63-74.

On the basis of alternative hypotheses in the literature, 9 invited Ss undergoing wintering-over isolation at Scott Base, Antarctica, were tested for EEG alpha and hypnotizability. 8-channels of EEG, bipolar skin conductance (SC) and hypnotizability data were collected at Scott Base prior to and following the wintering-over isolation. Significant increases in alpha density and hypnotizability were found in Ss following isolation. The previously reported relationship between

simple eyes closed alpha density and hypnotizability was not found prior to isolation; however, this correlation approached significance following isolation. The possible influence of psychophysiological arousability on baseline EEG alpha records was considered. Correction of EEG records using SC indices of arousal resulted in a significant correlation between EEG alpha and hypnotizability following isolation. A tendency toward significance was evident in the pre-isolation, SC corrected, correlation. The significant influence of environment on EEG alpha and hypnotizability is discussed as is the use of SC arousal indices to enhance EEG alpha/hypnotizability correlations.

**Karlin, Robert; Morgan, Donald; Goldstein, Leonide (1980). Hypnotic analgesia: A preliminary investigation of quantitated hemispheric EEG and attentional correlates. Journal of Abnormal Psychology, 39 (4), 591-594.**

The effects of hypnotically induced analgesia were studied in six subjects rated as moderately hypnotizable and five subjects rated as highly hypnotizable. Subjective pain reports and electroencephalographic (EEG) activation were recorded during 1-minute periods of cold-pressor stimulation. Both groups of subjects reported decreased pain during hypnosis, but the decrease was greater for the highly hypnotizable group. During hypnotic analgesia, immersion of either the right or the left hand in ice water was correlated with contralateral EEG activation for moderately hypnotizable but not for highly hypnotizable subjects ( $p < .05$ ). Lack of contralateral shift was correlated for the whole sample ( $p < .05$ ) and within groups ( $p = .05$ ) with success on an attentional task related by previous research to hypnotizability as well as with reports of reduced pain ( $p < .05$ ).

#### NOTES

A previous study shows hypnotizability predicts ability to allocate attention selectively (to selectively increase and decrease the salience of stimuli. This study shows hypnotizability also is related to ability to control cortical activation from a pain stimulus, so that pain is not [subjectively] experienced. The test of ability to attend selectively (in waking state) correlated with the [expected contralateral] cortical activation .58. Thus highs have attentional skills not as evident among mediums or lows. Whether these are amplified by hypnosis is another question.

#### SUMMARY

Contingent negative variation behavior was studied in 12 voluntary normal subjects in basal conditions and in the hypnotic trance state under different emotional suggestions. A CNV voltage decrease and the appearance of a PINV were observed in the hypnotic state. Furthermore 12 nonhypnotizable control subjects were tested under the same experimental conditions and no CNV modification was found" (p. 505).

Lehrer, Paul M. (1978). Psychophysiological effects of progressive relaxation in anxiety neurotic patients and of progressive relaxation and alpha feedback in nonpatients. Journal of Consulting and Clinical Psychology, 46 (3), 389-404.

Gave 10 anxiety neurotic patients 4 sessions of individual instruction in progressive relaxation; 10 patients served as waiting list controls. 10 nonpatients were assigned to each of the same conditions, and an additional 10 nonpatients were given 4 sessions of alpha feedback. Nonpatients showed more psychophysiological habituation over sessions than patients in response to hearing 5 very loud tones and to a reaction time task. Patients, however, showed greater physiological response to relaxation than did nonpatients. After relaxation, the autonomic responses of the patients resembled those of the nonpatients. The effects of relaxation were more pronounced in measures of physiological reactivity than in measures of physiological activity. Defensive reflexes yielded to orienting reflexes more readily in nonpatients than in patients. There was also a tendency for progressive relaxation to generalize to autonomic functions more than alpha feedback.

Parwatarikar, Sadashiv D.; Brown, Marjorie S.; Stern, John A.; Ulett, George A.; Sletten, Ivan S. (1978). Acupuncture, hypnosis and experimental pain - I. Study with volunteers. Acupuncture and Electro-Therapeutic Research: International Journal, 3, 161-190.

An experiment was designed to evaluate the protective effects of different agents - acupuncture, hypnosis, Morphine, aspirin, Diazepam and placebo - upon experimentally-induced pain in humans. Twenty normal, healthy volunteers were subjected to cold water and tourniquet- induced pain and the protective effects of 35 minutes of hypnotic suggestion, electro- stimulation of both acupuncture points and non-acupuncture points, 10 mg/kg of Morphine, 5 grains of aspirin, 10 mg of Diazepam and a mild sugar placebo were evaluated. Data was collected on subjective evaluation of pain, EKG, EEG, respiration, skin temperature, peripheral vascular activity and EMG. A special study was also done to evaluate the effects of all the above agents on the somatosensory evoked potentials and EEG. The data were further analyzed on the basis of hypnotic susceptibility of the volunteers. The results indicated: 1) Hypnosis, acupuncture at specific sites with electrical stimulation and Morphine Sulphate had about the same reduction in experimental pain. 2) Hypnosis produced different effects from those resulting from acupuncture stimulation on EEG. 3) Acupuncture stimulation in specific loci resulted in a latency increase in the early secondary response on somatosensory evoked potential. 4) Cold water pain was remarkably reduced after true acupuncture point stimulation. 5) Tourniquet (ischemic) pain was reduced by both hypnosis and true acupuncture site stimulation. 6) Skin temperature was significantly reduced on the side of acupuncture points (true) stimulation.

Crosson, B.; Meinz, R.; Laur, E.; Williams, D.; Andreychuk, T. (1977). EEG alpha training, hypnotic susceptibility, and baseline techniques. International Journal of Clinical and Experimental Hypnosis, 25, 348-360.

3 alpha feedback sessions of 40 minutes were administered after a similar baseline period without feedback to 12 Ss high in hypnotic susceptibility and 12 Ss low in hypnotic susceptibility. Hypnotic susceptibility was not a significant dimension in alpha feedback training and previously reported relationship between alpha density and hypnotic susceptibility were not generally found. Evidence did support the efficacy of the current baseline procedure over others more commonly used. The possibility under certain conditions of there being a relationship between hypnotic susceptibility and alpha density and theoretical considerations in recording baseline are discussed.

Fisher, R. (1977). On flashback and hypnotic recall. International Journal of Clinical and Experimental Hypnosis, 217-235.

This essay deals with both the intra-individual and inter-individual varieties of arousal state-bound experiences. The former are labelled as "flashbacks" while the latter embrace the great fantasies and repetitive schemes, the ever re-written plots and images of literature, art, and religion.

Flashbacks are both arousal-state and stage (i.e., set and setting) bound experiences. Flashback and hypnotic recall differ only in the ways by which they are induced. Induction methods should be distinguished from induced states on the hyperaroused perception-hallucination and hypoaroused perception-meditation continuum.

Flashbackers may be characterized by their (a) variability on perceptual-behavioral tasks; (b) tendency to minimize (or reduce) sensory input; (c) high resting heart rates; (d) hypnotizability; and, hence (e) preferential right-cerebral-hemispheric cognition; and (f) a display of EEG-alpha dominance in the resting, waking state.

Pelletier, K. R.; Peper, E. (1977). Developing a biofeedback model: Alpha EEG feedback as a means for pain control. International Journal of Clinical and Experimental Hypnosis, 25, 361-371.

3 adept meditators voluntarily inserted steel needles into their bodies while physiological measures (EEG, EMG, GSR, EKG, and respiration) were recorded. Although each adept used a different passive attention technique, none reported pain. During the insertion, 2 of the 3 Ss increased their alpha EEG activity. The role of alpha EEG and its relationship to pain control is discussed.

#### NOTES

The three adepts studied were: (1) RCT, a 34 yr old Ecuadorian who had "demonstrated control over pain by placing bicycle spokes through his body, being suspended from hooks inserted under his shoulder blades, and walking through fire -- all without reported pain or observed damage to his skin;" (2) JSL, a 31 yr old Korean karate expert, who "suspended a 25-pound bucket of water from a

sharpened spoke placed through a fold of skin on his forearm;" and (3) JS, a 50-yr old Dutch meditator who had "demonstrated pain and bleeding control" (pp. 363-365). "RCT, JSL, and JS each remarked that pain is principally fear of and attention to pain, and they maintained that anyone can learn to control pain through relaxation and passive attention" (p. 367). Both JS and RCT had increased alpha EEG activity during piercing, whereas JSL showed no increase. The authors suggest that "the karate expert practiced a very focused meditation, during which he mentally saw and felt the ki energy as a point, while RCT and JS employed passive attention and did not attend to the body stimuli. Thus, it is possible for physiological measurements to reflect strategies used in dissociation of pain perception, and that the quality of pain perception is altered if S is at either extreme of focused or unfocused conscious attention" (p. 368). "We hypothesize that, for nonadepts, alpha EEG training without alpha blocking to stimuli could become a distraction technique whereby S again could learn self-control and competence as he becomes more successful in controlling his EEG" (p. 369).

1976

Cooper, Leslie M.; London, Perry (1976). Children's hypnotic susceptibility, personality, and EEG patterns. International Journal of Clinical and Experimental Hypnosis, 24, 140-148.

19 boys and 16 girls, aged 7 to 16, were given the EEG and then the Children's Hypnotic Susceptibility Scale, while a parent watched. About 1 week later, after some separate tests and interviews, each child was given a puzzle to solve in the parent's presence, while Es recorded offers and requests for help. Hypnotic susceptibility was positively correlated with the alpha duration with eyes open, but not with eyes closed. Both susceptibility and alpha duration tended to be negatively correlated with age. Highly susceptible children tended to wait longer than low susceptibles before asking parents for help with the puzzle, and their parents tended to be more strict, anxious, and impatient than did the parents of low susceptible children.

London, Perry (1976). Kidding around with hypnosis. International Journal of Clinical and Experimental Hypnosis, 24 (2), 105-121.

This paper reviews a long term research project relating hypnotic susceptibility to performance and personality variables. Several experiments indicated that people who are low in hypnotic susceptibility try harder than high susceptibles for maximum performances on strength, endurance, psychomotor coordination, and cognitive tests, though high susceptibles are generally more pleased with their own performances. Other experiments indicated that people of high hypnotic susceptibility have slower brain-wave patterns under relaxed, nonhypnotic conditions, than do low susceptibles. These findings, together with a third set of findings on the developmental character of hypnotic susceptibility, led to the theory that hypnotic susceptibility and brain-wave patterns are both inversely correlated with achievement motivation and with its developmental roots in childhood independence training. An elaborate research program was initiated to investigate the hypothesized relationships.

Melzack, Ronald; Perry, Campbell (1975). Self-regulation of pain: The use of alpha-feedback and hypnotic training for the control of chronic pain. Experimental Neurology, 46, 452-469.

Patients suffering chronic pain of pathological origin received alpha- feedback training methods in association with prior hypnotic training. Changes in the intensity and quality of pain were measured with the McGill Pain Questionnaire. The combined procedures produced a substantial decrease in pain (by 33% or greater) in 58% of the patients during the training sessions. Both the sensory and affective dimensions of the pain were diminished. The EEG records indicated that the majority of patients learned to increase their alpha output during the training sessions. In contrast, patients who received the alpha training alone reported no decreases in pain even though they showed increases in alpha output. Patients who received hypnotic training alone also produced increased EEG alpha during the training sessions and showed substantial (though not statistically significant) decreases in pain. The results demonstrate that chronic, pathological pain can be reduced in a significant number of patients by means of a combination of alpha-feedback training, hypnotic training, and placebo effects. It is concluded, however, that the contribution of the alpha training procedure to pain relief is not due to increased EEG alpha as such but, rather, to the distraction of attention, suggestion, relaxation, and sense of control over pain which are an integral part of the procedure.

**NOTES**

The study employed 24 patients with variety of pains, divided into 3 groups randomly:

hypnosis alpha/biofeedback combined procedures - the only group which decreased group mean of pain significantly.

Hypnosis - 50% of patients showed decrease in pain Combined Treatment - 50% " " " " " Alpha/biofeedback - None " " " " " "

All patients demonstrated higher alpha levels; the authors inferred it was due to relaxation, distraction, a sense of control over pain, or direct suggestion itself.

1975

Saletu, B.; Saletu, M.; Brown, M.; Stern, J.; Sletten, I.; Ulett, G. (1975). Hypno-analgesia and acupuncture analgesia: A neurophysiological reality?. Neuropsychobiology, 1, 218-242.

The effects of hypnosis, acupuncture and analgesic drugs on the subjective experience of pain and on objective neurophysiological parameters were investigated. Pain was produced by brief electric stimuli on the wrist. Pain challengers were: hypnosis (induced by two different video tapes), acupuncture (at specific and unspecific loci, with and without electrical stimulation of the needles),

morphine and ketamine. Evaluation of clinical parameters included the subjective experience of pain intensity, blood pressure, pulse, temperature, psychosomatic symptoms and side effects. Neurophysiological parameters consisted of the quantitatively analyzed EEG and somatosensory evoked potential (SEP). Pain was significantly reduced by hypnosis, morphine and ketamine, but not during the control session. Of the four acupuncture techniques, only electro-acupuncture at specific loci significantly decreased pain. The EEG changes during hypnosis were dependent on the wording of the suggestion and were characterized by an increase of slow and a decrease of fast waves. Acupuncture induced just the opposite changes, which were most significant when needles were inserted at traditional specific sites and stimulated electrically. The evoked potential findings suggested that ketamine attenuates pain in the thalamo-cortical pathways, while hypnosis, acupuncture and morphine induce analgesia at the later CNS stage of stimulus processing. Finally some clinical-neurophysiological correlations were explored.

London, Perry; Cooper, Leslie M.; Engstrom, D. R. (1974). Increasing hypnotic susceptibility by brain wave feedback. Journal of Abnormal Psychology, 83 (5), 554-560.

Presents a reanalysis of earlier studies by D. R. Engstrom et al (1970) as well as additional findings which show that successful training to increase alpha rhythm duration raises people's hypnotic susceptibility. Ss in the previous studies were 30 volunteers who had low to moderate hypnotic susceptibility and low alpha production. It was found, subsequent to publication, that some Ss had had previous exposure to alpha training. When they were eliminated in reanalysis, the previous findings were still confirmed; alpha training was more effective for experimental than for control Ss, and hypnotic susceptibility accordingly increased more among experimentals than among controls. In addition, base-rate alpha production in each training session was correlated with feedback alpha output among experimental Ss but not among controls. 1972

Kratochvil, Stanislav; Macdonald, Hugh (1972). Sleep in hypnosis: A pilot EEG study. American Journal of Clinical Hypnosis, 15 (1), 29-37.

Six highly susceptible Ss were hypnotized and allowed to sleep in the laboratory during the night. Hypnotic rapport was tested after each of two awakenings, and simple suggestions were also administered in different stages of sleep. After awakening, hypnotic rapport was still present. In sleep, the Ss did not react to suggestions in stages 3 and 4. They sometimes reacted in stage 2, but usually woke up either during listening or during responding to the suggestion. In stage REM the Ss usually responded well to the suggestions; they sometimes woke up and sometimes not. The results are taken as a proof that hypnosis can continue after periods of sleep which occur during hypnosis. The question whether hypnosis and sleep can occur simultaneously or only alternately is discussed.

ATTEMPTED TO CONFIRM THE FINDINGS OF A. G. HAMMER AND W. J. ARKINS (SEE 39:1) OF SIGNIFICANTLY GREATER IMPROVEMENT IN HYPNOTIC PERFORMANCE AS A RESULT OF 11-CPS INTERMITTENT PHOTIC STIMULATION THAN WITH FREQUENCIES OUTSIDE THE RANGE OF EEG ALPHA ACTIVITY. USING THE BRAIN WAVE SYNCHRONIZER, 3 GROUPS OF SS WERE GIVEN STIMULATION AT 5, 11, AND 30 CPS. TESTS OF HYPNOTIC PERFORMANCE WERE MADE DURING AND IMMEDIATELY AFTER STIMULATION, AND A WEEK OR MORE LATER. NO EVIDENCE OF FREQUENCY-SPECIFIC EFFECT WAS OBTAINED, AND THE ORIGINAL FINDING WAS NOT CONFIRMED. (SPANISH + GERMAN SUMMARIES) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1967

Dittborn, J. M.; O'Connell, D. N. (1967). Behavioral sleep, physiological sleep and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 15, 181-188.

A SLEEP-INDUCTION PROCEDURE REQUIRING MANUAL RESPONSE TO A REPETITIVE AUDITORY SIGNAL WAS ADMINISTERED TO 52 SS WHO HAD CLEAR ALPHA ACTIVITY IN THEIR WAKING EEG AND WHOSE HYPNOTIZABILITY WAS KNOWN. THE OCCURRENCE OF SLEEP WAS DEFINED BY PHYSIOLOGICAL, BEHAVIORAL, AND SUBJECTIVE CRITERIA. NEITHER THE TENDENCY TO DEVELOP EEG SLEEP NOR THE ABILITY OF SOME SS TO RESPOND WHILE IN EEG SLEEP WAS RELATED TO HYPNOTIZABILITY. HYPNOTIZABILITY WAS RELATED TO A TYPE OF DISSOCIATION BETWEEN EEG SLEEP AND BOTH BEHAVIORAL AND SUBJECTIVE SLEEP SHOWN BY 5 SS, ALL HIGHLY HYPNOTIZABLE. 1960

Diamant, J.; Dufek, M.; Hoskovec, J.; Kristof, M.; Pekarek, V.; Roth, B.; Velek, M. (1960). An electroencephalographic study of the waking state and hypnosis with particular reference to subclinical manifestations of sleep activity. International Journal of Clinical and Experimental Hypnosis, 8, 199-212.

(Author's Conclusions) EEG records have been investigated in 10 patients in a waking state and under hypnosis. It was shown that no differences existed between these two states in terms of EEG. EEG signs of decreased wakefulness can be demonstrated in some of the patients, but these were also present without hypnosis. This latter effect appears to be subclinical sleep activity (Roth), frequently seen particularly in neurosis. Reactibility to external stimuli under hypnosis was also, in most cases, equivalent to reactions in the waking state. The authors incline to the view that EEG data does not support the concept that the nature of hypnosis and sleep is qualitatively the same.

Roberts, Donald R. (1960). An electrophysiological theory of hypnosis. International Journal of Clinical and Experimental Hypnosis, 8, 43-55.

It is theorized that general hypnosis is brought about by an electrical blockage between the brain stem reticular formation and the specific-sensory, parasensory, and coordinate neuronal channels; the selective activity of brain rhythms of the delta frequency is proposed as a possible mechanism of inhibition. Kroger, William S.; Schneider, Sidney A. (1959). An electronic aid for hypnotic induction: A preliminary report. International Journal of Clinical and Experimental Hypnosis, 7, 93-98.

#### NOTES

The BWS or brain wave synchronizer is "an instrument specifically designed to induce various levels of hypnosis by subliminal and photic stimulation of the brain waves" (p. 93). It was developed after noticing that radar operators on ships sometimes fell into deep hypnotic states while watching signals on a radar screen. It has been used with 2500 subjects, 200 of whom were receiving pre-natal training for childbirth under hypnosis.

"For the first five minutes there is a gradual increase in the number of subjects who enter deep hypnosis. At this level, a figure of 50% reach the deep state" (p. 95).

The instructions given were, "Concentrate on the center of the instrument. When your eyes become tired and heavy, as they will, just let them close and feel yourself going deeper and deeper into a relaxed state." It is acknowledged that this procedure worked when Ss expected to experience hypnosis; the rate of deep hypnosis increased as the expectancy of hypnosis increased. "Deep hypnosis in individual inductions reached 80% under the following conditions:

A. Synchronizer on 5 minutes

B. Expectation Level of 50 [on a scale in which 100 represented having seen demonstrations of conventional hypnosis and an explanation of what the instrument would do]" (p. 97).

## **EFFORT/ENDURANCE**

**1999**

**Kirsch, Irving; Burgess, Cheryl A.; Braffman, Wayne (1999). Attentional resources in hypnotic responding. International Journal of Clinical and Experimental Hypnosis, 47 (3), 175-191.**

Theories of hypnotic responding differ regarding attentional processes. Predictions derived from neodissociation, dissociation control, response set, and ironic process theory were tested by administering suggestions with and without cognitive load to high suggestible participants and low suggestible simulators. Cognitive load interfered with responses to ideomotor and cognitive suggestions but not with responses to challenge suggestions. The effect of cognitive load on suggested amnesia depended on the assessment of that response. Although cognitive load decreased recall on the amnesia trial, it did so even more on recall trials before the amnesia suggestion was given and after it was canceled. These data indicate that attentional effort is required for both recall and memory suppression. Under conditions of low cognitive load, simulators displayed less recall than did nonsimulating participants during suggested amnesia, and they reported smaller subjective responses to ideomotor and challenge suggestions.

**1998**

**King, Brenda J.; Council, James R. (1998). Intentionality during hypnosis: An ironic process analysis. International Journal of Clinical and Experimental Hypnosis, 46 (3), 295-313.**

Two studies were completed to test whether responding to hypnotic suggestions requires intentional effort. Hypnotic suggestions for amnesia were used as an analog of thought suppression, and Wegner's model of ironic processing was applied to hypnotic responding. In the first study, participants were required to maintain suggested amnesia while performing a cancellation task with and without a cognitive load. The second study required suppression of thoughts of a favorite car, once with "blank-mind" instructions and then with a suggestion for amnesia. The results of these studies indicate that dissociated control theory provides the best explanation for hypnotic responding in one subset of highly hypnotizable participants, whereas more intentional responding provides the best explanation for others.

## **NOTES**

"In a well-known study, Wegner (1994) asked participants not to think of a white bear. This led participants to think of white bears, whereas there had been no such

thoughts prior to the request. Wegner suggested that such ironic effects stem from two complementary processes involved in the self-control of mental states. The first is an effortful operating process that seeks to maintain the desired state of mind (free of white bears). The second is an automatic and effortless monitoring process that searches for evidence of failure of intentional control (points out any white bear thoughts), so that corrective action can be taken. According to Wegner, a cognitive load will increase ironic effects, because reduced cognitive capacity may allow the monitoring process to supplant the operating process and make the person more sensitive to mental processes that are opposite of those that are intended" (p. 297).

1992

Mittleman, K. D.; Doubt, T. J.; Gravitz, Melvin A. (1992). Influence of self-induced hypnosis on thermal responses during immersion in 25 degrees C water. Aviation, Space & Environmental Medicine, 63, 689-695.

The efficacy of self-induced posthypnotic suggestion to improve thermogenic responses to head-out immersion in 25 degrees C water was evaluated in 12 males. An online computerized system permitted the change in body heat storage to be used as the independent variable and immersion time as the dependent variable. Two one- hour hypnotic training sessions were used. There were no differences in rates of heat production, heat loss, mean skin temperature, or rectal temperature between control and hypnotic immersions. Individual hypnotic susceptibility scores did not correlation with changes in thermal status. Ratings of perceived exertion during exercise were similar for both immersions, but perceived sensation of cold was lower during the second rest period of the hypnotic immersion. Three subjects used images of warm environments during their hypnotic immersion and lost heat at a faster rate than during control immersions. These results indicate that brief hypnotic training did not enhance the thermogenic response to cool water immersion.

1986

Pereira, Robert Peter (1986, July). The role of organismic involvement in hypnotic emotional behavior (Dissertation, Wayne State University). Dissertation Abstracts International, 47 (1), 385-B. (Order No. DA8605027

"Two hundred college undergraduates were pretested via the Harvard Group Scale of Hypnotic Susceptibility: Form A. Fifty subjects scoring in the range 7-12 were designated as Reals, while 25 subjects scoring in the range 0-4 were designated as Simulators. Reals and Simulators were given differential instructions before the administration of a second hypnotic induction procedure, which was accompanied by a task in which subjects were asked to relive each of three emotional experiences, i.e., fear, anger, and happiness. Reals were given instructions encouraging cooperation, while Simulators were instructed to try to convince a group of experienced hypnotists that they were deeply hypnotized, when, in fact, they would not be. "Physiological, overt-behavioral, and cognitive measures taken either during or following the relived-emotions task served as indices of Sarbin's organismic

involvement construct. A post-experimental measure of the realness of subjects' relived emotional experience was regressed on these organismic indices in order to test Sarbin's assumption of a positive linear relationship between organismic involvement and belief-in imaginings, using data from the Real group only. Results indicated that, across all three emotions, the linear composite of organismic indices shared statistically significant amounts of variance with the criterion of experiential realness. Obtained amounts of shared variance ranged from 22% (during anger) to 55% (during happiness). These findings were interpreted as offering clear and robust support for Sarbin's theory of hypnosis. Suggestions for further research were offered. "The question of Real-Simulator differences was explored through several multivariate analyses of variance and covariance, using the organismic indices as dependent variables. These analyses were performed on the original sample of Reals and Simulators, and on two subsamples of Reals/Highs and Simulators/Lows which were created through the use of pre- and/or post-experimental exclusion criteria. Reals/Highs showed statistically higher levels of effort than did Simulators/Lows during all three emotions, as well as higher levels of skin conductance and finger temperature during anger. These findings were interpreted as being of theoretical and practical significance. Multiple replications of the physiological findings were recommended in order to assess the extent to which the skin conductance and finger temperature variables might be used in practical, i.e., forensic contexts" (p. 385-B).

1980

Pajntar, Marjan; Jeglic, Anton; Stefancic, Martin; Vodovnik, Lojze (1980). Improvements of motor response by means of hypnosis in patients with peripheral nerve lesions. International Journal of Clinical and Experimental Hypnosis, 28 (1), 16-26.

In order to accelerate rehabilitation of patients with peripheral nerve lesions, hypnosis was employed to encourage them voluntarily to move those muscles with weak re-innervation and to achieve the best possible activity of the affected muscle groups. By measuring muscle force and endurance and by observing the electrical activity of the affected muscles, it was found that the activity of the affected muscles was much better while patients were in hypnosis than when they were in the waking state. The patients were able to contract even paretic muscles having only weak re-innervation with such strength, that clinically perceptible contraction of the muscles and movement of paretic extremities occurred. Such early and improved activation is very important for prevention of much permanent damage.

55 male Ss were assigned to 5 groups: control, hypnosis alone, motivation alone, low susceptible hypnosis with motivation, or high susceptible hypnosis with motivation. Ss performed 2 runs on a treadmill to their maximum capacity, as measured by oxygen consumption, blood lactate concentration, and respiratory quotient. Groups involving hypnosis performed in the posthypnotic state. A significant increase in endurance performance was revealed in the motivation alone Ss and in high susceptible hypnosis Ss who were given motivational suggestions. Maximum

ventilation was significantly increased in high susceptible hypnosis Ss when compared with control Ss and significant increases in blood lactate concentrations were revealed when the high susceptible hypnosis Ss were compared with low susceptible hypnosis and motivation alone Ss. The reasons for the changes in metabolic variables are discussed. Findings demonstrated that in achieving greater endurance performance, motivational suggestions alone are as effective as identical suggestions given to high susceptible Ss.

1964

Levitt, Eugene E.; Brady, J. P. (1964). Muscular endurance under hypnosis and in the motivated waking state. International Journal of Clinical and Experimental Hypnosis, 12, 21-27.

8 female Ss scoring at least 10 on the Stanford Hypnotic Susceptibility Scale were required to hold a weight in the outstretched hand in 3 states: (a) under hypnosis, (b) under hypnosis with the upper arm and shoulder anesthetized hypnotically, and (c) in the waking state with motivation provided by a verbal exhortation and monetary payment. Order of performance in the 3 states was varied. No significant differences among states were found. The interaction between states and orders was significant, but it appears more likely to be the result of intersubject variability rather than of position or fatigue effects. Ss' expectancies and estimates of performance time, obtained postexperimentally, did not appear to be related to performance itself. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

## EGO/EGO-STRENGTHENING

2002

Ginandes, Carol (2002). Extended, strategic therapy for recalcitrant mind/body healing: An integrative model.. American Journal of Clinical Hypnosis, 45 (2), 91-102.

The development of the power therapies, behavioral medicine, and short term interventions have reported such success even with trauma cases that it is relevant to question the justification for lengthy psychotherapy. Yet some patients with complex mind/body conditions impervious to medical treatment/hypnosis may require extended, multi-modal, integrative therapy. This paper details a single complex case of paruresis as a prototype for illustrating a holographic treatment model for recalcitrant conditions: Component features of the proposed model presented include: 1) the sequential utilization of hypnotherapeutic and analytic approaches; 2) uncovering work providing access to the somatic ego state associated with the illness condition; 3) the extended treatment time frame required for deep psycho-physiological change; and 4) the stages of counter-transference expectably evoked by such patients (e.g. urgency, exuberant optimism, frustration, discouragement), and the transformation of such reactions to achieve maximum therapeutic efficacy.

## NOTES

Paruresis is a social phobia involving urinary retention and "thought to affect some 17 million or 7% of the American population" (p. 92). Also known as "bashful bladder."

McNeal, Shirley A. (2002). A character in search of character: Narcissistic personality disorder and ego state therapy. American Journal of Clinical Hypnosis, 45 (3), 233-243.

The individual diagnosed with narcissistic personality disorder presents with grandiosity, extreme self-involvement, and lack of interest in and empathy for others. This paper reviews current theories concerning the development and treatment of this disorder, and presents a case study in which ego state therapy was successfully utilized and integrated into hypnotically facilitated psychotherapy with a 48-year-old man diagnosed with narcissistic personality disorder. The ego state model of treatment is described and demonstrated with case material. Initially ego states that reveal the grandiosity are accessed. As therapy progresses, ego states that hold the underlying feelings of emptiness, rage, and depression are able to emerge. With further treatment, transformation and maturation of the ego states occur, reflecting the changes in internal structure and dynamics as well as improvement in external interpersonal relationships. Issues concerning ego state therapy as utilized with personality disorders are discussed and contrasted with more traditional methods of treatment. 1999

Daniel, Sheryll (1999). The healthy patient: Empowering women in their encounters with the health care system. American Journal of Clinical Hypnosis, 42 (2), 108-114.

Many women's expectancies when they assume the role of patient include the experiences of regression, helplessness, passivity and fear. This paper describes techniques for interrupting this negative set and for facilitating the development of a self-efficacious state in which the woman experiences herself as an active and informed participant in her encounters with medical personnel.

1995

Ganaway, George K. (1995). Hypnosis, childhood trauma, and dissociative identity disorder: Toward an integrative theory. International Journal of Clinical and Experimental Hypnosis, 43 (2), 127-144.

It is contended that prevailing exogenous trauma theory provides in most cases neither a sufficient nor a necessary explanation for the current large number of diagnosed cases of dissociative identity disorder (multiple personality disorder) and related dissociative syndromes purported to have arisen as a response to severe early childhood physical and sexual abuse. Relevant aspects of instinctual drive theory, ego psychology, object relations theory, self psychology, social psychological

theory, sociocultural influences, and experimental hypnosis findings are drawn on to demonstrate the importance of adopting a more integrative theoretical perspective in the diagnosis and treatment of severe dissociative syndromes. Further cooperative experimental and clinical research on the etiology, prevalence, and clinical manifestations of the group of dissociative disorders is strongly encouraged.

Guyer, Charles G. II; Van Patten, Isaac T. (1995). The treatment of incest offenders -- a hypnotic approach: A brief communication. International Journal of Clinical and Experimental Hypnosis, 43 (3), 266-273.

Incest has become more prominent in public awareness over the past 15 years. The major focus of this interest has been on the incest survivor. The incest offender has received less attention. A hypnotic approach to treating incest offenders is outlined that involves a seven-stage approach. A case example is presented and future research directions suggested.

1993

Watkins, Helen H. (1993). Ego-State therapy: An overview. American Journal of Clinical Hypnosis, 35, 232-240.

Ego-state therapy is a psychodynamic approach in which techniques of group and family therapy are employed to resolve conflicts between the various "ego states" that constitute a "family of self" within a single individual. Although covert ego states do not normally become overt except in true multiple personality, they are hypnotically activated and made accessible for contact and communication with the therapist. Any of the behavioral, cognitive, analytic, or humanistic techniques may then be employed in a kind of internal diplomacy. Some 20 years experience with this approach has demonstrated that complex psychodynamic problems can often be resolved in a relatively short time compared to more traditional analytic therapies.

1992

Frederick, Claire C.; Phillips, Maggie (1992). The use of hypnotic age progressions as interventions with acute psychosomatic conditions. American Journal of Clinical Hypnosis, 35 (2), 89-98.

Age progression as a hypnotherapeutic technique is mentioned infrequently in the literature when compared with its counterpart, age regression. In this paper we explore the use of progressions, or 'views of the future,' as prognostic indicators of therapeutic progress and as valuable tools for ego strengthening and for the integration of clinical material. Age progressions vary in the types of suggestions given and can be used to promote growth on multiple levels, facilitating treatment goals and deepening the working-through process. We present six cases in which we used different types of age progressions, and we discuss the significance of the progressions used in each case, within the context of relevant clinical material. We conclude from our observations that the use of hypnotic progressions can be a

sustaining, valuable aspect of hypnotherapy, particularly in providing an index of the current direction and progression of the therapy process itself. - Journal abstract.

**Goodman, Linda; Holroyd, Jean (1992). Ego receptivity and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 40 (2), 63-67.**

Ego receptivity has been described as important for the psychotherapy process and as a characteristic of hypnosis (Deikman, 1974; Dosamantes-Alperson, 1979; Fromm, 1979). Receptivity also has been associated with a measure of absorption (Tellegen, 1981). In the first pilot study with 6 dance/movement therapy students, higher observer ratings of receptivity were associated with greater hypnotizability ( $r = .79$ ,  $df = 4$ ,  $p < .05$ , 2-tailed test). In the second pilot study, the correlation was replicated ( $r = .51$ ,  $df = 12$ ,  $p = .06$ , 2-tailed test) with 14 dance/movement therapy students. In the second pilot study, receptivity did not correlate with absorption. Receptivity and absorption, however, accounted for 54% of hypnotizability population variance in a step-wise multiple regression. Receptivity accounted for a unique part of the variance after the effects of absorption were removed. It was concluded that receptivity should be explored as a potential predictor of hypnotizability, and that a reliable scaled measure of receptivity should be developed.

#### NOTES

Receptivity was rated by dance instructor on the following scale. "TABLE 1 Criteria for Ranking Ss on Receptivity A. Individuals were rated high if they could consistently do the following most of the time:

1. If they moved with emotional involvement.
  2. If they could readily verbally describe their movement experience in terms of sensations or feelings.
  3. If they were able to image while moving. That is, their movement experience could be transformed into representational visual images.
  4. In their describing their movement experience verbally, if they readily alluded to the images which were generated from their body movement.
  5. If they could relate their movement experiences to other contexts outside of the therapeutic one.
  6. If they could develop a working alliance with the therapist (based on students' capacity to risk experiencing self with increased emotional depth).
- B. Individuals were rated low, if they were not able to do the above most of the time. C. Individuals were rated in the mid-range if they were able to do the above some of the time" (p. 65).

#### 1991

**Stanton, Harry E. (1991). The reduction in secretarial stress. Contemporary Hypnosis, 8, 45-50.**

30 secretaries from a large business firm were matched on their stress thermometer scores and one member of each pair was allocated at random to either an experimental group or a control group which discussed stress management procedures. The experimental group had two treatment sessions in which they learnt a technique of induction, deepening and ego-enhancement which included (1) physical relaxation; (2) mental calmness; (3) disposal of unwanted mental and physical 'rubbish'; (4) removal of a negative barrier; and (5) enjoyment of a special place. The stress thermometer was administered on two further occasions, one immediately after completion of the second training session and one as a follow-up 2 months later. In addition, on these two occasions, subjects completed anecdotal reports, recording their impressions of the experiment. After completion of this first stage of the study, control group secretaries experienced the same two treatment sessions as had the experimental group. Results indicated that stress level was significantly lower both immediately after treatment and at the two-month follow-up.

1989

Peebles, M. J. (1989). Through a glass darkly: The psychoanalytic use of hypnosis with post-traumatic stress disorder. International Journal of Clinical and Experimental Hypnosis, 37, 192-206.

A severe case of post-traumatic stress disorder stemming from consciousness (with auditory and pain perception) during surgery was treated with 8 sessions of hypnosis. Abreaction and revivification used alone initially retraumatized the patient, and her symptoms worsened. Ego-mastery techniques were then added; emphasis was placed on the role of the therapist as a new object presence to be internalized in restructuring the traumatic memory; memory consolidation and working-through techniques were instituted. The patient's symptoms abated and her condition remitted. The similarities between hypnotic and analytic work are highlighted. In addition, the case material provides a clinical example of the existence and potential traumatic effects of conscious awareness during surgery.

1988

Hines, Larry; Handler, Leonard (1988, November). Hypnotizability and ego functions. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

#### NOTES

Researchers employed Bellak's Ego Functions Test (based on the clinical interview). Ss were 47 students and 1 non-student, some of whom had previously experienced hypnosis. They were all volunteers. Studied 12 ego functions. Used plateau hypnotizability which was defined as no improvement in Stanford Hypnotic Susceptibility Scale Form C after two hypnotic inductions; if they did not reach a plateau by Session 4, the highest score was used. Stanford Hypnotic Susceptibility Scale scores ranged 4-12. High 10-12, Medium 6-9, Low 4-5.  $\bar{x}=9.04$ ,  $SD=2.21$ .

On the Bellak Test, High 12-13, Medium 10-11 (average functioning.), Low 1-9. Range 5-13; widest range was in Adaptive Regression in Service of Ego Highest Mean = reality testing Lowest Mean = ARISE Majority fell into the medium range on all 12 ego functions measured.

A significant difference was found between High and Low hypnotizables on the following ego functions. [N.B. There may be transcription errors in the figures that follow.] 1. ARISE  $p < .02$   $r = .31$  Highs have greater ability to experience pleasure in regression. 2. Stimulus Barrier  $p < .003$  Highs are more flexible in their ability to separate from stimuli in their environment, Lows experienced stimulus overload. 3. Autonomous Functioning  $p < .01$  Primary acct./ in attention, learning, memory, motor function. 4. Objective Relativity  $p < .07$  5. Regulating control of drive  $p < .06$  Multiple regression accounted for 33% of variance in 12 ego functions. Stimulus Barrier alone accounted for 14% ( $p < .005$ ); ARISE accounted for 5% ( $p < .01$ ). 47% of Ss were High hypnotizables, 42% were in the Medium range.

Koe, G. Gerald; Oldridge, O. A. (1988). The effect of hypnotically induced suggestions on reading performance. International Journal of Clinical and Experimental Hypnosis, 36, 275-283.

52 volunteer Ss, 19 years or older, at U. of British Columbia, were hypnotized and given post hypnotic achievement and esteem suggestions to investigate the influence of these suggestions on reading performance as measured by the total score on the Nelson-Denny Reading Test (Nelson & Denny, 1960). Differences among groups were compared using a hierarchical regression approximation of analysis of covariance. Hypnotizable Ss scored higher than un hypnotizable Ss. Other-esteem suggestions were found to improve reading performance.

Young, W. C. (1988). Psychodynamics and dissociation: All that switches is not split. Dissociation, 1, 33-38.

Contrasts the roles of splitting and dissociation in multiple personality disorder. It is proposed that dissociation is a unique defensive process that serves to protect the patient from the overwhelming effects of severe trauma and that multiple personality disorder need not call upon splitting as its central defensive process. Fantasies of restitution may be incorporated into the dissociative defense. Psychological, physiological, and behavioral models all are of use, making it likely that ultimately dissociation will be understood along multiple lines of study.

1987

Baker, Elgan L. (1987). The state of the art of clinical hypnosis. International Journal of Clinical and Experimental Hypnosis, 35 (4), 203-214.

This paper reviews the contemporary status of clinical hypnosis in light of the current emphasis on briefer, pragmatic forms of therapy and consumer demands to demonstrate effectiveness. Conceptual shifts and an expansion of clinical applications are related to changes in hypnotic strategies and technique. Suggestions

for future avenues of clinical research are outlined and the importance of the continued integration of scientific rigor, empirical clarity, and clinical acumen and sensitivity is emphasized.

**1986**

Markus, Hazel; Nurius, Paula (1986). Possible selves. *American Psychologist*, **41** (9), 954-969.

The concept of possible selves is introduced to complement current conceptions of self-knowledge. Possible selves represent individuals' ideas of what they might become, what they would like to become, and what they are afraid of becoming, and thus provide a conceptual link between cognition and motivation. Possible selves are the cognitive components of hopes, fears, goals, and threats, and they give the specific self-relevant form, meaning, organization, and direction to these dynamics. Possible selves are important, first, because they function as incentives for future behavior (i.e., they are selves to be approached or avoided) and second, because they provide an evaluative and interpretive context for the current view of self. A discussion of the nature and function of possible selves is followed by an exploration of their role in addressing several persistent problems, including the stability and malleability of the self, the unity of the self, self-distortion, and the relationship between the self-concept and behavior

**1983**

Baker, Elgan L. (1983). Resistance in hypnotherapy of primitive states: Its meaning and management. *International Journal of Clinical and Experimental Hypnosis*, **31** (2), 82-89.

This paper examines various aspects of resistance that become manifest in hypnotherapy with borderline, narcissistic, and psychotic patients. Specific clinical presentations are described and contrasted with forms of resistance encountered in work with neurotic patients. An ego psychology theoretical perspective is presented to conceptualize these more primitive resistance phenomena in terms of transference issues and dynamics relating to separation/attachment conflicts, and specific suggestions for management are outlined. 2 case examples are presented to demonstrate both conceptual and technical aspects of this approach.

Hurley, John D. (1980). Differential effects of hypnosis, biofeedback training, and trophotropic responses on anxiety, ego strength, and locus of control. *Journal of Clinical Psychology*, **36** (2), 503-507.

Pretested 60 college students on three scales: the IPAT Anxiety Scale, the Barron Ego-strength scale, and the Rotter I-E scale. The Ss then were assigned randomly to one of four treatment groups designated: hypnotic treatment, biofeedback treatment, trophotropic treatment, and control. Three of these groups met separately for 60 minutes once a week for 8 weeks. The control group did not meet

during this time. During the sessions, each group was trained in a different technique for self-regulation. At the end of the 8-week period the scales were readministered to all groups. A series of covariance analyses indicated that hypnosis was a more effective self-regulatory technique for lowering anxiety levels when compared to biofeedback or trophotropic response procedures. With regard to increasing ego strength, both the hypnotic training group and the biofeedback training group proved to be significant. No significant difference was found between the experimental and control groups on the I-E scores.

1979

Watkins, John G.; Watkins, Helen H. (1979-80). Ego states and hidden observers. Journal of Altered States of Consciousness, 5 (1), 3-17.

Hilgard and Hilgard discovered that subjects who had been rendered hypnotically deaf, or whose hand had been anesthetized under hypnosis, were hearing and sensing the pain at levels below the threshold of normal awareness. They described this phenomena as a cognitive structural state and termed it "the hidden observer." Federn theorized that the ego is subdivided into segments (organized patterns of behavior and experience) which are semi-autonomous in normal individuals, and which are manifested as completely separate entities (multiple personalities) when the internal boundaries between such parts are rigid and impermeable. He termed these entities "ego states." When activated under hypnosis each ego state experiences its self as subject (I) and the other states as objects (he, she, or it). We have discovered in hypnoanalytic therapy that these ego states act like "covert" multiple personalities, and that clashes between them often create anxiety and psychosomatic symptoms. Ego-state therapy thus becomes a kind of family or group therapy aimed at resolving conflicts between the various ego states which constitute "a family of self" within a single individual. Two studies are reported here to investigate the possibility that Hilgard's "hidden observers" are the same phenomena as these "ego states." The data derived appear to support such a hypothesis. Consideration is given to the possible influence of suggestion and operator variables.

1978

Kir-Stimon, W. (1978). Hypnosis as a tool for termination of therapy. International Journal of Clinical and Experimental Hypnosis, 26 (3), 134-142.

Cases are presented with varied induction methods to illustrate the use of hypnosis as a final step in psychotherapy. In each situation, therapy had been clinically active without hypnosis. Problems in termination revolved around patients' fear of taking the ultimate step in controlling their own lives. Hypnosis helped to provide a bridge between previous and current self-concept and an acceptance of individual creativity. Discussion focuses on the use of hypnosis as an adjunct in overcoming anxiety in the ego's relation to the umwelt rather than for initiating rapport or working through transference. Hypnosis then becomes a positive factor in

enhancing self-mastery and autonomy as well as in handling resistance to the full utilization of ego strength.

1977

Fromm, Erika (1977). An ego-psychological theory of altered states of consciousness. International Journal of Clinical and Experimental Hypnosis, 25, 372-387.

In this paper a new ego-psychological theory is proposed for the understanding of altered states of consciousness. The dichotomies of primary and secondary process, ego activity and ego receptivity, and automatization and de-automatization of ego functions in daydreaming, in the inspirational phase of creativity, in hypnosis, in psychedelic states, and in meditation are discussed; so are the roles of fantasy, imagery, and various forms of attention.

#### NOTES

The author provides a table titled "Typology of Waking State and Several Altered States of Consciousness by Attention Mode." The states listed in the table are: Waking, normally alert, and concentrated; Waking, fascinated, entranced; Free association; Daydreaming; Dreaming; Psychedelic drugs; Hypnosis; Self-hypnosis; Biofeedback; Transcendental meditation; Concentrative meditation; Satipatthana [mindfulness of body, feelings, mind, and mental events]; Classical vipasyana [Clear intuitive insight into physical and mental phenomena as they arise and disappear, seeing them for what they actually are]. She summarizes, "In general, the present author strongly feels that the advantage of hypnotherapy over therapy in the waking state is that hypnosis allows the therapist to help patients work with more primary process thinking, more fantasy, more imagery, more ego receptivity than they would employ in the waking state" (p. 385). "What helps the therapy is not the depth itself; it is that in the hypnotic state there is greater mobility, a greater ability to dip into the unconscious and to bring the unconscious material back into the waking state of consciousness" (p. 385).

Stanton, Harry E. (1977). The utilization of suggestions derived from rational-emotive therapy. International Journal of Clinical and Experimental Hypnosis, 25 (1), 18-26.

A series of positive suggestions derived from Ellis' rational-emotive therapy were compared with Hartland's "ego-strengthening" technique in terms of patients' belief in their efficacy. Both pre- and post-treatment ratings were collected. Patients tended to approach treatment with a positive feeling that the treatment would help them with their problem and this belief was strengthened after the 10 therapy sessions had been completed. Further ratings taken 6 months later indicated that patients' belief in the value of the suggestive therapy had not decreased over time.

3 groups of hospitalized chronic schizophrenic patients received "the taped hypnotic treatment" twice a week for 4 weeks. The treatment differed for each of the 3

groups of 18 patients, but neither the patients nor the nursing staff were informed of this difference. The first group was exposed to music only, the second group was given music with superimposed hypnotic suggestions, and the third group heard music with superimposed hypnotic suggestions for improving self-confidence. The staff filled in an evaluation form about the patient's health beforehand, immediately afterward, and then 1 month after the treatment program. No difference between the groups was found if the comparison was based only upon the directions of the changes. However, twice as many positive changes as negative ones were observable in every group after the control period. If the changes noted are restricted only to those attaining the statistically significant ( $p < .05$ ) level, the majority of positive ones was more evident. From this point of view, the reactions of the groups to the treatments were also different. Improvement appeared directly after the treatment of the Music and Self-confidence groups, but was not evident during the observation time 1 month later. In the Relaxing group, there was, on the contrary, only slight improvement directly after the treatment, but 1 month later during the follow-up observation time, the improvement was considerable. Thus, while encouraging hypnotic suggestions proved on the follow-up to be ineffective, hypnosis appeared to have a real influence when only relaxing suggestions were used.

1976

Lavoie, Germain; Sabourin, Michel; Ally, Gilles; Langlois, Jacques (1976). Hypnotizability as a function of adaptive regression among chronic psychotic patients. International Journal of Clinical and Experimental Hypnosis, 24, 238-257.

The Rorschach and the Stanford Hypnotic Susceptibility Scale, Form A (SHSS:A) were administered to a sample of 56 chronic psychotic patients, mainly schizophrenics ( $N = 48$ ). Verbatim transcriptions of tape-recorded Rorschach protocols were scored according to the Holt system (Holt et al., 1963), which provides an index of adaptive regression. Experimental procedures were conducted single blind. With one exception, all the patients high on SHSS:A were among those obtaining a higher adaptive regression index, while 50% of those obtaining higher adaptive regression index were high on SHSS:A. A systematic investigation of ego functions was proposed for a better understanding of this asymmetry, although the results already gave ostensible positive support to the Gill and Brenman (1959) theory, and to the theory of ego autonomy.

Levin, L. A.; Harrison, R. H. (1976). Hypnosis and regression in the service of the ego. International Journal of Clinical and Experimental Hypnosis, 24, 400-418.

28 highly hypnotizable female Ss were selected to test the hypothesis that hypnosis is characterized by regression in the service of the ego (adaptive regression). 2 tasks, producing a hypnotic dream and telling a TAT story, were administered individually under hypnotic and normal waking conditions. Scoring for adaptive regression yielded 2 factors, one for the regressive aspects of the fantasies produced, the other for cognitive mastery of those fantasies. An increase in primary process thinking was found in hypnosis, particularly in the hypnotic dream. There was a

relationship between S's capacity for adaptive regression and the amount of adaptive regression found in hypnosis. Although facilitating regression from secondary to more primary process thinking, hypnosis does not inherently provide mechanisms by which primary process manifestations can be utilized adaptively by the ego. Such mechanisms are ego functions which tend to be amplified by hypnosis only in Ss who demonstrate good capacity for adaptive regression.

1975

Spear, J. E. (1975). The utilization of non-drug induced altered states of consciousness in borderline recidivists. American Journal of Clinical Hypnosis, 18, 111-126.

Utilizing non-drug induced altered states of consciousness, various modes of interior reflection, behavior modification and reprogramming of conscious attitudes and values were utilized with 49 borderline recidivists. Such offenders were so determined by the Department of Corrections, Probation and Parole Office, District II. No coercion was used to induce such individuals to enter the program and there was no reprisal for stopping therapy at any time. Over a two and one-half year period the recidivist rate among this group was less than 5%. It is suggested that non-drug induced altered states of consciousness combined with indirect as well as symbolic techniques may prove to be the most effective means of criminal rehabilitation.

#### NOTES

Borderline recidivists were "individuals, who, in the opinion of the P.O. [probation officer] were, in all probability, to be returned to prison within a few months, or less, if there wasn't a major change in attitude and actions" (p. 111). Therapy employed closed circuit TV with bi-directional audio and induction of altered state of consciousness using an ophthalmology-type rotary prism. Therapy involved (s) recall of relaxed state when under stress, (2) exploration of early conditioning events, (3) self evaluation during the ASC, (4) use of symbolic mental exercises and mental practice for similar circumstances in normal waking state, (5) suggestions for setting goals and ideals, (7) a type of logotherapy, (7) 'nudging' the person to examine their relationship with their concept of God. The author noted in the parolees: (1) low levels of self esteem, (2) depression, (3) going into deep levels of altered states once trust was established with the therapist.

1971

Kihlstrom, J. F.; Edmonston, W. E., Jr. (1971). Alterations in consciousness in neutral hypnosis: Distortions in semantic space. American Journal of Clinical Hypnosis, 13, 243-248.

30 highly hypnotizable Ss were equally divided into three groups, equated for age, sex and hypnotic susceptibility. A semantic differential scale was administered to each S in waking, individual sessions. An oral form of the same scale was administered during: (a) hypnosis (E), (b) waking -- post hypnosis (C1), and (c)

waking -- no hypnosis (C2). All groups showed significant change between administrations of the scale; E showed more change than C1, and the latter more than C2. Ratings of "My Self" changed toward the negative pole in the evaluative factor. Results were interpreted as indicating a distortion in semantic space and an alteration in ego-state occurring spontaneously with hypnosis.

Fromm, Erika; Oberlander, Mark I.; Gruenewald, Doris (1970). Perceptual and cognitive processes in different states of consciousness: The waking state and hypnosis. Journal of Projective Techniques and Personality Assessment, 34, 375-387.

Hypnosis was assumed to influence perceptual and cognitive functioning in the direction of increased primary process ideation and adaptive regression. The Rorschach test was administered to 32 Ss in the waking state and under hypnosis in counterbalanced order. Hypnosis was induced by a standardized procedure. Ss received identical instructions for the Rorschach in both conditions. Protocols were scored according to Holt's system for manifestations and control of primary process. Hypnotic Rorschachs showed an increase in primary process manifestations, but no changes in defensive and coping functioning, and no overall changes in the Adaptive Regression Score. However, the nature of the data was found to be influenced by Ss' sex and level of adjustment.

1965

Klempner, Edith (1965). Past ego states emerging in hypnoanalysis. International Journal of Clinical and Experimental Hypnosis, 13 (3), 132-144.

Patients with anxiety, conversion, or phobic reactions differ from those with obsessive-compulsive reactions in the type of visualization shown in hypnoanalytic regression or revivification. The former produce visualizations showing a well-rounded picture with logical progression of activity and few symbolic distortions. The latter, however, produce visualizations lacking a logical progression of activity and showing a somewhat disorganized and poorly-rounded picture. Symbolic distortions are frequent, often recurring intermittently. Case studies are presented. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

#### NOTES

Author's Summary: "Insight occurs on different levels of psychological awareness and with varying degrees of curative effect. The complex interplay between psychodynamic factors and therapeutic situations does not permit any accurate predictability of either the patient's level of insight at any one moment or of his readiness to assimilate deep disclosures. Psychoanalytic theory sheds the greatest light upon these phenomena as well as upon the analogous aspects in hypnotherapy. The hypnotic state is peculiarly suited to overcome resistance and to utilize consequent insight with great effectiveness. Progress in hypnotherapeutic technique has evolved an approach that assures the assimilation of crucial revelations at a pace in accordance with the strength of the ego to tolerate the resultant anxiety" (p. 145).

#### ELECTRICAL STIMULATION

1988

Danziger, N.; Fournier, E.; Bouhassira, D.; Michaud, D.; De Broucker, T.; Santarcangelo, E.; Carli, G.; Chertock, L.; Willer, J. C. (1988). Different strategies of modulation can be operative during hypnotic analgesia: A neurophysiological study. Pain, 75 (1), 85-92.

Nociceptive electrical stimuli were applied to the sural nerve during hypnotically-suggested analgesia in the left lower limb of 18 highly susceptible subjects. During this procedure, the verbally reported pain threshold, the nociceptive flexion (RIII) reflex and late somatosensory evoked potentials were investigated in parallel with autonomic responses and the spontaneous electroencephalogram (EEG). The hypnotic suggestion of analgesia induced a significant increase in pain threshold in

all the selected subjects. All the subjects showed large changes (i.e., by 20% or more) in the amplitudes of their RIII reflexes during hypnotic analgesia by comparison with control conditions. Although the extent of the increase in pain threshold was similar in all the subjects, two distinct patterns of modulation of the RIII reflex were observed during the hypnotic analgesia: in 11 subjects (subgroup 1), a strong inhibition of the reflex was observed whereas in the other seven subjects (subgroup 2) there was a strong facilitation of the reflex. All the subjects in both subgroups displayed similar decreases in the amplitude of late somatosensory evoked cerebral potentials during the hypnotic analgesia. No modification in the autonomic parameters or the EEG was observed. These data suggest that different strategies of modulation can be operative during effective hypnotic analgesia and that these are subject-dependent. Although all subjects may shift their attention away from the painful stimulus (which could explain the decrease of the late somatosensory evoked potentials), some of them inhibit their motor reaction to the stimulus at the spinal level, while in others, in contrast, this reaction is facilitated.

Abstract from National Library of Medicine, PubMed

Borgens, Richard B. (1988). Stimulation of neuronal regeneration and development by steady electrical fields. In Waxman, S. G. (Ed.), Functional recovery in neurological disease (47, pp. 547-564). New York: Raven Press.

#### NOTES

At the end of the review, author notes that a combination of electromyography and computer modeling of agonist-antagonist, flexor-extensor muscle contraction patterns in the functional body parts of hemiparetic patients, artificially imposed on the paralyzed portions of the body using repetitive electrical stimulation to effect more normal movement, sometimes leads to functional recovery. Such recovery has been observed in some chronic cases of paralysis associated with head injury, stroke, and cerebral palsy. These clinical observations challenge the way we should view paralysis in general. Perhaps there are many redundant pathways in the CNS that will support certain kinds of functional return in the absence of the original pathways destroyed by trauma. Perhaps CNS-associated paralysis is a problem, at least in part, of too much competing signal in spared pathways, not one of impoverished signal. Can use of these neuronal pathways be entrained or retrained? Is the return of function in patients who experience repetitive functional electrical stimulation due to a reorganization within the CNS? These are exciting questions whose answers will possibly lead to our ability to further modify the plasticity of the brain and spinal cord.

[This would fit with the inhibition model of hypnosis, and with the high theta power findings during hypnosis, the implication being that hypnosis facilitates filtering out non-essential competing stimuli.]

DeBenedittis, Giuseppe; Sironi, Vittorio A. (1988). Arousal effects of electrical deep brain stimulation in hypnosis. International Journal of Clinical and Experimental Hypnosis, 36, 96-106.

**In an earlier study, DeBenedittis and Sironi (1986) demonstrated that during depth EEG studies, electrophysiological correlates of hypnotic behavior emphasize the role of the limbic system in mediating the trance experience. In the case of a young man who was affected by medically resistant temporal lobe epilepsy and who was a potential candidate for surgical treatment, diagnostic depth EEG in hypnotic and non- hypnotic conditions offered a unique opportunity to stimulate limbic structures. This permitted an evaluation of the subjective and behavioral responses, as well as of the electrophysiological correlates. During hypnosis, repeated stimulations of the left and the right amygdala produced arousal from the hypnotic state each time, whereas the stimulation of other cerebral structures (e.g., temporal neocortex, Ammon's horn) or pseudostimulations were ineffective on the hypnotic state. These data represent the first experimental, controlled evidence of the amygdala's effects on the arousal from the hypnotic state in man, thus suggesting that hypnotic behavior is mediated, at least in part, by a dynamic balance of antagonizing effects of discrete limbic structures--the amygdala and the hippocampus.**

#### **NOTES**

**The patient was a 30-year-old man who had suffered from medically resistant psychomotor temporal lobe epilepsy since age 7; a diagnostic EEG showed right temporal seizure focus, concomitant with independent, contralateral, temporal spiking abnormalities. Hypnotizability was measured at 6 on the SHSS:C; the patient was given two training sessions in hypnosis, with suggestions for "dissociation, rehearsal and reframing of spontaneous seizure events, desensitization of their negative emotional impact, and amnesia" (p. 99).**

**Electrodes were implanted in deep cerebral structures (amygdala, Ammon's horn) and corresponding superficial areas of temporal cortex, with confirmation of placement by X-ray. Two weeks later the patient's brain was stimulated on two consecutive days, first in the waking state (Session 1) and then in hypnosis (Session 2). (Antiepileptic medication was discontinued three days before the stimulation sessions.) False (placebo) stimulations were randomly provided along with the true stimulations.**

**The false (placebo) stimulations did not result in subjective or behavioral changes in either the waking or the hypnosis condition.**

**In the waking condition, a psychomotor seizure was produced by stimulation of Right amygdala and Left Ammon's horn; stimulation of Left amygdala evoked only the aura patient usually had before a seizure, or a brief lapse of consciousness. Stimulating the temporal neocortex did not evoke seizure activity.**

**In the hypnosis condition, arousal from hypnosis into the waking condition occurred with stimulation of amygdala (either Right or Left). Stimulation of the temporal neocortex or of the Right Ammon's horn did not arouse the patient. Stimulation of Left Ammon's horn led to abortive seizures, such that it could not be determined whether the hypnotic state had been interrupted. Stimulating the Right amygdala "triggered a psychomotor attack similar to that recorded during the waking stimulation, but with reduced emotional involvement" (p. 100). For the Left**

Ammon's horn, "waking stimulation always induced clinical seizures with prolonged after-discharge, whereas hypnotic stimulation evoked only abortive seizures, without after-discharge" (p. 100).

In their Discussion, the authors note that animal experimental literature suggests that stimulation of the cortico-medial amygdala facilitates arousal functions, of the baso- lateral amygdala diminishes arousal and produces sleep, and lesions of the amygdala lead to 'amygdala hangover' (Weiskrantz, 1956). "The animal with amygdala destruction appears tame and placid, with reduced social reactivity, insensitive to environmental changes and reluctant to initiate new behavior, unless highly motivated (Isaacson, 1976)" (p. 101-102).

In contrast, the animal research on hippocampus suggests it is involved in inhibitory functions (Isaacson, 1976), and may be the 'internal inhibitor' theorized by Pavlov (1955) to be responsible for animal hypnosis. With lesions, animals are more willing to undertake new behaviors, less inactive, less distractible during goal-oriented behavior (Isaacson, 1976). "Moreover, normal hippocampograms show typical, slow (theta) synchronous activity opposed to the arousal desynchronized activity of the electroencephalogram. During hypnosis, desynchronization of the normal, slow activity of the hippocampal Ammon's horn has been registered as compared with the waking hippocampogram, opposite to the slow synchronous activity of the amygdala" (p. 102).

The authors note that their results are at variance with the finding by Crasilneck et al. (1956) that their patient, during brain surgery for an epileptogenic focus, aroused from hypnosis each time they stimulated the hippocampus. They explain the discrepancy as due to the fact that the hippocampus was not simply stimulated, but in fact there was 'coagulation' of a hippocampal vessel each time. Quoting from Crasilneck et al. "'The patient did not complain of pain during this [brain] excision [in hypnosis] except on one noteworthy occasion, when a blood vessel of the hippocampal region was being coagulated. The patient suddenly awoke from the hypnotic trance ... She was immediately rehypnotized. ... The surgeon then purposefully 'restimulated' the same region of the hippocampus. Once again, the patient abruptly awakened from trance... [p. 1607].'"To the present authors, the description appears misleading and responsible for subsequent misinterpretation of the observation. Because on the first occasion the hypnotic arousal effect followed 'coagulation' of the hippocampal region, it may be assumed that 'restimulation' is a misnomer for repeated coagulation. From this it may be inferred that the arousal effect observed by Crasilneck et al. (1956) could probably be ascribed to a hippocampal microlesion rather than to hippocampal stimulation. This could explain the apparent discrepancy" (p. 104).

1974

Bloom, Richard F. (1974). Validation of suggestion-induced stress.

#### NOTES

Technical Memorandum 23-74 (October 1974), US Army Human Engineering Laboratory, Aberdeen Proving Ground, Maryland 21005, AMCMS Code

5910.21.68629, Contract No. DAAD05-73-C-0243, Dunlap and Associates, Inc. (now Stamford, CT), AD002557.

Sixty college men, divided into three equal groups, each attended two induced stress sessions in which their physiological, psychological and performance reactions were measured. Their responses were compared to determine if valid stress reactions could be induced through suggestion in an altered state (in this case, hypnosis), and also to determine the validity of such reactions if the subject had never before experienced that stress situation. It was demonstrated that valid stress reactions can be induced in an individual with the aid of suggestions, especially if the real stress situation has been experienced before. If no previous experience with that real situation exists, the subject still exhibits stressful reactions; however, the closest resemblance to real stress is found in the subjective or psychological measures, less similarity is found in the physiological measures, and the least similarity is found in the performance measures.

1961

McCartney, James L. (1961). A half century of personal experience with hypnosis. International Journal of Clinical and Experimental Hypnosis, 9, 23-33.

#### NOTES

(Author's Summary and Conclusions). "After fifty years of experience with hypnosis, it is evident that it is not a superficial and careless technic but should be utilized only by capable, trained physicians, as are the other complex and difficult medical technics. ... In order to induce hypnosis, the patient must be perfectly willing to be hypnotized, he must have confidence in the practitioner, and he must concentrate on doing exactly as he is told. In selected cases, drugs or electrical impulses may be used for the initial induction of hypnotic sleep, but if hypnotherapy is to be continued, the physician must keep in contact with the patient by repeated suggestions. The technic used should fit the individual patient, but in most cases, verbal suggestions are all that is necessary to bring about dissociation. Hypnosis may be used to facilitate the beginning of mental catharsis, the establishment of transference, and may be easily instituted following narcosynthesis, electroshock therapy, minimum stimulus, or Sedac. Suggested activity under hypnosis may be carried out at a designated time, place, and manner after awakening. This is a result of autosuggestion and may be mistaken for psychopathic behavior. Such suggestions may be instituted by television, movies, radio, telephone, or recorded or written instruction. Hypnosis may be used to plant suggestions; if misused, it may create an obsessive-compulsive neurosis, while when properly used, it may overcome many functional symptoms and may be used to supplement other forms of psychotherapy" (p. 32).

19954

Thaheld, Feri Herndon (1954). Nonconclusive electrostimulation under narcotic hypnosis. Journal of Clinical and Experimental Hypnosis, 2, 175-177.

## NOTES

Hypnosis was used in an attempt to reduce the side effects of nonconvulsive electrostimulation in a single subject. Subject was given 2 gr of nembutal, followed by hypnotic induction, then repeated suggestions that the "subject could feel no pain and that therefore as a result of this there could not be any physical response at all to this very harmless and quite painless treatment which was being administered" (p. 176).

Subject had 42 treatments (unidirectional, modulated, spiked current averaging 5-9 ma, through electrodes placed above the ears, for usually 3 minutes but sometimes 5-8 minutes) over 3 wk period. Ordinarily in such a situation pain would be experienced, with physiological changes (dilation of pupils, increase in pulse rate, flushing of skin, perspiration, some contraction of muscles) and emotional outbursts observed. In this subject, "none of the usual side reactions were found to be present and the further use of posthypnotic suggestions eliminated any after-effects or complications which might have arisen" (p. 176).

The author discussed the possibility that trance depth was facilitated by the pyramiding action of layering one set of suggestions on top of another, something like Vot's fractionation technique (in which subject is repeatedly hypnotized and de-hypnotized with suggestions of increasing depth).

## ELECTROMYOGRAM (EMG)

1997

Jasiukaitis, Paul; Nouriani, Bitā; Hugdahl, Kenneth; Spiegel, David (1997). Relateralizing hypnosis: Or, have we been barking up the wrong hemisphere?. International Journal of Clinical and Experimental Hypnosis, 45 (2), 158-177.

Research and theory over the past couple decades have suggested that the right cerebral hemisphere might be the focus of brain activity during hypnosis. Recent evidence from electrodermal responding, visual event-related potentials, and Stroop interference, however, can make a case for a role of the left hemisphere in some hypnotic phenomena. Although hemispheric activation on hypnotic challenge may depend in large part on the kind of task the challenge might involve, several general aspects of hypnosis might be more appropriately seen as left-rather than right-hemisphere brain functions. Among these are concentrated attentional focus and the role of language in the establishment of hypnotic reality. A left-hemisphere theory of hypnosis is discussed in light of recent findings and theories about a left-hemisphere basis for synthetic or generational capabilities (Corballis, 1991) and a neuro-evolutionary model of a left-hemisphere dopaminergic activation system for the implementation of predetermined motor programs (Tucker & Williamson, 1984). -- Journal Abstract

1996

DeBenedittis, Giuseppe De (1996). Hypnosis and spasmodic torticollis -- report of four cases: A brief communication. International Journal of Clinical and Experimental Hypnosis, 44 (4), 292-306.

**Dystonia and particularly spasmodic torticollis are neuromuscular disorders that are extremely resistant to most therapies (physical, medical, or surgical). Torticollis is a unilateral spasm of the neck muscles, particularly of the sternocleidomastoid, that produces violent, tonic turning of the head to one side. The etiology remains uncertain, although the role of psychogenic factors has been emphasized. This article reviews the literature and reports four cases of spasmodic torticollis treated successfully with hypnosis. In all four cases, psychogenic causes were involved. Postural hypnosis (i.e., hypnosis in the standing position) was employed to counteract and minimize muscle spasms due to postural reflexes. A hypnobeavioral approach was adopted along with hypnotic strategies that included hierarchical desensitization, sensory-imaging conditioning, ego-boosting suggestions, and hypnosis-facilitated differential muscle retraining. In two cases, a combined hypnosis and electromyographic-biofeedback approach was used to equilibrate and retrain affected neck muscles. Although the hypnotherapeutic process took several months to induce and stabilize significant changes, outcome results were good to excellent in all cases, with marked reduction of the torticollis and the hypertrophy of the neck muscles as well as a reduced interference of symptoms in daily living. -- Journal Abstract**

**1992**

**Zitman, Frans G.; Van Dyck, Richard; Spinhoven, Philip; Linszen, A. Corrie G. (1992). Hypnosis and autogenic training in the treatment of tension headaches: A two-phase constructive design study with follow-up. Journal of Psychosomatic Research, 36, 219-228.**

**Tension headaches can form a chronic (very long duration) condition. EMG biofeedback, relaxation training and analgesia by hypnotic suggestion can reduce the pain. So far, no differences have been demonstrated between the effects of various psychological treatments. In a constructively designed study, we firstly compared an abbreviated form of autogenic training to a form of hypnotherapy (future oriented hypnotic imagery) which was not presented as hypnosis and secondly we compared both treatments to the same future oriented hypnotic imagery, but this time explicitly presented as hypnosis. The three treatments were equally effective at post-treatment, but after a 6- month follow-up period, the future oriented hypnotic imagery which had been explicitly presented as hypnosis was superior to autogenic training. Contrary to common belief, it could be demonstrated that the therapists were as effective with the treatment modality they preferred as with the treatment modality they felt to be less remedial.**

#### **NOTES**

**An earlier review by these authors found that EMG biofeedback and relaxation training were equally effective with headache [Zitman, 1983, Biofeedback and chronic pain, In Advances in Pain Research and Therapy (Edit by Bonica, Lindblom, Iggo) V. 5, pp 794-809. N. Y.: Raven Press]. Other authors also found that hypnotic suggestion, EMG biofeedback and EMG biofeedback plus progressive**

relaxation training were equally effective [Schlutter, Golden, Blume, 1980, A comparison of treatments for prefrontal muscle contraction headache. *Br J. Med Psychol*, 53, 47-52.]. The authors raise the question whether any treatment element or perhaps combination of elements can enhance a basic relaxation training procedure, with respect to chronic headache.

The first phase of this research compared autogenic training (AT) and future oriented hypnotic imagery (FI) which was not labeled as hypnosis. Results were the same for both groups, and were reported earlier [van Dyck, Zitman, Linssen et al. *International Journal of Clinical and Experimental Hypnosis*, 1991, 39, 6-23]. The current study added a third group which received future oriented hypnotic imagery but also was told that they were getting hypnosis (FI-H). Thus the AT and FI groups were 'historical' comparison groups for the FI-H group in this study.

Patients were described as having headache complaints of at least 6 months (76% had been suffering for >2 years), were over 18 years old, had no drug dependence and no psychiatric disorder, and no previous therapy with autogenic training or hypnosis; no other treatment during the project; fluent in Dutch.

The autogenic training consisted of six exercises learned in a fixed order. The FI method, in which the hypnotized patient imagines himself in a future, pain-free, situation, had been described by Milton Erickson [1954, Pseudo-orientation in time as a hypnotherapeutic procedure. *JCEH*, 2, 261-283]. For that future situation the investigators used descriptions that the patients provided. Both kinds of intervention taught patients muscular and mental relaxation. Both methods required home practice of the technique, using audio cassettes.

In order to substantiate the labeling of the hypnotic procedure as hypnotic future oriented imagery (FI-H) "hand levitation induction was employed during session two with the purpose of inducing positive expectancies concerning hypnosis as a procedure capable of changing ordinary experiences in an unexpected way [17]. This hand levitation procedure, however, was not presented on tape. Except for the labeling as hypnosis and the hand levitation induction, the hypnotic future oriented imagery procedure was identical to the future oriented imagery procedure in the first phase" (p. 221).

Treatment lasted for 8 weeks and provided 2 1/2 hours of therapist and 24 1/2 hours of home training with taped instructions. The outcome measures included: 1. Budzinsky-type headache index (mean daily sum of intensity rating for each hour of headache activity recorded during 3 separate days of the week of an assessment session) 2. State Anxiety 3. Zung-type Self-rating Depression Scale 4. Perceived credibility of treatment (4 Question's developed by Borkovec & Nau using a visual analogue scale) 5. Neuroticism from the CPI

## RESULTS

Of 96 patients who agreed to participate, 17 dropped out before the post-treatment assessment. Of the remaining 79, 28 completed AT treatment, 27 FI, and 24 FI-H. Sixty-six attended the follow-up assessment; there were no dropouts from the FI-H, and the drop-outs were equally divided between the AT and FI condition. The headache index scores were logarithmically transformed because the distribution was positively skewed.

Using ANOVA, in terms of post-treatment scores, there were no significant main effects for therapist or treatment, nor were there any significant interaction effects when analyzing headache index, state anxiety, and depression. There was a significant main effect for Time for three outcome measures: headache index score, state anxiety, and depression.

Post-treatment, neither amount of medication used nor subjective estimates of headaches differed by treatment or by therapist. However, over time there were beneficial results for both treatment groups. "Patients rated their headaches as significantly reduced compared to pre-treatment (a mean pain reduction of 40%). ...they had significantly reduced their use of analgesic medication (a mean decrease of 14%)" (p. 224).

Using ANOVA, in terms of follow-up scores, again there were no significant main effects for Treatment or Therapist on the outcome measures of headache index, state anxiety, or depression. There now were three time periods (pre-, post-, and follow-up), and once again there was significant main effect for Time for headache index (though not for state anxiety). That is, people benefitted over the time of the treatment and follow-up. Moreover, there was a significant interaction effect between Therapy and Time on the headache index measure. "A posteriori contrasts revealed that the patients from the FI-H condition showed a greater reduction in their headaches between pre-treatment and follow-up than patients from the AT condition" (p. 225).

The authors write in their Discussion, "Our data indicate that at least in tension headache patients, defining a procedure explicitly as hypnotherapy may not lead to greater effects at post-treatment, but does lead to longer lasting effects" (p. 226).

"The paucity of differences between the three conditions may be a consequence of the study design: the small number of patients and the large SD may have prevented the detection of more differences in effect between the three conditions" (p. 226).

"Other critical remarks are related to the difference in headache reduction at follow-up between AT and FI-H. Firstly, the differences at follow-up were found only with respect to the headache index and not with respect to the subjective estimate of the pain. Secondly, in defining future oriented hypnotic imagery explicitly as hypnosis, we hoped to enhance the efficacy via increased credibility. We found increased efficacy, but we did not find enhanced credibility. Therefore, the differences in effect at follow-up must have another cause. The different effects at follow-up could be linked to the fact that the FI-H condition was the only one without drop-outs. This absence of drop-outs was due to a new research assistant who tried extraordinarily hard to make the patients return for follow-up. By doing so, she may have prevented the patients who gained much from the treatment from dropping out as well as those who gained little" (p. 226-227).

"In this study, despite the differences in therapists' preferences, both therapists were equally effective with all three treatments. This is an intriguing finding which goes against the belief commonly held by clinicians that therapists are more effective with the type of therapy they prefer" (p. 227).

"The effects were modest, but it must be kept in mind that most of our patients referred by a neurologist were chronic headache sufferers (76% had been suffering

for > 2 yr). In such a group of patients even small effects are important, especially when these effects are long-lasting" (p. 227).

**Mauer, D. R. (1991, October). A comparison of cognitive-behavioral and hypnotic techniques in the management of electromyography pain (Dissertation, University of Iowa). Dissertation Abstracts International, 53 (4), 1070-B. (Order No. DA 9217180)**

Compared a cognitive behavioral technique that included providing specific sensory and procedural information combined with relaxation with a hypnotic technique (relaxation with guided imagery) and a control group for management of acute EMG pain and anxiety. Pain and anxiety ratings were gathered from 45 EMG patients and observers for both nerve conduction and needle electrode components of the EMG exam. It was found that only the hypnosis group significantly reduced pain and anxiety during the needle electrode portion of the procedure. Patients with unexplained or functional symptoms reported more EMG pain and anxiety than patients who had an organically based disease. Because having had a prior EMG seemed to have an effect on the efficacy of treatment, the data were reexamined. Results determined that inexperienced EMG patients who were treated had less pain and anxiety than patients who experienced EMG before, but inexperienced control patients had an increase in pain and anxiety over experienced patients" (p. 1070).

**Sturgis, Laura M.; Coe, William C. (1990). Physiological responsiveness during hypnosis. International Journal of Clinical and Experimental Hypnosis, 38, 196-207.**

Four physiological measures - electromyogram, respiration rate, heart rate, and skin conductance - were recorded for 11 high and 11 low hypnotizability Ss. It was hypothesized (a) that physiological responsiveness during hypnosis would vary depending on the nature of the task instructions, and (b) that high hypnotizability Ss would show more physiological responsiveness than low hypnotizability Ss. The first hypothesis was substantiated across all 4 measures. Only heart rate levels supported the second hypothesis. The results are discussed as they relate to the 1 hypotheses and to future research.

**Pagano, Robert R.; Akots, Normund J.; Wall, Thomas W. (1988). Hypnosis, cerebral laterality and relaxation. International Journal of Clinical and Experimental Hypnosis, 36, 350-358.**

This study attempted to determine if hypnosis produces a shift towards more dominant right hemisphere functioning and if this increased dominance can be adequately explained by general somatic relaxation rather than being due to some other aspect of the hypnotic process. 14 right-handed, medium to highly hypnotizability Ss performed a dichotic listening task while in a prehypnosis,

hypnosis, and post-hypnosis repeated measures design. Throughout the experiment, somatic relaxation was monitored physiologically by recording heart rate, respiration rate, and frontalis EMG. The results showed a highly significant shift toward a greater left ear advantage during hypnosis. There was no change in EMG. Respiration rate increased during the hypnosis condition and remained at an increased rate during the posthypnosis condition. Heart rate decreased during the hypnosis condition and remained at a decreased rate or decreased further during the posthypnosis condition. These results replicate and extend those reported by Frumkin, Ripley, and Cox (1978) and do not support the view that changes in general somatic relaxation can adequately account for this hypnotic effect.

## NOTES

Frumkin et al. (1978) presented syllables simultaneously to two ears of subjects, requiring them to state which syllable they heard most clearly (e.g. 'Ka' vs 'Ga'). They found a right ear advantage (REA) during waking conditions, which shifted toward a left ear advantage (LEA) during hypnosis. Their interpretation was that hypnosis results in more right cerebral hemisphere involvement. Two recent investigations did not find the shift in ear with advantage (H. J. Crawford, K. Crawford, & Koperski, 1983; Levine, Kurtz, & Lauter, 1984) but they were not actual replications of the Frumkin et al. (1978) investigation. This study is a replication of Frumkin et al., and is designed to learn whether relaxation could account for the results.

Subjects were 14 volunteer students of medium to high hypnotizability (Stanford Hypnotic Clinical Scale: Adult scores of 3-5). The dichotic listening tape has been used in other research at Haskins Laboratories (Yale University), and was developed by Dr. Terry Halwes. "Each run of the tape consisted of 96 dichotic pairs presented in 4 groups of 24. Six syllables from the English stop consonants k, g, p, d, b, and t preceded and followed by the vowel a, composed the pairs" (p. 352). The experimenters also recorded heart rate (HR), respiration rate (RR), and EMG.

There were two sessions for each subject: (1) screening and measuring hypnotizability with SHCS: Adult, (2) dichotic listening task within three conditions: pre- hypnosis, hypnosis, and posthypnosis. Table 1 (not shown here) gives for each S the SHCS score and the Laterality Quotient for each of the three conditions.

## RESULTS

Laterality quotients were computed for each S by the formula  $(R - L / R + L) \times 100$ , where R = right ear score and L = left ear score. A positive score indicates a predominate REA, and a negative score indicates a predominate LEA" (p. 353).

The analysis by ANOVA for repeated measures indicated that there was a significant shift to LEA during hypnosis; the means were 11.34 prehypnosis, 3.17 hypnosis, 8.93 posthypnosis. All 14 subjects demonstrated this directional shift. Heart rate decreased between prehypnosis (70.4 beats/minute) and hypnosis (67.8) and remained lower (67.9) during posthypnosis. However respiration significantly increased during hypnosis, from 13.5 breaths/minute prehypnosis to 16.2 for hypnosis and 15.2 for posthypnosis. There were no significant changes for EMG.

Self-reported depth of hypnosis remained the same for the first and second sessions. In their Discussion, the authors interpret the shift toward greater LEA during hypnosis (and return to greater REA posthypnosis) as greater right hemisphere involvement, confirming Frumkin et al. They noted that the changes were not due to increased error in the right ear, but to identification of more syllables in the left ear. Several experimental design differences could account for why this study and Frumkin obtained the shift and two other investigations did not. These investigators and Frumkin used a competing response paradigm (requiring that subjects identify which syllable is heard more clearly) and the other two studies did not.

"In evaluating the possible confound of general somatic relaxation with hypnosis per se, the physiological data provide salient information. Davidson & Schwartz (1976) have discussed the limitations in evaluating the relaxation response as a unitary concept and have recommended looking at patterns of multiple physiological measures. Failing this, the best single measure is HR (Davidson & Schwartz, 1976)" (p. 356). In this case, HR decreased over the three conditions, remaining low in posthypnosis when laterality shifted back to REA. If the cerebral shift were due to relaxation, presumably there would not have been low HR during posthypnosis.

The authors note the lack of convergence in physiological measures (EMG showing no change, RR increasing during hypnosis and remaining high, HR decreasing during hypnosis and remaining low). Lack of convergence is typical in physiological studies of the relaxation response (Davidson & Schwartz, 1976). "However, whether the three physiological measures are considered as an overall pattern in determining level of somatic relaxation or whether HR is considered alone, increased somatic relaxation due to hypnosis cannot adequately account for both the shift toward more dominant right hemisphere activity in the hypnosis condition and the shift back to more dominant left hemisphere activity during the posthypnosis condition" (p. 356).

The authors acknowledge that the absence of either a low hypnotizable subject group or a relaxation control group suggests caution in interpretation of the results.

De Pascalis, Vilfredo; Marucci, Francesco; Penna, Pietronilla M.; Pessa, Eliano (1987). Hemispheric activity of 40 Hz EEG during recall of emotional events: Differences between low and high hypnotizables. International Journal of Psychophysiology, 5, 167-180.

This study evaluates individual differences in hypnotizability as reflected in waking-state hemispheric engagement during recollection of 3 positively and 3 negatively valenced personal life events. The State-Trait Anxiety Inventory, Maudsley Personality Inventory, Tellegen Absorption Scale and Harvard Group Scale of Hypnotic Susceptibility (Form A) were administered. Electromyogram (EMG) and bilateral electroencephalogram (EEG) activities within the 40-Hz band were recorded during rest and task conditions in 22 high and 21 low hypnotizable women. Self-report rating scores for vividness of visual imagery and emotional feeling of the material recalled were evaluated. The 40-Hz EMG amplitude and both

hemisphere 40-Hz EEG densities were obtained. A 40-Hz EEG ratio, as a measure of hemispheric asymmetry, and a hemispheric specificity index were also computed. High hypnotizables showed significantly lower 40-Hz EEG density than low hypnotizables in all experimental conditions. The relationship between lateralization of 40-Hz EEG and emotional processing was moderated by hypnotizability. High hypnotizables, with respect to rest condition, showed an increase of density over both left and right hemispheres during two of the three positive emotional tasks, while they showed a depressed activity over the left and an increased activity over the right during negative emotional tasks. Low hypnotizables, on the other hand, did not exhibit differential hemispheric patterns that could be attributed to different emotional valences. The high group showed greater hemispheric specificity in the predicted direction than the low group. High subjects exhibited greater ratings of absorptive ability and emotional feeling than low subjects. Anxiety and EMG levels did not differ between groups. EMG was dependent on the type of emotion which showed greater activity in the negative emotion condition compared with the positive one.

1986

Sargent, Joseph; Solbach, Patricia; Coyne, Lolafaye; Spohn, Herbert; Segerson, John (1986). Results of a controlled, experimental, outcome study of nondrug treatments for the control of migraine headaches. Journal of Behavioral Medicine, 9, 291-323.

Headache variables were examined for 136 subjects who participated for 36 weeks in one of four groups: No Treatment, Autogenic Phrases, EMG Biofeedback, Thermal Biofeedback. All subjects kept daily records of headache activity and medication usage and participated in 22 laboratory sessions during which frontalis EMG and hand temperature measurements were taken; those in the 3 treatment groups practiced at home. There was a substantial reduction in headache variables in all groups. The No- Treatment Group differed significantly from the treatment groups combined, with the least reduction in headache variables. The thermal biofeedback group vs EMG biofeedback and autogenic phrases groups showed a suggestive trend toward improvement in the frequency and intensity of total headache.

]1985

Miller, Lorence S.; Cross, Herbert J. (1985). Hypnotic susceptibility, hypnosis, and EMG biofeedback in the reduction of frontalis muscle tension. International Journal of Clinical and Experimental Hypnosis, 33, 258-272.

Biofeedback and hypnosis have been used in the treatment of similar disorders. While each has been useful, it is unclear whether they involve similar or conflicting processes. Bowers & Kelly (1979) have hypothesized that high hypnotizable Ss are more likely to benefit from hypnosis and similar procedures, than moderate and low hypnotizable individuals. In contrast, Qualls & Sheehan (1979, 1981 a, b, c) have argued that hypnosis and biofeedback involve antithetical abilities. In the present

study, high, moderate, and low hypnotizable individuals (N = 60) were randomly assigned to either EMG biofeedback or hypnosis conditions and instructed to relax. It was found that the mean percent reduction in frontalis muscle tension over the last 5 trials was significantly greater for the high hypnotizable Ss during hypnosis than the moderate and low hypnotizable Ss. The moderate and low hypnotizable Ss demonstrated greater reductions in frontalis muscle tension during EMG biofeedback than during hypnosis. These findings are partly supportive of the predictions of Qualls and Sheehan that hypnosis and biofeedback involve antithetical processes.

#### NOTES

Qualls and Sheehan (1979, 1981a) "have hypothesized that biofeedback and hypnosis abilities involve antithetical or antagonistic cognitive processes. Specifically, they argued that the biofeedback signal interferes with the natural ability of high absorption Ss to 'direct their attention in an effortless manner toward subjective, imaginal experience [1981a, p. 33],' by forcing them to attend to the external environment. In contrast, low absorption Ss, as well as moderate hypnotizable Ss, possess inadequate abilities to direct their attention in such an effortless and absorbing manner towards inner, subjective experiences, and therefore, the biofeedback signal better enables them to focus their attention. While the pattern of EMG results among the high, moderate, and low hypnotizable Ss ... was somewhat consistent with these predictions, the self-report data did not reveal differences in Ss' awareness of the biofeedback signal or hypnotic suggestions. In addition, there was only a trend for the high hypnotizable Subjects to report less effort in attempting to relax. It is, therefore, unclear whether the explanations postulated by Qualls and Sheehan (1979, 1981a) for the differences found in this study are valid" (p. 269).

Subjective relaxation response results were complex. Ss were asked how relaxed they were during the experimental session in comparison to the previous hypnosis sessions (screening tests). Biofeedback Ss rated the experimental session less favorably than hypnosis Ss. Ss were asked to what degree the feedback (or hypnotic suggestions) helped them to relax; there were significant main effects for treatment and trait, as well as a significant trait x sex interaction. Hypnosis Ss reported that this procedure was more helpful than was reported by the biofeedback Ss. Newman-Keuls comparison revealed that the main effect for trait was due to the high hypnotizable Ss reporting more help from the procedures than the low hypnotizable Ss, and moderate hypnotizable Ss. The Trait x Sex interaction was the result of the high hypnotizable female Ss indicating more help from either relaxation procedure, than was reported by the low hypnotizable male Ss and moderate hypnotizable female Ss and the high hypnotizable male Ss indicated that the procedures were significantly more helpful than was reported by the low hypnotizable male Ss.

Schlesinger, Jay Lawrence (1985). Hypnotizability in relation to success in learning biofeedback training: Attentional involvement (Dissertation, Adelphi University). Dissertation Abstracts International, 45 (n8-B), 2701. (Order No. DA 8424937)

## NOTES

This study investigated the role of attentional focus in the relationship between hypnotizability and success in learning two types of biofeedback training. 40 female college students, aged 18-25, were measured for hypnotic responsiveness, and given one session of EMG biofeedback and one session of temperature biofeedback. For the biofeedback training, 20 Ss received written instructions designed to establish a passive, non-volitional attentional focus on the feedback signal, and 20 received written instructions intended to establish an active, volitional attentional focus on the feedback signal.

"It was hypothesized that level of hypnotizability would be positively related to success in learning EMG and temperature biofeedback training for the Ss given passive, non-volitional attentional instructions, while level of hypnotizability would be negatively related to success in learning biofeedback training for the Ss given active, volitional attentional instructions. It was also hypothesized that higher hypnotizables would perform better with temperature biofeedback than with EMG biofeedback, and that lower hypnotizables would perform better with EMG biofeedback than with temperature biofeedback.

"The hypotheses were not supported, nor was any overall relationship between level of hypnotizability and success in learning biofeedback demonstrated. There was support to suggest that an active, volitional attentional focus on the biofeedback signal was most adequately maintained by the 20 Ss given the active volitional instructions. Clinical implications of these findings and directions for future research were discussed" (p. 2701).

### 1983

Radtke, H. Lorraine.; Spanos, Nicholas P.; Armstrong, L. A.; Dillman, N.; Boisvenue, M. E. (1983). Effects of electromyographic feedback and progressive relaxation training on hypnotic susceptibility: Disconfirming results. International Journal of Clinical and Experimental Hypnosis, 31 (2), 98-106.

The efficacy of relaxation training in modifying hypnotic susceptibility was investigated. Following 2 pretests of hypnotic susceptibility, 24 Ss who scored 7 or below on both tests were randomly assigned to 1 of 2 relaxation training groups (EMG-biofeedback or progressive relaxation) or a no-treatment control group. Relaxation training was conducted over 10 20-minute sessions and was monitored by measurement of frontalis EMG. All Ss were then administered a posttest of hypnotic susceptibility. Hypnotic susceptibility did not increase significantly from pretest to posttest. Moreover, change in frontalis EMG was unrelated to change in susceptibility. These results fail to confirm earlier work conducted by Wickramasekera (1972, 1973, 1977).

### 1982

Credidio, Steven G. (1982). Comparative effectiveness of patterned biofeedback vs meditation training on EMG and skin temperature changes. Behaviour Research and Therapy, 20, 233-241.

Examined whether a low arousal, relaxation pattern of frontalis EMG decreases and peripheral skin temperature increases could be attained more effectively through biofeedback or meditation training. 30 21-59 yr old females were randomly assigned to 1 of 3 groups: patterned biofeedback, clinically standardized meditation, or control. Prior to training, Ss were administered the Eysenck Personality Inventory. Each S was seen weekly for 7 sessions. Subjective experiences and time spent practicing at home were also recorded. Results indicate that the meditation group showed significantly lower EMG levels at the end of treatment than did the control group. The biofeedback group had difficulty in patterning the 2 feedback signals simultaneously. Extraverts in the control group had the highest EMG levels. The most positive subjective reports came from Ss in the meditation group. It is suggested that meditation offers a viable alternative as a relaxation procedure, requiring little time to learn and devoid of any performance criteria levels.

Holroyd, Jean; Nuechterlein, Keith; Shapiro, David; Ward, Frederick (1982). Individual differences in hypnotizability and effectiveness of hypnosis or biofeedback. International Journal of Clinical and Experimental Hypnosis, 30 (4), 45-65.

8 high and 8 low hypnotizable Ss used biofeedback and hypnosis to lower blood pressure in one session and forehead EMG activity in another session. Results were analyzed by repeated measures analyses of covariance using baseline physiological level on the dependent variable as the covariate. Electromyographic level was reduced more immediately by biofeedback than by hypnosis. When the task was to lower blood pressure, blood pressure and skin conductance were more effectively reduced by hypnosis than by biofeedback, considering only the first half of each session to eliminate within-session transfer effects. Hypnotizability did not predict overall outcome. Factors which may have prevented demonstrating a clearer relationship between hypnotizability and success using biofeedback or hypnosis are discussed. State and trait anxiety, cognitive strategies used during the tasks, and self-reported hypnotic depth are examined for correlates of successful performance.

Schuyler, Bradley A. (1982). Further investigation of volitional and nonvolitional experience during posthypnotic amnesia (Dissertation, California School of Professional Psychology, Fresno). Dissertation Abstracts International, 44 (n6-B), 1977. (Order No. DA 8324472)

Electrodermal responses were compared between highly responsive hypnotic Ss who were classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia. Three contextual conditions were employed: Two were meant to create pressure to breach posthypnotic amnesia (lie detector instructions alone or with feedback that Ss had been detected as not having told all they could remember); the other provided feedback, in addition to the lie detector instructions, that Ss had told all they could remember. The recall data confirmed earlier findings of Coe and Yashinski and

showed that voluntary and involuntary Ss did not differ in response to the contextual conditions. However, lie detector instructions alone did not create pressure to breach as in previous studies. In addition, electrodermal results were insignificant. The results are discussed as they relate to (a) amnesia, (b) the physiological detection of deception and physiological activation, (c) the voluntary/involuntary classification of Ss, and (d) theories of hypnosis" (p. 1977).

**1981**

**Cott, A.; et al. (1981). The long-term therapeutic significance of the addition of electromyographic biofeedback to relaxation training in the treatment of tension headaches. Behavior Therapy, 12, 556-559.**

Eight tension headache sufferers seeking traditional medical treatment from a neurologist participated in either a therapist-delivered relaxation training (RT) condition or an RT plus EMG feedback condition. Mean hours of pain/day, headache severity, and medication ingestion were significantly lower in both groups following treatment. Results were maintained at a 1-year follow-up for hours of pain/day and medication ingestion. Findings thus indicate no benefit of adding EMG feedback to relaxation training.

**Tellegen, Auke (1981). Practicing the two disciplines for relaxation and enlightenment: Comment on 'Role of the feedback signal in electromyograph biofeedback: the relevance of attention' by Qualls and Sheehan. Journal of Experimental Psychology: General, 110, 217-226.**

High and Low Absorption Ss differ in set rather than in capability for attending to external or internal stimuli, as Qualls and Sheehan suggest. Trait x Treatment interaction for Absorption illustrates concept of personality dispositions being inherently interactive functional units. Provides a content analysis of Absorption scale (subscales) and relates absorption to other constructs in psychology. "It is not the internal versus external focus per se that play a decisive role but the subject's experiential versus instrumental set. For example, with two treatment levels, one would expect to obtain an Absorption x Treatment interaction even if both treatment conditions required an external attentional focus, as long as they contrasted an experiential and an instrumental set" (pp 223-224).

**1979**

**Quall, Penelope J.; Sheehan, Peter W. (1979). Capacity for absorption and relaxation during electromyograph biofeedback and no-feedback conditions. Journal of Abnormal Psychology, 88 (6), 652-662.**

The present research examined the relation between absorption capacity and relaxation during electromyograph biofeedback and no-feedback (instructions only) conditions. Sixteen high absorption and 16 low absorption female subjects underwent a biofeedback and no-feedback session with the order of conditions counterbalanced. For high absorption subjects in the first session, EMG reductions

were greater during no- feedback than during biofeedback, although the performance of biofeedback subjects improved in the second session. For low absorption subjects, no differences in EMG reductions were apparent across experimental conditions. Postexperimental self-report data demonstrated differences between absorption groups in subjects' state of arousal and quality of consciousness. It was concluded that for subjects with high capacity for absorbed attention, experimental conditions that allow for a withdrawal from the external environment are most conducive to relaxation, whereas for subjects with limited capacity for absorbed attention, conditions such as biofeedback that place an attentional demand on subjects may be preferable.

**1978**

Acosta, Frank X.; Yamamoto, Joe; Wilcox, Stuart A. (1978). Application of electromyographic biofeedback to the relaxation training of schizophrenic, neurotic, and tension headache patients. Journal of Consulting and Clinical Psychology, 46 (2), 383-384.

This study examined the effects of electromyographic (EMG) biofeedback on tension reduction by schizophrenic, neurotic, and tension headache patients. Fourteen patients participated voluntarily in at least 10 weekly EMG biofeedback sessions at a public outpatient clinic. All had complained of chronic tension. Patients showed significant decreases in their muscle tension levels with successive biofeedback training sessions. No significant differences were found between the schizophrenic, neurotic, and tension headache groups. A further contribution was the finding that patients with diverse socioeconomic and educational levels benefitted similarly from EMG biofeedback training.

Counts, D. Kenneth; Hollandsworth, James G., Jr.; Alcorn, John D. (1978). Use of electromyographic biofeedback and cue-controlled relaxation in the treatment of test anxiety. Journal of Consulting and Clinical Psychology, 46 (5), 990-996.

The effect of using electromyographic (EMG) biofeedback to increase the efficacy of cue-controlled relaxation training in the treatment of test anxiety was studied. Forty college undergraduates scoring in the upper third on a self-report measure of test anxiety were randomly assigned to one of four treatment conditions - EMG-assisted cue- controlled relaxation, cue-controlled relaxation alone, attention-placebo relaxation, and no-treatment control. Pre-post self-report measures of test anxiety, state anxiety, and trait anxiety were obtained. In addition, a performance measure in the form of a mental abilities test was administered. Subjects from the three relaxation groups received six 45- minute individual sessions over a period of 2 weeks. All treatments were conducted using audiotape recordings. The results indicate that cue-controlled relaxation is effective in increasing test performance for test anxious subjects, that EMG biofeedback does not contribute to the effectiveness of this procedure, and that self-report measures of anxiety are susceptible to a placebo effect.

Parwatikar, Sadashiv D.; Brown, Marjorie S.; Stern, John A.; Ulett, George A.; Sletten, Ivan S. (1978). Acupuncture, hypnosis and experimental pain - I. Study with volunteers. Acupuncture and Electro-Therapeutic Research: International Journal, **3**, 161-190.

An experiment was designed to evaluate the protective effects of different agents - acupuncture, hypnosis, Morphine, aspirin, Diazepam and placebo - upon experimentally-induced pain in humans. Twenty normal, healthy volunteers were subjected to cold water and tourniquet- induced pain and the protective effects of 35 minutes of hypnotic suggestion, electro- stimulation of both acupuncture points and non-acupuncture points, 10 mg/kg of Morphine, 5 grains of aspirin, 10 mg of Diazepam and a mild sugar placebo were evaluated. Data was collected on subjective evaluation of pain, EKG, EEG, respiration, skin temperature, peripheral vascular activity and EMG. A special study was also done to evaluate the effects of all the above agents on the somatosensory evoked potentials and EEG. The data were further analyzed on the basis of hypnotic susceptibility of the volunteers. The results indicated: 1) Hypnosis, acupuncture at specific sites with electrical stimulation and Morphine Sulphate had about the same reduction in experimental pain. 2) Hypnosis produced different effects from those resulting from acupuncture stimulation on EEG. 3) Acupuncture stimulation in specific loci resulted in a latency increase in the early secondary response on somatosensory evoked potential. 4) Cold water pain was remarkably reduced after true acupuncture point stimulation. 5) Tourniquet (ischemic) pain was reduced by both hypnosis and true acupuncture site stimulation. 6) Skin temperature was significantly reduced on the side of acupuncture points (true) stimulation.

1975

Alexander, A. Barney (1975). An experimental test of assumptions relating to the use of electromyographic biofeedback as a general relaxation technique. Psychophysiology, 656-662.

Twenty-eight normal adults participated in an experimental test of two assumptions underlying the use of electromyographic (EMG) biofeedback as a general relaxation training technique: 1) that trained EMG reduction in one muscle generalizes to untrained muscles; and 2) that subjective feelings of relaxation are related to EMG reduction. An experimental group received 5 sessions, during the middle 3 of which EMG biofeedback training was offered on the frontalis muscle. Throughout all sessions, EMG recordings were also taken from the forearm and lower leg, and rating of subjective relaxation feelings were obtained at regular intervals. A control group, matched with the experimental group on baseline frontalis EMG, received 5 similar sessions without feedback. Employing a maximum p of .05, the results revealed no evidence of generalization of EMG reduction from the frontalis to the untrained sites, nor any tendency for successful frontalis EMG reduction to result in increased feelings of relaxation beyond what was obtainable from relaxing without the benefit of training. The results were interpreted as suggesting the EMG

biofeedback cannot yet be accepted as a viable general relaxation training technique.

**Andrews, Reagan H., Jr. (1975). Placebo effects in EMG biofeedback (Dissertation). Dissertation Abstracts International, 36, 1424.**

Differential instructions were employed in a negative placebo model to alter expectancies of success in achieving criterion frontalis EMG voltage levels in 30 female subjects. The negative placebo model dictated that all subjects receive true feedback during both of two 10-minute experimental trials. On one of the two trials they were informed that feedback would be accurate, and on the other trial, that feedback would be accurate only 50% of the trial period. Data was collected for 20 subjects in a 2 X 2 Latin Square design, while 10 subjects were designated control subjects and received high-success expectancy instructions on both experimental trials. Pre-trial measures included administration of a standard hypnotic susceptibility scale and a pre-test subjective questionnaire. Dependent variable was the time from onset of feedback to 70% reduction of resting EMG levels of the frontalis. Significant differences were found between high and low-expectancy trials for experimental subjects. Effects were strongest on the first experimental trial and tended to diminish on the following trial. Correlation of hypnotic susceptibility scores with response latencies was not significant, but subjects' impression of their degree of relaxation during susceptibility scale administration was significantly correlated with criterion latencies. Importance of subject expectancies, instrumentation standards and implications for future studies in the biofeedback area were discussed" (p. 1424).

**Wickramasekera, Ian (1973). Effects of electromyograph feedback on hypnotic susceptibility: More preliminary data. Journal of Abnormal Psychology, 82 (1), 74-77.**

The purpose of this double-blind study was to determine if taped verbal relaxation instructions and response-contingent electromyographic feedback training would increase suggestibility or hypnotic susceptibility over that obtained with instructions and false or noncontingent feedback, The present data appear to confirm the hypothesis

**1954**

**Malmo, Robert B.; Boag, Thomas J.; Raginsky, Bernard B. (1954). Electromyographic study of hypnotic deafness. Journal of Clinical and Experimental Hypnosis, 2 (4), 305-317.**

**NOTES**

**Summary and Conclusions.** The main purpose of the present study was to investigate the question of similarities and differences between hysterical deafness, previously studied, and hypnotically induced deafness. The study was designed to

repeat the objective physiological tests previously carried out with a case of 'total hysterical deafness.' There was also the more general aim of securing objective data to enrich our general understanding of hypnosis.

"Similarities between hysteria and hypnosis which we observed may be listed as follows: (a) Significantly reduced motor reaction (exclusive of blink) to strong auditory stimulation in the deaf state. (b) Complete hearing loss in the hysteric and in one of the hypnotic subjects, even with strong auditory stimulation (i.e., denial of any auditory sensation). (c) With elicitation of strong startle reaction to the first stimulus in the deaf state, much smaller reaction to the next stimulus than would have been predicted on the basis of habituation. (d) Suggestion of substitution of somesthetic for auditory sensations in all subjects (although this was much less definite in the hypnotic subjects than the hysteric).

"The most outstanding dissimilarity lay in the absence of emotional reaction when 'hypnotic defense against sound' was broken through, in contrast to marked affective reaction in the hysterical subject under these conditions.

"The question of inhibitory mechanisms in hysteria and hypnosis was discussed" (pp. 316-317).

**1993**

Lyskov, E.; Juutilainen, J.; Jousmaki, V.; Hanninen, O.; Medvedev, S.; Partanen, J. (1993). Influence of short-term exposure of magnetic field on the bioelectrical processes of the brain and performance. International Journal of Psychophysiology, 14, 227-231.

The influence of an extremely-low-frequency (ELF) magnetic field on the bioelectrical processes of brain and performance was studied by EEG spectral analysis, auditory-evoked potentials (AEP), reaction time (Roletaking) and target-deletion test (TDT). Fourteen volunteers were exposed for 15 min to an intermittent (1 s on/off) 45- Hz magnetic field at 1000 A/m (1.26 mT). Each person received one real and one sham exposure. Statistically significant increases in spectral power through alpha- and beta- bands, as well as in mean frequency of the EEG spectrum were observed after magnetic field exposure. Field-dependent changes of N100 were also revealed. No changes in the amplitudes or latencies of the earlier peaks were observed. No direct effects on Roletaking, nor on TDT performance were seen. However, practice effects on Roletaking (decrease of Roletaking in the course of the test-sessions) seemed to be interrupted by exposure to the magnetic field.

**1992**

Frederick, Claire C.; Phillips, Maggie (1992). The use of hypnotic age progressions as interventions with acute psychosomatic conditions. American Journal of Clinical Hypnosis, 35 (2), 89-98.

Age progression as a hypnotherapeutic technique is mentioned infrequently in the literature when compared with its counterpart, age regression. In this paper we explore the use of progressions, or 'views of the future,' as prognostic indicators of therapeutic progress and as valuable tools for ego strengthening and for the integration of clinical material. Age progressions vary in the types of suggestions given and can be used to promote growth on multiple levels, facilitating treatment goals and deepening the working-through process. We present six cases in which we used different types of age progressions, and we discuss the significance of the progressions used in each case, within the context of relevant clinical material. We conclude from our observations that the use of hypnotic progressions can be a sustaining, valuable aspect of hypnotherapy, particularly in providing an index of the current direction and progression of the therapy process itself. - Journal abstract.

1989

Bierman, Steven F. (1989). Hypnosis in the emergency department. American Journal of Emergency Medicine, 7, 238-242.

Five cases are presented wherein hypnosis was used by the emergency physician either as the primary mode of treatment or as an adjuvant to standard medical care. Common hypnotic phenomena (e.g. anesthesia, analgesia), as well as novel effects, are reported. The technique used for trance induction and utilization is briefly outlined, and criteria are set forth for the bedside recognition of hypnotic trance.

Venn, Jonathan (1988). Hypnotic intervention with accident victims during the acute phase of posttraumatic adjustment. American Journal of Clinical Hypnosis, 31, 114-117.

Victims of accidents or other trauma often experience acute symptoms of confusion, disorganization, and intrusive memories. Victims can be extremely suggestible

during their initial adjustment, and they readily comply with suggestions to enter hypnosis. Reframing and other hypnotic interventions can be useful in managing acute symptoms and may facilitate long-term adjustment. A case is presented in which hypnosis was successfully used with a man who was acutely distressed after accidentally killing a pedestrian. Whether the heightened suggestibility experienced during acute posttraumatic adjustment entails an increase in hypnotizability is an interesting topic for future research, and one which has theoretical import.

1986

Kohen, D. P. (1986). Applications of relaxation/mental imagery (self-hypnosis) in pediatric emergencies. International Journal of Clinical and Experimental Hypnosis, 34 (4), 283-294.

Problems for which children come to Emergency Rooms are anxiety-producing for children and parents, whether or not these problems are perceived as "true" emergencies by health care professionals. Fear and pain are important factors in the response to such situations. Self-hypnosis (relaxation/mental imagery) is a useful adjunct for rapid reduction of anxiety and discomfort in pediatric emergency situations; it can serve to diminish fear, improve self-control, and alter the perception of discomfort. Hypnosis can also enhance development of a sense of mastery in the injured or ill child. 6 case examples are described which illustrate the variety of specific clinical applications and hypnotherapeutic approaches.

1981

Kleinhauz, Moris; Beran, B. (1981). Misuses of hypnosis: A medical emergency and its treatment. International Journal of Clinical and Experimental Hypnosis, 29 (2), 148-161.

Hypnosis is an intense interpersonal relationship requiring 2-way respect and involvement. Inadequate understanding of this dynamic relationship, and a consequent inability to cope with its potential dangers, may result in posthypnotic trauma. Unless treated carefully by a hypnotherapist who is experienced in both the techniques of dehypnotization and the utilization of psychotherapy, such traumas may persist for a very long time. In this paper, one striking case illustrates mishandling of the hypnotic event and immediate posthypnotic treatment and details the procedure by which successful treatment was eventually determined.

1972

Hodge, James R. (1972). Hypnosis as a deterrent to suicide. American Journal of Clinical Hypnosis, 15 (1), 20-24.

A method that has been found successful in temporarily deterring suicide attempts is to give the post-hypnotic suggestion that the patient will not be able to carry out an actual suicide attempt until he has discussed it with the psychiatrist, in advance of the attempt, and in the psychiatrist's office, and further, that the patient will

agree to enter a trance at any time the psychiatrist insists, even though the patient may not wish to do so. The rationale for this approach is that, (a) A temporary deterrent is often all that is necessary to prevent a given suicide attempt, (b) Hypnosis can have only a temporary deterring effect on suicide, (c) A direct and permanent confrontation that he can never commit suicide would be bound to fail and would not promote therapy of the personality, and (d) It gives the patient an alternative to suicide.

1972

Weitzenhoffer, A. M. (1972). Open-ended distance hypnotherapy. American Journal of Clinical Hypnosis, 14 (4), 236-248.

Distance hypnosis and hypnotherapy, i.e., via the telephone or the postal service, is not new, having been mentioned a number of times in the scientific literature of the late 19th Century. However, despite its actual as well as potential usefulness, distance hypnotherapy appears to have remained relatively unknown and unused. This article presents the detailed modus operandi of the technique and a number of illustrative cases.

1959

Hodge, James R. (1959). The management of dissociative reactions with hypnosis. International Journal of Clinical and Experimental Hypnosis, 7 (4), 217-221. (Abstracted in Psychological Abstracts 61:920)

## NOTES

### Conclusions

A case report is given of an unusual type of dissociative reaction, and treatment by a variety of hypnotic techniques is described. A distinction is made between the emergency and long term aspects of treatment by hypnosis, and emphasis is laid upon understanding the symptom and avoiding a too rapid challenge of the symptom. Special mention is made of the technique of predicting the future of the symptom" (p. 221).

"The patient was a 19 year old white Marine who became subject to hysterical seizures in which he acted the part of his own dog which had died several years before. The attacks occurred at irregular intervals; but when the patient was first seen they were occurring about twice weekly. During these seizures, which came on without warning, the patient would get down on all fours, bark and growl like a dog, attack ward personnel, paw at the floor, and respond to simple commands like those given to a dog such as 'Down, boy' or 'Play dead'. He would become motorically hyperactive and sometimes pound his head against the floor or walls. The really dangerous act which he performed, however, was to attempt to gouge out his own eyes with his hands; and for this reason cuff restraints had to be applied during each attack. There were no methods, until hypnosis was tried, which could control or terminate these attacks, which usually lasted from 30 to 60 minutes" (p. 217).

1955

Rosen, Harold (1955). Regression hypnotherapeutically induced as an emergency measure in a suicidally depressed patient. Journal of Clinical and Experimental Hypnosis, 3 (1), 58-70.

## NOTES

After cautioning that regressive techniques are only to be undertaken by very experienced therapists, the author states in conclusion, "However, if the therapist have a thorough grounding in dynamic psychiatry, he may as an emergency measure, through the adjunctive use of hypnotic techniques of the type described in this article even induce regressive phenomena in the potentially homicidal or suicidal psychotic patient, in order that they may be integrated and utilized in the service of the ego, at first by blotting out ego-boundaries between patient and therapist, so that later on during the course of the therapeutic process these self-same ego-boundaries may be re-defined and re-constituted on a more mature emotional level and with much healthier personality functioning.

## EMOTION/MOOD

### 1995

Crawford, Helen J.; Kapelis, Lia; Harrison, David W. (1995). Visual field asymmetry in facial affect perception: Moderating effects of hypnosis, hypnotic susceptibility level, absorption, and sustained attentional abilities. International Journal of Neuroscience, 82 (n1-2), 11-23.

Effects of hypnotic level, affect valence and cerebral asymmetry on reaction time (RT) in the discrimination of Ekman and Friesent (1978) stimuli of angry and happy faces were studied in counterbalanced conditions of waking and hypnosis. Assessed previously on two hypnotic susceptibility scales (Harvard Group Scale of Hypnotic Susceptibility; Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C)], non-depressed subjects were 16 low (0-4 SHSS:C) and 17 highly (10-12 SHSS:C) hypnotizable, right-handed college students. Subjects were required to identify affect of faces, presented tachistoscopically to left (LVF) or right (RVF) visual fields, by using a forced-choice RT paradigm. Highs were significantly faster than lows in angry and happy affect recognition. Hypnosis had no significant effects. For highs only, angry emotional valence was identified faster when presented to the right hemisphere (RVF), but there were no significant hemispheric effects for happy emotional valence. For lows there were no hemispheric differences. Gender was a nonsignificant factor. Significant correlations showed that faster reaction times to angry and happy stimuli, in both LVF and RVF in waking and hypnosis, were obtained by subjects who reported more deeply absorbed and extremely focused and sustained attention on the Tellegen (1982) Absorption Scale and a subscale of the Differential Attentional Processes Inventory (Grumbles & Crawford, 1981). Vividness of Visual Imagery Questionnaire (Marks, 1973) and Affect Intensity Measure (Larsen, 1985), in general, did not correlate with RTs. The potential role of the fronto-limbic attentional system in the recognition of external visual sensory affect is discussed.

## NOTES

1:

In the last 5-6 years we see a beginning of a consistency in this type of research on EEG and hypnosis. Baseline EEG theta for high and low hypnotizable Ss was higher significantly in frontal and temporal areas; less significantly in parietal and occipital areas. It begins to look like a signature of hypnotizability. Our research will be published in the Journal of Abnormal Psychology next year.

In Japan they see theta as sustained attention; some aspects of theta relate to MAO and also to dopamine. Betsy Faith did the same research, replicating almost exactly. There are no differences between Highs and Lows in alpha or beta; but we find differences in theta (especially frontal, and in 40 Hz more posteriorly). It may not be L-R hemisphere difference as previously thought, but more a rostral-caudal dimension.

The signature to hypnotizability is more frontal theta at baseline. This may also relate to a drop in theta after induction, but those results are not so clear. Highs have a larger drop in theta from pre to post induction than is observed in the Lows. We did a "chaos analysis" of EEG. There are three main measures, including dimensionality. Dimensionality is a measure of complexity. People demonstrate high dimensionality when asked to do tasks, low dimensionality in anesthesia.

High hypnotizable Ss start an induction with higher dimensionality than the Low hypnotizable Ss, and as we go through the induction they remain the same. So this measure shows individual differences but does not give evidence of a state (because it doesn't change).

Chaos dimensions for 2 mental math problems show lower dimensions in frontal compared to posterior areas; but for imagery [labeled on slide as positive and negative emotional tasks] the dimension is the same across areas.

For the dimension measures, lows look like they are doing mental math and highs look like they are doing imagery, in baseline.

**SECOND PART OF RESEARCH--DISSOCIATION.** For 100 years dissociation and hypnosis have been viewed as similar. Two dissociation scales were used - Putnam's DES and Reilly's scale. A factor analysis found four factors: 1. absorption or derealization 2. depersonalization 3. segment amnesia 4. in situ amnesia (Segment amnesia differs from in situ amnesia because you wake up to it at that moment in the in situ vs the segment case.)

We have 20-30 people who score very high on hypnotizability.

Colin Ross finds the same factors as our factors 1 and 2, but he finds only one amnesia factor where we find two.

The correlation between DES and Harvard ranges .05 to .18. Are the high hypnotizables related to high dissociatives, with others not related? A scatter plot did not reveal that.

FFT EEG bands during baseline for high and low dissociation Ss find no differences for high and low dissociative subjects. We conclude that dissociation and hypnosis are two orthogonal processes.

Now we are beginning to look at the pathways that lead one to become highly hypnotizable or dissociative.

**COMMENTS FROM THE AUDIENCE:**

**Ian Wickramasekera:** Have you introduced threat to high or low DES people?

**Answer:** High and Low DES people with happy and unhappy imagery tasks do the opposite, with the dimensionality measure. With emotionality you don't see stable baseline differences, you see reactivity differences.

**A. Barabasz:** I think the DES isn't a good measure of dissociation in hypnosis which is voluntary and not pathological.

**D. Spiegel:** Sabourin's study found more theta in left frontal during hypnosis, whereas you found less. **Answer:** That's why I don't know what to do about the state effects.

**J. Crawford:** Sabourin had Ss doing tasks, so they may have been more active than yours.

**1993**

**Bruehl, Stephen; Carlson, Charles R.; McCubbin, James A. (1993). Two brief interventions for acute pain. Pain, 54, 29-36.**

This study evaluated two brief (3-5 min) interventions for controlling responses to acute pain. Eighty male subjects were randomly assigned to 1 of 2 intervention groups (Positive Emotion Induction (PEI) or Brief Relaxation (BR)) or to 1 of 2 control groups (No-instruction or Social Demand). The PEI focused on re-creating a pleasant memory, while the BR procedure involved decreasing respiration rate and positioning the body in a relaxed posture. All subjects underwent a 60-sec finger pressure pain trial. Analyses indicated that the PEI subjects reported lower ratings of pain, fear, and anxiety, and experienced greater finger temperature recovery than controls. The BR procedure resulted in greater blood pressure recovery, but did not alter ratings of pain or emotion relative to controls. Further research is needed to explore the clinical use of the PEI for acute pain management.

**Pekala, Ronald J.; Ersek, Barrett (1993). Firewalking versus hypnosis: A preliminary study concerning consciousness, attention, and fire immunity. Imagination, Cognition and Personality, 12, 207-229.**

This study assessed the subjective effects associated with firewalking, and compared them with the subjective effects associated with hypnosis and a baseline condition (eyes closed sitting quietly). Twenty-seven subjects, who walked over hot coals during a firewalk ceremony, completed questionnaires about what they subjectively experienced during the firewalk. Their experiences were subsequently compared with those of subjects (n = 246) who experienced hypnosis and a baseline condition. The data suggested that firewalking, as assessed across all subjects, is characterized by high levels of volitional control and rationality, and a very absorbed attentional

style wherein the mind is one-pointed, and consciousness is characterized by strong feelings of joy and high levels of internal dialogue. Firewalking was also found to be associated with significantly more joy, one-pointedness of thought, absorption, and internal dialogue than hypnosis or the baseline condition. In addition, a cluster analysis suggested two subgroups of firewalkers based on their subjective experiences of the firewalk. Interestingly, analyzing the attentional experiences among these firewalkers who got slightly burned, versus those who did not, revealed significant differences. A one-pointed and absorbed attentional focus may be the critical variable for the fire immunity observed in firewalking.

## NOTES

1:

About 500 people walked across coals, in 3-4 steps. At end of weekend, 71 said they would complete a questionnaire and it was mailed to them. Of those, 27 responded (25 of 26 in an average of 23 days). Hence, 5% of the population who walked responded to the questionnaire, and it was some time later. Three of 24 reported minor blisters. Those who didn't get burned reported less detachment, less of a feeling of being out of their bodies, and more thoughts than the firewalkers who got slightly burned.

Pekala has defined an altered state of consciousness as associated with the perception of being in an altered state of awareness (the \_subjective sense\_ of \_altered state\_ --SSAS [30]), and a change in the patterning or configuration of the subsystems or dimensions of consciousness. A discrete state of consciousness, as defined by Pekala, is associated with a significant pattern change but no perceived alteration in state of consciousness (no SSAS). An identity state of consciousness, on the other hand, is defined as having neither a significantly perceived alteration in state of awareness nor a perceived pattern change among dimensions of consciousness in reference to another state of consciousness. Since the PCI can measure both intensity and pattern effects, it can be used to assess for altered, discrete, and identity states of consciousness.

Using a cluster analysis they found that one group of 16 subjects reported the firewalk experience to be characterized by a significant alteration in awareness and experience (body image, time sense, etc.), and significant intensities of internal dialogue, positive and negative affect, and arousal, while a second group of six subjects reported little alteration in consciousness or experience, little losses in rationality or control, and less internal dialogue, positive and negative affect or arousal than the larger group.

Whereas hypnosis is usually associated with a loss in control (the classic suggestion effect), firewalking was found to be associated with increased control, a more aroused state, and more fear! Firewalking appears to be a more absorbed and one-pointed state than even hypnosis.

The nature of attentional experience is similar across firewalkers (DAQ results).

Both firewalking and hypnosis meet the criteria for altered states of consciousness (different pattern and different subjective experience), but they are not altered states in reference to each other; they are \_discrete states of consciousness\_ in reference to each other, because there is a significantly different patterning of PCI dimensions between the two conditions, but no significant SSAS. This suggests that

the firewalk state is qualitatively different from the hypnotic state (as induced by the induction procedure to the Harvard Scale) and probably represents a different type of state of consciousness than hypnosis. Firewalkers obtained a lower mean hypnoidal state score than hypnosis subjects, so it does not appear that the fire immunity is due to being in a "hypnotized" state.

The fact that there appears to be two groups of successful firewalkers, one of which did not report much alteration in consciousness, calls into question the theorizing concerning the importance of alteration in state of consciousness as being etiologically related to successful firewalking. Since about 25 percent of the firewalkers clustered into what appears to be a nonaltered state of awareness, this suggests a sizable percentage of subjects who did not report any significant alteration in consciousness and experience.

Hence, what may be important is not an alteration in consciousness, but rather an alteration in attention. The cluster analysis revealed a relatively unitary attentional state across all subjects suggesting that attention was deployed in a rather similar manner across all subjects, that is, with very high absorption and one-pointedness. It was also the DAQ dimensions, and not the PCI dimensions, that successfully discriminated a trend between the blistered and nonblistered firewalkers. Hence, high levels of one-pointedness and absorption, that is, how attention is deployed during firewalking may be more critical (than an alteration in consciousness in general) for the fire immunity observed during firewalking.

Bindler, Paul (1992, October). Hypnosis and Psychotherapy: The clinical utility of altered states of consciousness. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

NOTES

1:

Author assesses state, especially attentional changes, with Multidimensional Consciousness Scale (receptivity, arousal, .... etc.)

Clinical management of anxiety is goal. Cites Nash as characterizing anxiety disorders with cognitive/affective characteristics similar to hypnotized state. Wickramasekera's model has people high in neuroticism and high in hypnotizable being hypersensitive to stress, with physiological hyperarousal. Lows have alexithymia, may be unresponsive to symbolic events but very responsive to concrete events; poor verbalization of alexithymics leads to somatization.

Author focuses on relaxation and anxiety reduction. Suggests that Crawford's attention model (highs better able to shift cognitive and attentional strategies) is useful.

Instructions facilitate focusing attention inward so external stimuli become irrelevant. Therapist helps patient focus attention on the link between cognitions and tension.

Isenberg, S. A.; Lehrer, P. M.; Hochran, S. (1992). The effects of suggestions and emotional arousal on pulmonary functions in asthma: A review and a hypothesis regarding verbal mediation. Psychosomatic Medicine, 54, 192-216.

This paper reviews the empirical literature on the relation between asthma, suggestion, and emotion, and proposes the hypothesis that these effects are mediated parasympathetically. The literature indicates that, among asthmatics, suggestion can produce both bronchoconstriction and bronchodilation, and that stress can produce bronchoconstriction. The proportion of asthmatic subjects showing bronchoconstriction to both suggestion and stress averages 35%-40% across studies, but, because of methodological considerations, might be conservatively estimated as closer to 20%. The effect is smaller for suggestion of bronchodilation, and is very short-lived among nonasthmatics. No clear connection has been found between these responses and such subject variables as age, gender, asthma severity, atopy, or method of pulmonary assessment, although some nonsignificant tendencies appear. Most studies in this literature used small n's and did not systematically examine various somatic, environmental, and demographic factors that could influence results. A hypothesis is presented regarding vagal mediation of psychological effects on the airways, as well as possible alternative mechanisms, and recommendations for future research to evaluate these hypotheses.

1992

Kihlstrom, John F.; Barnhardt, Terrence M.; Tataryn, Douglas J. (1992). The psychological unconscious. American Psychologist, 47, 788-791.

In response to Greenwald's article on contemporary research on unconscious mental processes, the authors address three issues: (a) the independence of much recent research and theory from psychodynamic formulations; (b) the broad sweep of the psychological unconscious, including implicit perception, memory, thought, learning, and emotion; and (c) the possibility that the analytic power of unconscious processing may depend both on the manner in which mental contents are rendered unconscious and the manner in which they are to be processed.

Mare, Cornelia; Lynn, Steven Jay; Segal, David; Sivec, Harry; Marsden, Kim; Myers, Bryan (1992, October). The 'dream hidden observer': A real-simulator comparison. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

NOTES

1:

In previous research, after the Stanford Scale Form C dream suggestion, the authors gave the suggestion to the Ss that "in hypnosis you can discover part of the unconscious mind that is aware of new thoughts, images, that might be related or might not be related to your dream; let your index finger lift when that happens." There were strong demand effects observed in those Ss.

94% of highs and 78% of mediums passed the hidden observer test, with more personal and more primary process material produced in the hidden observer

condition. All Ss recalled their suggested dreams after awakening, but only 1/3 recalled their hidden observer. The authors think it was because Ss thought the hidden observer was "unconscious."

Authors compared highs with low simulators in the present study. Michael Nash says two things differentiate highs: more primary process thinking, and more affect availability in hypnosis. In this study, if high hypnotizables' dreams have more of these, it would support the psychoanalytic model.

N = 18 Highs who passed 9 Harvard Scale suggestions; 18 lows passed 3 or fewer suggestions. Simulating instructions were from Orne, 1977.

Hypnotists were blind to the hypotheses and to the hypnotizability of Ss. This differs from the first study in two ways: (1) instructions to Ss (here they were more like Hilgard's original suggestions), and (2) more probing about dream content before receiving the hidden observer instructions.

We did a 5-point scale on bizarre content, on different thoughts after the experience, and on additional content. Primary process was measured by Bizarre Content and by Shifts in Time or Location. Did ANOVA on 2 primary process and 3 affect measures. Many other analyses also were used. Even under multiple probes, most Ss passed hidden observer test. (In both groups only 1 didn't pass the hidden observer test.) So it is a very reliable suggestion, suggesting that hidden observer instructions are a very credible metaphor (for clinical practice).

The 2 groups were comparable on rates of reporting more personally revealing information in the hidden observer condition: so this suggestion could be useful to get additional information from patients.

The results supported one hypothesis: dream reports were associated with more primary process thinking. This was more true of highs than lows. Results supported the view that primary process is not attributed to role playing because the blending of dream and hidden observer responses occurred in the high hypnotizables; more novel content was found in the highs.

No support was found for the hypothesis that more affect is produced under these conditions.

Though simulators were unable to role-play the primary process thinking of highs, they may have been vigilant and may have suppressed primary process thinking.

Perry, Campbell (1992, October). J. Phillip Sutcliff's contributions to the field of hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

1:

Sutcliff did research that led him to conclude that the high hypnotizable was deluded rather than truly perceiving things, and he said the high is simply strongly emotionally invested in the suggested belief.

Putnam, Frank W. (1992). Using hypnosis for therapeutic abreactions. Psychiatric Medicine, 10, 51-65.

Abreaction, the dramatic reliving of traumatic events under hypnosis, is a powerful therapeutic intervention useful in the treatment of victims of trauma. First

systematically applied in World War I, abreaction coupled with psychotherapeutic processing of the recovered material is increasingly being used with victims of child abuse and chronic PTSD. Abreactions are helpful in recovering dissociated or repressed traumatic material, reconnecting missing affect with recalled material and for transforming traumatic memories. Although abreactions can be induced with medications, hypnosis is the method of choice except in acute situations where it is not possible to establish rapport. A variety of hypnotic techniques for the induction and management of abreaction are discussed, together with the indications and contraindications for their use.

**1991**

**Brown, Peter (1991). Ultradian rhythms of cerebral function and hypnosis. Contemporary Hypnosis, 8, 17-24.**

As a consequence of his observations of the clinical work of Milton Erickson, Ernest Rossi has proposed an 'ultradian rhythm theory of hypnosis'. Rossi demonstrated that the spontaneous changes in cognition, affect and behaviour which occur as part of the ultradian cycle (which Erickson referred to as 'the common everyday trance') are similar to the changes which occur during hypnosis. A review of studies of the phasic changes in hemispheric function suggests that ultradian changes do parallel the changes found in hypnosis.

**NOTES**

**1:**

Falling asleep and waking up are regulated by two separate mechanisms rather than being opposite poles of one mechanism (Winfrey, 1980). Kleitman (1961) suggested a 90-min cycle, the basic rest-activity cycle (BRAC). In addition to physiological alterations, there are alterations in cognition, mood and behavior (Rossi & Cheek, 1988); vigilance (Okawa, Matousek & Petersen 1984); peripheral blood flow (Ramano & Gizdulich, 1980); respiratory amplitude (Horne & Whitehead, 1976); visual evoked potentials (Zimmerman, Gortelmeyer & Wiemann, 1983); pupillary diameter, stability and reactivity to light, and saccadic eye movements (Lavie & Kripke, 1981).

These diurnal variations may relate to hypnotic behavior. There is a recurring increase in daydream and fantasy, as well as visual imagery (Kripke & Sonnenschein, 1978). "There is evidence for a parallel recurring cognitive and emotional cycle with increased emotional responsiveness and a more subjective cognitive processing of information (Evans, 1972; Holloway, 1978; Overton, 1978; Thayer, 1987). Subjects appear to repeat the cycle approximately 16 times per day, with a range of 70-120 minutes. Kripke and Sonnenschein (1978) noted that the subjects were personally unaware of any repeating cycle in their mental lives" (p. 19).

The brainstem arousal mechanisms seem to be implicated in periodic changes in the EEG. Ultradian rhythms are "more easily detected under conditions of increased sleep need, reduced external performance demand and lowered motivation to focus externally (Broughton, 1985)" (p. 20). Sterman (1985) observed that the rhythm was most marked in resting state and disappears during complex visuomotor tasks.

Relationship of EEG patterns to attentional patterns indicate there may be two different forms of attention, one for focused awareness (often thought to be associated with trance state) and the other a generalized vigilance (which would be reduced in hypnosis). Ultradian changes in consciousness reflected in the EEG may suggest increased internal absorption associated with visual imagery, a feature of the trance state.

"There has recently been a partial direct confirmation of Rossi's hypothesis. Aldrich and Bernstein (1987 [International Journal of Clinical and Experimental Hypnosis]) reported a bimodal distribution of Harvard Group Scale Hypnotic Susceptibility (HGSHS) scores when they are done at different times throughout the day. They note the parallel of the changes in HGSHS scores and the circadian variations in body temperature which suggest changes in hypnotic responsiveness coinciding with the fluctuations of physiological rhythms.

"Other support comes from some highly original work involving breathing rhythms. There are cyclic alterations in relative air flow between the left and right nostrils with an average period of 2-3 hours (Hasegawa & Kern, 1977). This nasal ultradian rhythm is correlated with an increase in contralateral cerebral hemispheric activity (Werntz, Bickford, Bloom & Shannahoff-Khalsa, 1981, 1983; Klein, Pilon, Prosser & Shannahoff-Khalsa, 1986). The alterations in hemispheric function do appear to be related to changes both in the style of cognition, particularly in an increase in vivid visual imagery, and in performance on specific tasks (Klein et al., 1986). Thus these studies support the notion of an ultradian rhythm of cerebral function which is associated with characteristic physical manifestations mediated by the autonomic nervous system. Whether or not these changes are directly related to the findings reported by Aldrich and Bernstein has yet to be established" (p. 21).

The authors conclude that "the most consistent evidence for ultradian rhythms is demonstrated by the mechanisms of the hypothalamic-limbic system and by brain-stem mechanisms that regulate arousal and attention processes (Parmeggiani, 1987); neuroendocrine regulatory mechanisms (Follenius, Simon, Brandenberger & Lenzi, 1987) and autonomic nervous system function (Bossom, Natelson, Levin & Stokes, 1983; Gordon & Lavie, 1986). These studies also suggest an ongoing dynamic interaction between cortical and subcortical structures throughout the ultradian cycle (Parmeggiani, 1987), and suggest that these interactions may be of great significance in hypnosis" (p. 21).

Cornell, William F.; Olio, Karen A. (1991). Integrating affect in treatment with adult survivors of physical and sexual abuse. American Journal of Orthopsychiatry, 61 (1), 59-69.

Presents a theoretical and technical model for affectively centered treatment of adults abused as children, focusing on the function of denial and dissociation as central defense mechanisms. The concept is introduced of working at an "affective edge." At this experiential point, a client can maintain both cognitive understanding and emotional and bodily awareness without triggering denial and dissociation. This approach fosters careful monitoring of the client's functioning both during and

between therapeutic sessions. The proposed therapeutic approach uses noninvasive touch and body-centered techniques. Focus is on integrating affect and on the importance of the therapeutic relationship.

DeKoninck, J.; Brunette, R. (1991). Presleep suggestion related to a phobic object: Successful manipulation of reported dream affect. *Journal of General Psychology*, 118, 185-200.

When compared with subjects who received presleep suggestions for negative affect, subjects who received positive affect suggestions had significantly higher levels of positive emotions in their dreams, rated their own dreams as more pleasant, and had significantly lower levels of anxiety, sadness, and aggression. This supports the hypothesis that presleep suggestion can be an effective technique in influencing the affective dimension of the dream.

Madrid, Antonio D.; Barnes, Susan v.d.H. (1991). A hypnotic protocol for eliciting physical changes through suggestions of biochemical responses. *American Journal of Clinical Hypnosis*, 122-128.

We employed brief hypnotherapy to effect physical changes in patients suffering from medical disorders including allergies, rectal bleeding, systemic lupus, hyperemesis, headache, asthma, and chronic pain. We present, in language appropriate to the individual patient, considerations and suggestions to effect the release of healing biochemicals. Ideomotor signals indicated the patient's awareness of the healing. We hypothesize that the technique triggered novel state-dependent memory, learning, and behavior.

#### NOTES

1:

They hypothesize that the technique they use triggers novel state-dependent memory, learning, and behavior (See for example Rossi, 1987, and Rossi & Cheek, 1988).

Hypnotic Protocol: "1. Tell the patient that he can heal himself by allowing his body to supply its own biochemicals needed to make him well. If a specific biochemical is known, such as cortisone or endorphins, name it. "2. Hypnotize the patient. Resistant or hard to hypnotize patients need not be deeply hypnotized because the patients, using this protocol, will automatically go into trance while accomplishing the next task of accessing and using ideomotor signals (Erickson, 1980; Rossi & Cheek, 1988). "3. Tell the patient that his index finger will automatically and involuntarily twitch and float when his body releases the biochemicals he needs. This ideomotor response (Rossi & Cheek, 1988) is the sole physical response required of the patient. Rossi hypothesizes that the ideomotor response correlates with biochemical changes (Rossi & Cheek, 1988). "4. Next, ask the patient to consider some things (as described below). Present the considerations one after another until one of them triggers the ideomotor response. "5. In some instances, ask the patient to practice on his own. Many patients who have dramatic emotional

reactions during or at the completion of the task may not need to practice on their own" (p. 123).

They present several 'considerations' to the patient, one after the other, tailored to the patient's specific case, until his finger twitches or floats, indicating a biochemical response. For example, the following 'considerations' have been used: "1. Psychodynamic: 'Consider that you are not blamed for anything; that you are in fact perfect just the way you are; that you are loved by those you care about.' 'Consider that you can forgive whoever needs forgiving for hurting you.' 'Consider that there are no longer any threats; everything is better; everything is as it used to be.' "2. Autosuggestion: 'Tell your body to heal. It knows what to do; so ask it to do it.' 'Tell your adrenal glands to produce the steroids that your body needs.' 'Allow a glowing light to permeate that injured back, filling it with healing energy.' "3. Incompatible responses: 'Cover yourself with a cool breeze, cooling the injured leg.' 'Imagine your back getting slack and limp and relaxed.' 'Imagine your stomach lining becoming smooth and moving with easy, ocean-like waves.' "4. Emotion calling: 'Consider yourself feeling very happy with everything, for no reason at all.' 'Consider yourself getting angry at someone--your mother, your wife (husband), your boss, your lawyer.' "5. Bargaining: 'Tell yourself that you will heal if you agree to stay away from that job.' 'Tell yourself you will heal by allowing your right arm to begin to hurt when you are over- exerting yourself.' 'Tell yourself that you will heal in exchange for something else, not so serious, to replace this disease and to serve the same function'" (pp. 123-124).

They present seven cases involving, respectively, allergies, rectal bleeding, systemic lupus, hyperemesis of pregnancy, adult onset asthma, chronic pain, and cluster headaches. Two cases were particularly interesting because they represented patients who did not respond initially.

Their procedure involves reframing the state or emotion originally associated with the onset of disease using considerations, and then giving a suggestion that it is within the power of the person, rather than factors outside, to heal the body. First they instruct the patient that the body can heal itself; then they give the list of suggestions for the patient to consider, persisting with different considerations until they get an ideomotor response. Incorporation of the patient's psychodynamic issues appears to be very important.

The authors regard it as unimportant if the patient cannot be hypnotized; "As Cheek (Cheek & LeCron, 1968; Rossi & Cheek, 1988) points out, the patient's inability to be hypnotized may be synonymous with his disease. It is actually beneficial if the patient cannot achieve ideomotor responses at first because both he and the therapist then trust the validity of the response when it does occur after the appropriate consideration" (p. 127).

Pekala, Ronald J. (1991). Hypnotic types: Evidence from a cluster analysis of phenomenal experience. Contemporary Hypnosis, 8, 95-104.

The phenomenological experiences of very-low and very-high, and low, medium and high susceptible individuals were cluster analyzed, attempting to determine if individuals of differing levels of hypnotic susceptibility report experiencing different types of phenomenological experience during hypnosis. Phenomenological

experience was assessed by means of a self-report questionnaire called the Phenomenology of Consciousness Inventory (PCI); it allows for quantification of 12 dimensions of phenomenological experience. K-means cluster analysis yielded two relatively distinct clusters of individuals for both low/very-low and high/very-high susceptible individuals. These results suggest at least two types of very-low/low and very-high/high susceptible individuals as determined by their reported experiences during hypnosis.

## NOTES

1:

The author notes that Sheehan and McConkey (1982) found three types of highs: concentrative, independent, and constructive. Spanos, Lush & Gwynn, 1989, found two groups of lows--one capable of learning hypnotic skills and the other less so.

In this study the author did two cluster analyses: (1) Harvard lows (0-1) and highs (11-12), and (2) all subjects divided into lows, mediums and highs, with cluster analyses performed separately for these three groups.

In the first analysis, there were two groups of very low hypnotizable subjects distinguished on the basis of altered state of awareness and rationality; and two very high groups, distinguished on the basis of imagery and positive affect.

One group of very lows reported "little alteration in altered state and altered experience and almost complete volitional control, self-awareness, rationality and memory" (p. 98) and were called 'classic very lows' because they were like refractory subjects in their self reports. The other group of very lows reported "moderate alterations in altered state and altered experience, and major decrements in volitional control, self-awareness, rationality and memory" (p. 98) and were called 'pseudo very lows' because their reports were a little like medium or high hypnotizables.

One group of very high hypnotizables had "great alterations in state of consciousness and moderate altered experiences; a loss of control, self awareness, rationality and memory; and little vivid imagery" (p. 98) and were called 'classic very highs' because their reported experience was like that of somnambules. The other type of highs were called 'fantasy very highs' because they had "moderate alteration in consciousness and experience, a great deal of vivid imagery, moderate positive affect, and only mild-to-moderate losses in rationality and memory" (p. 100).

When low, medium, and high susceptible subjects' PCIs had separate cluster analyses, the lows had three clusters: classic, dialoging, and pseudo lows. The dialoging group was between the other two in their experiencing yet reported a great deal of internal dialogue. Among the highs, the same two clusters appeared as for the very highs.

Among the mediums there were two groups: high mediums who reported a significant drop in volitional control, self-awareness, rationality, memory, and internal dialogue, and an alteration in state of awareness; and low mediums who had milder changes.

Comparing results to Sheehan and McConkey (1982), the classic highs may correspond to their concentrative type and the fantasy highs to their independent type, because the latter generated imagery without a request to do so.

Regarding the pseudo-lows, "it is intriguing that there appear to be some individuals who make little response on the behaviorally oriented Harvard Scale, and yet report some phenomenological alterations. Are they individuals for whom hypnosis may be somewhat more effective even though they are not that hypnotizable (as measured by the 'direct' Harvard Scale) or could they be Spanos's (Spanos et al., 1989) 'trainable' low susceptibles?" (p. 102).

Persinger, M. A.; Makarec, Katherine (1991-92). Interactions between temporal lobe signs, imaginings, beliefs and gender: Their effect upon logical inference. Imagination, Cognition and Personality, 11, 149-166.

Rotton's Paralogic Test, Wilson-Barber's Inventory of Childhood memories and Imaginings (ICMI) and the PPI (Personal Philosophy Inventory) were administered to 100 male and 100 female university students. Both sexes displayed moderately strong (0.50) correlations between content-selected and factor analyzed clusters of possible temporal lobe signs, exotic beliefs and the numbers of childhood imaginings. Although there were no sex differences between the accuracy of logical statements that contained paranormal or neutral content, males who displayed more temporal lobe signs were more accurate for logical items that contained paranormal content. Females who displayed more imaginings were more accurate for valid than for invalid items. Accuracy for items with paranormal content increased with exotic beliefs but not with conservative religious beliefs for both sexes. The relationship between exotic beliefs and accuracy for items with paranormal content was especially strong for females. These results suggest: 1) gender differences in the neurocognitive processes that contribute to logical problem solving and 2) accuracy may depend upon the degree to which the subject matter is commensurate with the person's history of enhanced temporal lobe signs, capacity for fantasy and imaginings and beliefs in exotic concepts.

#### NOTES

1:

Review of related literature indicates that Personal Philosophy Inventory (PPI) temporal lobe signs are correlated with temporal lobe EEG alpha but not occipital lobe alpha (Makarec & Persinger, 1990), with increased suggestibility (Persinger & DeSano, 1986; Ross & Persinger, 1987), with creativity and proneness towards fantasy (Persinger & DeSano, 1986; Ross & Persinger, 1987; Makarec & Persinger, 1987), and with reports of psi experiences and beliefs in such things as reincarnation and aliens in UFOs ('exotic themes') (Persinger & Makarec, 1987; Persinger & Makarec, 1990).

This experiment was designed to answer four questions: " 1) Do imagery and temporal lobe signs emerge from the same source of variance?; 2) Do males and females differ significantly in their incidence of imaginings and temporal lobe signs?; 3) Do males and females differ in their ability to solve logical problems?; and 4) Is the accuracy of problem solving affected by the subject matter of the problem and the problem solver's temporal lobe signs and capacity for imagery?" (p. 151).

The PPI consists of 140 true-false items that were selected with a goal of discerning temporal lobe signs within a normal population. One 30-item subscale has items that

are similar to experiences reported by patients with verified electrical foci in the temporal lobes, albeit milder (the TLS or temporal lobe sign scale). Of these 30 items, 16 refer to ictal-like experiences (the CPES, or complex partial epileptic signs), and 14 refer to interictal-like behaviors (ILB). CPES items are items like "Sometimes an event will occur that has special significance for me only," and "While sitting quietly, I have had uplifting sensations as if I were driving over a rolling road." ILB items are items like "People tell me I blank out sometimes when people are talking," and "When I lose an argument I spend a lot of time thinking about what I should have said."

Wilson and Barber's Inventory of Childhood Memories and Imaginings (ICMI) has 52 true-false items that include reports of paranormal experiences (5 items), moderate imaginings (18 items) such as 'When I was a child I enjoyed fairytales,' and extreme imaginings (15 items) such as 'When I was a child or teenager, at times I was afraid my imagining would become so real to me that I would be unable to stop it.'

Rotton's Paralogic Test [unpublished, at Florida International University, Miami] has 16 syllogisms, each with major premise, minor premise, and conclusion. "The person must decide if the argument is valid (n = 8) or invalid (n = 8). Half of each of the valid and invalid arguments refer to mundane material while the other half of the arguments refer to paranormal-related material. An example of the former is 'If a president is a crook, he would be impeached; Congress did not impeach Nixon. Therefore Nixon is not a crook' and 'If flying saucers really existed, somebody would have photographed one. Nobody has ever photographed a flying saucer. Therefore, flying saucers do not exist'" (p. 153).

Correlations were computed separately for males and females. Both groups increased in accuracy for paranormal items as their belief in things like reincarnation and UFOs ('exotic concepts') increased. Males with a higher number of temporal lobe signs demonstrated more accuracy for logic test items with paranormal (psi) content than logic test items with mundane content.

"The single most important correlation was between exotic beliefs and the interaction term for the Rotton scale; the coefficient was unusually strong (0.54) and highly statistically significant ( $p < 0.001$ ) for females only. Because of the manner in which the interaction term was calculated, this correlation meant that females who reported more exotic beliefs were also more accurate for valid items that contained paranormal content only" (p. 159).

In their Discussion, the authors write, "The significant positive correlations between exotic beliefs and the clusters of CPES items and extreme Wilson-Barber imagining items are expected associations according to Bear's concept of sensory-limbic hyperconnectionism [Temporal Lobe Epilepsy: A Syndrome of Sensory-Limbic Hyperconnectionism, Cortex, 15, pp. 357-384. It would predict that concepts (or word trains) that are unusual, strange or infrequent would be charged with emotional significance and personal value. Ideas that generate substantial imagery, such as time- travel, reincarnation and alien intelligence, would be particularly prone to this affective infusion from limbic sources.

Induction of such unique or intensified affective states, especially during childhood, would facilitate the development of more frequent or more extreme periods of dissociation in the adult. We have collected (unpublished) clinical evidence to suggest that the emergence of this pattern is found in the propensity for creative thinkers, including writers, poets, musicians, artists and scientists, to have had developmental histories that could have promoted temporal lobe lability without overt seizure activity; clusters of such "promoters" include mild physical abuse, febrile episodes, minor head injuries and likely hypoxic periods during extreme physical exertion (competitive athletics)" (pp. 161-162).

Another conclusion of the study is that males and females do not differ in their accuracy in solving syllogisms, but "the neurocognitive processes, as inferred from inventories of temporal lobesigns or childhood imaginings, by which the two sexes arrive at solutions may be quite different" (p. 162).

1991

Radtke, H. Lorraine; Stam, Henderikus J. (1991). The relationship between absorption, openness to experience, anhedonia, and susceptibility. International Journal of Clinical and Experimental Hypnosis, 39, 39-56.

Examination of the absorption (Tellegen Absorption Scale [TAS] of Tellegen & Atkinson, 1974), openness to experience (OTE Inventory of Costa & McCrae, 1978), and anhedonia (ANH Scales of L. J. Chapman, J. P. Chapman, & Raulin, 1976) scales suggested that they might be conceptually related. Given the reliable relationship between TAS and hypnotic susceptibility, the authors were interested in studying OTE and ANH as possible personality correlates of hypnotic susceptibility. 2 studies, 1 involving a community sample and the other a sample of university students, were conducted to assess the relationships between the TAS, OTE, and ANH scales and hypnotic susceptibility. As predicted, in Study 1 (community sample) the TAS and OTE inventories were positively correlated with one another and both were negatively correlated with the ANH scale. This pattern of correlations was replicated in Study 2 (university sample), but only TAS correlated significantly with hypnotic susceptibility. Factor analyses further confirmed these findings. It was concluded that the conceptual relationship among the TAS and the OTE and ANH scales resides in some dimension other than hypnotic susceptibility.

NOTES

1:

Two studies used Tellegen Absorption Scale (TAS), Costa & McCrae's (1978) Openness to Experience Inventory (OTE), and Chapman, Chapman, & Raulin's (1976) Anhedonia scales (ANH). One involved a community sample, the other involved university students.

OTE and TAS  $r = .42$  and  $.62$

TAS and HGSHS:A  $r = .22$  ( $p < .10$ ) in one study "Thus, while there is a significant overlap in variability between TAS and the other person variables, the variance shared between TAS and hypnotic susceptibility is unique to those two measures. Further research is needed to determine the role of expectancies in contributing to this pattern of findings and the extent to which item overlap may be responsible for

the observed correlations (Nicholls et al., 1982). Inspection of the items included in the three scales indicated that only TAS assesses involvement in experiences; items on the ANH and OTE instruments focus on interest or willingness to engage in various experiences" (p. 51).

"Notably, the correlations between TAS and the 2 subjective indices of hypnotic susceptibility, SUB and O-I, were slightly stronger than the correlations between TAS and the two indices reflecting overt behavior (OBJ and HGSHS:A scores). This pattern of relationships is consistent with recent arguments that objective indices alone do not fully capture the hypnotic experience (e.g., Spanos et al., 1983).

"Interestingly, the correlations among the three personality scales tended to be stronger in Study 1 where a community sample was assessed in a nonhypnotic context than in Study 2 where a sample of university undergraduates was assessed in a hypnotic context. The two samples differed significantly on all three scales both in terms of mean level and variability, indicating possible ceiling effects and restricted range problems in the university sample. Given that almost all of the research on hypnotic susceptibility and its correlates has been conducted on university students, these findings point to the utility of obtaining research participants from a greater cross-section of the population" (pp. 51- 52).

"Of particular importance, these results indicate that the relationships among TAS and the OTE and ANH scales do not depend upon the hypnotic context and are not the product of expectancies generated by the anticipation of being hypnotized. Nevertheless, the conceptual relationship among the three scales resides in some dimension that is unrelated to hypnotic susceptibility. At this point, we can only speculate as to what this dimension might be. One possibility is that TAS and the OTE and ANH scales reflect an openness to various experiences; what absorption and hypnotic susceptibility uniquely share is the willingness to become involved in imaginal and sensory experiences" (p. 52).

**Terr, Lenore C. (1991). Childhood traumas: An outline and overview. American Journal of Psychiatry, 148, 10-20.**

Suggests 4 characteristics common to most cases of childhood trauma: visualized or otherwise repeatedly perceived memories of the traumatic event; repetitive behaviors; trauma-specific fears; and changed attitudes about people, life, and the future. Childhood trauma is divided into 2 basic types. Type I trauma includes full, detailed memories, "omens," and misperceptions while Type II trauma includes denial and numbing, self-hypnosis and dissociation, and rage. Characteristics of both types of childhood trauma can exist side by side. Such crossover Type I - Type II traumatic conditions of childhood are characterized by perceptual mourning and depression and childhood disfigurement, disability, and pain. Case examples are provided.

**1990**

**Fischer, Donald G.; Elnitsky, Sherry (1990). A factor analytic study of two scales measuring dissociation. American Journal of Clinical Hypnosis, 32, 201-207.**

The present study was designed to investigate the construct validity of dissociation. We administered the PAS and the DES to 507 male (48%) and female (52%) undergraduate students. Factor analysis on each scale separately showed that neither the PAS nor the DES adequately measures the three dimensions hypothesized to underlie dissociative experience. For both scales, a single factor emerged as replicable and reliable. Use of the scales, in their present form, therefore, should be limited to a single dimension representing disturbances in affect-control in the case of the PAS and disturbances in cognition-control if the DES is used at least with normal populations. Analysis of the combined items showed that the scales are measuring conceptually different but statistically correlated dimensions of dissociation. Further development of both scales is desirable, and further research should investigate the effect of different response formats on the internal structure of the scales.

#### NOTES

1:

The stated purpose of this study was to investigate the internal structure of the Perceptual Alterations Scale (PAS) and the Dissociative Experiences Scale (DES) using a large sample from a normal population.

"Sanders (1986) conceived of dissociation as a personality trait that is characterized by modification of connections between affect, cognition, and perception of voluntary control over behavior, as well as modifications in the subjective experience of affect, voluntary control, and perception. She chose items from the MMPI to represent this trait. Bernstein and Putnam (1986), utilizing the DSM-III definition of dissociation, constructed items from information derived from interviews with patients and clinicians to represent a number of different types of dissociative experiences" (0. 202).

The PAS (Sanders, 1986) is a 27-item scale; subjects respond by checking one of the following categories using a 4-point Likert format: never, sometimes, frequently, almost always. The items related to modifications of regulatory control, changes in self-monitoring, concealment from self and others, and modifications of sensory, perceptual, and affective experiences.

"The DES (Bernstein & Putnam, 1986) contains 28 items. Subjects indicate the percentage of time they experience the feelings or behavior described by the items on a 10-point scale. The items related to the experience of disturbances in identity, memory, awareness and cognition, and feelings of derealization or depersonalization" (pp. 202- 203).

Results were as follows. The one-factor solution for the PAS accounted for 18.5% of the total variance.; 11 of the 28 items did not load significantly on the factor. The one-factor solution for the DES accounted for 26.3% of the total variance; 7 of the 28 items did not load significantly on the factor.

"The 3-factor solution obtained by Sanders (1986) for the PAS was not replicated. An obvious reason for the different is that principal factor extraction was used in the present study, whereas principal components extraction was utilized by Sanders. ... Even when principal components analysis is performed on the present data, however, there are difficulties with the 3-factor solution" (pp. 204-205).

"All of the criteria suggest that a single factor best represents the latent structure of dissociative experience as measured by the PAS and DES. Although the total amount of variance accounted for is low, the one-factor solutions for both scales are interpretable, replicable, and have high internal consistency. The items for the PAS appear to represent primarily the affect and control dimensions, whereas those for the DES represent the cognitive dimension" (pp. 205-206).

"Overall, both scales contain similar items, although the DES has more items relating to disturbances in memory and altered perception of time (i.e., cognition), whereas the PAS has more items reflecting specific disturbances in identity and control. It appears, therefore, that the scales are measuring conceptually separate but statistically correlated dimensions of dissociation" (p. 206).

Gil, Karen M.; Williams, David A.; Keefe, Francis J.; Beckham, Jean C. (1990). The relationship of negative thoughts to pain and psychological distress. Behavior Therapy, 21 (3), 349-362.

Examined the degree to which negative thoughts during flare-ups of pain are related to pain and psychological distress in 3 pain populations: sickle cell disease, rheumatoid arthritis, and chronic pain. 185 adults completed the Inventory of Negative Thoughts in Response to Pain (INTRP), a pain rating scale, the SCL-90 (revised), and a coping strategies questionnaire. Factor analysis of the INTRP revealed 3 factors: Negative Self-Statements, Negative Social Cognitions, and Self-Blame. High scorers on Negative Self-Statement and Negative Social Cognitions reported more severe pain and psychological distress. Ss with chronic daily pain had more frequent negative thoughts during flare-ups than those having intermittent pain secondary to sickle cell disease or rheumatoid arthritis. The INTRP appears to have adequate internal consistency and construct validity.

## NOTES

1:

This chapter is a reprint of an article published in the American Journal of Clinical Hypnosis in 1987. It provides a conceptual framework for understanding psychotherapy processes in the context of a hypnotic state. Based on empirical and theoretical considerations, the author identified nine changes occurring with hypnosis: changes in attention and awareness, imagery, dissociation, reality orientation, suggestibility, mind-body interactions, initiative or volition, availability of affect, and relationship. "This chapter proposes that hypnotherapy exploits hypnotic phenomena-- takes advantage of them--in the service of standard therapy endeavors" (p. 125).

Martin, Maryanne (1990). On the induction of mood. Clinical Psychology Review, 10, 669-697

## NOTES

1:

Increasing interest in the relation between emotion and cognition has led to the development of a range of laboratory methods for inducing temporary mood states. Sixteen such techniques are reviewed and compared on a range of factors including success rate, the possibility of demand effects, the intensity of the induced mood, and the range of different moods that can be induced. Three different cognitive models (self- schema theory, semantic network theory, and fragmentation theory) which have been successfully used to describe long-term mood states, such as clinical depression, are elaborated to describe the process of temporary mood induction. Finally, the use of mood induction is contrasted with alternative methods (such as the study of patients suffering from depression) for investigating emotion.

1989

Bick, C. H. (1989). An EEG-mapping study of 'laughing': Coherence and brain dominances. International Journal of Neuroscience, 47, 31-40.

Laughter is triggered by pleasurable psychoemotional stimuli and may have healing potential. According to split-brain studies, psychoemotional stimuli are bound up with emotional activity in the right side of the brain. This suggested the idea of studying laughter generated by different sources with regard to electrical brain activity in the right and left hemispheres. This study first used subjects in normal consciousness and with laughter under hypnosis to study the neurophysiological processes connected with laughter.

Bryant, Richard A.; McConkey, Kevin M. (1989). Hypnotic emotions and physical sensations: A real-simulating analysis. International Journal of Clinical and Experimental Hypnosis, 37, 305-319.

Real hypnotizable Ss and simulating unhypnotizable Ss were administered a suggestion for either happiness, emotional neutrality, or sadness. The emotion was assessed through subjective and behavioral measures taken once before, twice during, and once after the emotion. Findings indicated that emotionally congruent changes occurred in both self-report and performance measures. Ss' physical sensations during the emotion were assessed on a 34-item self-report scale. It was demonstrated that Ss in the happy versus sad conditions reported different physical sensations; in particular, they reported different facial sensations. The responses of real hypnotizable subjects, however, were essentially paralleled by those of simulating unhypnotizable subjects. Therefore, the possibility exists that hypnotized subjects may have been responding on the basis of social demands. The findings are discussed in terms of the effects of the emotion suggestions, and the implications of real and simulating Ss displaying similar affective responses.

## NOTES

1:

Used the real-simulating model in an attempt to eliminate the possibility that hypnotized Subjects in previous studies may have been responding to the demand characteristics of the situation. Used both subjective and behavioral measures. Self-

report happiness and sadness, of emotion intensity; behavioral performance measure of speech rate, indexed by counting speed (which has been shown to distinguish between happiness and sadness). Used 34-item self-report Physical Sensations Scale based on Pennebaker, J. W. *The psychology of physical symptoms*. New York: Springer-Verlag, 1982.

They cite Weiss, et al (1987) who focused on the onset latency, and the fluctuation of muscular contraction associated with facial expression indicated a difference between posthypnotically cued and simulated emotions of anxiety and pleasure.

1989

Cooper, Nancy A.; Clum, George A. (1989). Imaginal flooding as a supplementary treatment for PTSD in combat veterans: A controlled study. *Behavior Therapy*, 20 (3), 381-391.

14 Vietnam veterans suffering from posttraumatic stress disorder (PTSD) were assigned either to standard treatment (control group), or standard treatment plus imaginal flooding (experimental group). The 2 groups were closely matched on medications and combat roles and tours of duty were comparable. Experimental Ss received up to 14 sessions of flooding for a maximum of one and one-half hours per session. Self-report measures were administered at pre-treatment, post-treatment, and at 3-mo follow-up. These measures included the Behavioral Avoidance Test, the Beck Depression Inventory, and a Modified Vietnam Experiences Questionnaire. Results indicate that flooding increased the effectiveness of usual treatment, particularly in such areas as re-experiencing symptoms and sleep disturbances. However, flooding had no effect on level of depression, trait anxiety, and violence-proneness.

Friswell, Rena; McConkey, Kevin M. (1989). Hypnotically induced mood. *Cognition and Emotion*, 3 (1), 1-26.

This article addresses theoretical and methodological issues that are central to an understanding of hypnotically induced mood. Initially, the hypnotic procedures that are typically used to induce moods are examined. Then the empirical research that has employed hypnotic moods is reviewed; specifically, the impact of hypnotic moods on physiological responses, behavioural performance, perceptual and cognitive responses, and personality, and clinical processes is examined. Finally, major theoretical and methodological issues are highlighted, and the research directions that will lead to a greater understanding of hypnotic mood are specified.

Pekala, Ronald J.; Bieber, Stephen L. (1989-90). Operationalizing pattern approaches to consciousness: An analysis of phenomenological patterns of consciousness among individuals of differing susceptibility. *Imagination, Cognition and Personality*, 9 (4), 303-320.

Pattern differences in subjective experience, as assessed by a self-report inventory, the Phenomenology of Consciousness Inventory (PCI), were compared across low,

low-medium, high-medium, and high hypnotically susceptible individuals during hypnosis and eyes-closed. A hierarchical factor analytic approach was utilized that allowed for the determination of pattern differences among PCI dimensions as a function of hypnotic susceptibility. The factor analyses found that the four susceptibility (sic) groups were 'pattern equivalent' during eyes-closed, partially pattern dissimilar during hypnosis, and partially pattern dissimilar when comparing hypnosis against eyes-closed. The nature of these results support previous analyses (1) which compared pattern structure differences as a function of correlational matrices. The results suggest the complementarity of Bieber's (2) and Pekala's (3) approaches for assessing pattern differences in consciousness and are congruent with the theorizing of Tart (4), Izard (5), and the PDP researchers on the importance of pattern structure changes in understanding states of consciousness.

#### NOTES

1:

This paper is based on the presentation at SCEH in Ashville, 1988.

Pekala, Ronald J.; Kumar, V. K. (1989). Phenomenological patterns of consciousness during hypnosis: Relevance to cognition and individual differences. Australian Journal of Clinical and Experimental Hypnosis, 17 (1), 1-20.

Relationships among phenomenological subsystems of consciousness associated with a baseline condition and an hypnotic induction condition were compared across individuals of differing hypnotic susceptibility. Phenomenological experience on 12 subsystems of consciousness was quantified by means of the Phenomenology of Consciousness Inventory (PCI) and the relationships between dimensions were statistically assessed. The results replicated previous findings and suggested that hypnosis has differential effects upon the reported organization of phenomenological structures of consciousness across subjects of differing susceptibility. The data from the previous and present studies were pooled and the combined data were reanalyzed. The results provided further support for the differential pattern structure across low and high susceptibles during hypnosis. Furthermore, differences in pattern structure were augmented when comparing very low versus very high susceptible individuals.

#### NOTES

This paper is based on a paper presented to Division 30, Psychological Hypnosis, at annual meeting of the American Psychological Association, Aug 1987.

Sansom, Deborah; Rachman, S. (1989). The effect of induced mood on fear reduction. British Journal of Clinical Psychology, 28 (3), 227-238.

Investigated the effect on fear reduction in a laboratory study of fearful people. A musical mood-induction technique was utilized to induce either a happy mood or a sad mood in 84 female undergraduates who were fearful of spiders or snakes. Following the mood induction, Ss' fears were reduced by participant modeling. Measures of subjective fear and self-efficacy were taken before and after mood

induction, after modeling, and 4 weeks later. Compared to the induced sad-mood condition, induced happiness was followed by a decrease in subjective fear and greater self-efficacy. No difference was found in the length of time taken to reduce fear for happy and sad Ss. Fear reduction during a sad mood was associated with greater return of fear than fear reduction during a happy mood.

Spiegel, David; Bloom, J. R.; Kraemer, H. C.; Gottheil, E. (1989, October 14). The beneficial effect of psychosocial treatment on survival of metastatic breast cancer patients: A randomized prospective outcome study. Lancet, 888-891.

The effect of psychosocial intervention on time of survival of 86 metastatic breast cancer patients was studied using randomized prospective design. The one-year treatment consisted of weekly supportive group therapy with training in self-hypnosis for pain management, and resulted in significant reductions in mood disturbance and pain. Both the treatment and control groups had routine oncologic care. At ten-year follow-up, only three of the original 86 patients were still alive, and death records were obtained for the other 83. Survival from the time of randomization and onset of intervention was 36.6 (sd = 37.6) months for the treatment group, compared with 18.9 (sd = 10.8) months for the control group, and this difference was highly significant ( $Z = 3.94$ ,  $p < .0001$ ) using the Cox life table regression model. Kaplan-Meier survival analysis indicated that the divergence in survival began at 20 months after entry into the study, or 8 months after the treatment intervention ended. These unexpected findings suggest that intensive psychosocial support affects the course of the illness, although the mechanism by which it does so is not clear.

Suler, John R. (1989). Mental imagery in psychoanalytic treatment. Psychoanalytic Psychology, 6, 343-366.

Mental imagery techniques may facilitate the therapeutic process by stimulating patients' insight into unconscious dynamics, by helping them uncover and master warded-off affect, and by enhancing the clinician's empathic contact and access to countertransference. The history of imagery techniques in the psychoanalytic movement and the effect of these techniques on the traditional psychoanalytic method are reviewed. A conceptual framework based on the theory of primary and secondary process suggests spontaneity, experiential scope, associative elaboration, and object impact as four dimensions for the clinical evaluation of imagery experience.

1988

Borgeat, Francois; Rezanowicz, Thaddeus; Chaloult, Louis (1988). La stimulation preconsciente et consciente de l'imaginaire erotique. Revue Canadienne de Psychiatrie, 33, 394-398.

The stimulation of erotic fantasies through the association of relaxation and erotic conscious or preconscious suggestions has been evaluated. This study was attempted following positive results in the stimulation of fantasmatic activity in alexithymic

subjects with a similar procedure. Thirty female subjects, allocated into three groups practiced relaxation daily for two weeks including three sessions with psychological measures. During the second week, erotic suggestions, preconscious for one group and conscious for another one were added. The third group (control) received only relaxation throughout. Results have shown an increase of sexual arousal and erotic imagery during the sessions with erotic suggestions. Sexual activities and desire increased in the two experimental groups. There was no difference between the effects of the preconscious and conscious suggestions. Possible clinical applications of such a procedure are discussed.

Brink, Nicholas E. (1988-89). Using imagery as a planning and treatment guide in therapy. Imagination, Cognition and Personality, 8, 187-200.

Procedures and case studies of how imagery can provide a means to redefine the problem, an agenda for therapy, information for determining the appropriate interventions, a criteria for evaluating progress, and the appropriate time for termination are presented. Images are evoked using one of several imagery situations. These images may converge on the common dynamic pattern clarifying the problem, represent different aspects of the problem, or represent different problems, depending upon the hypnotic suggestion used in evoking the images. The emerging pattern(s) provide the agenda for therapy. Emotional energy in imagery work is used to determine the appropriate timing and content for the therapeutic interventions. Emotional release provides a means of evaluating progress. When each of the items on the agenda are resolved with an emotional release the time for termination is near at hand. Therapy begins by evoking a minimum of three images using one of several situations, including time regression, seeing behind doors on a hallway, or going down in an elevator. These images may represent different aspects of the problem, different problems, or, by using the affect bridge, may converge on a common dynamic pattern clarifying the nature of a single problem.

Kumar, V. K.; Pekala, Ronald J. (1988). Hypnotizability, absorption, and individual differences in phenomenological experience. International Journal of Clinical and Experimental Hypnosis, 36, 80-88.

The phenomenological effects associated with a baseline condition of eyes- closed and a hypnotic induction condition were compared across individuals of differing absorption capacity and hypnotizability. The results indicated that individuals of differing absorption capacity and hypnotizability reported different intensities of phenomenological experience during the baseline eyes-closed condition. The induction further augmented intensity differences for low, medium, and high absorption and hypnotizable Ss, but more so for high (and medium) than low hypnotizable Ss. The results support both a trait and state interpretation of hypnotizability, and highlight the importance of the interaction between these factors on the resulting hypnotic experience of S.

## NOTES

1:

Based on a review of relevant literature, the authors predicted that (1) during hypnosis and a baseline condition (eyes-closed), high absorption and high hypnotizable Ss will report the phenomenological effects at greater intensity relative to low absorption and low hypnotizable Ss, respectively; (2) hypnotic induction will be associated with increased absorption; greater alterations in awareness and experience; and decreased volitional control, rationality, and memory; (3) phenomenological intensity differences (hypnosis compared to eyes-closed) will be significantly greater for high than for low hypnotizable Ss.

They used the Phenomenology of Consciousness Inventory (PCI) developed by Pekala (1982), which is a 53 item self-report instrument that is completed retrospectively in reference to a preceding stimulus condition. The PCI measures the following dimensions and subdimensions: internal dialogue; self-awareness; state of awareness; imagery (amount, vividness); positive affect (joy, sexual excitement, love); negative affect (anger, fear, sadness); altered experience (time sense, body image, perception, unusual meanings); attention (absorption, direction); memory; rationality; volitional control; and arousal.

The 217 Ss were administered the Tellegen Absorption Scale, then sat quietly with eyes closed for four minutes, then completed the PCI, Form 1, relative to that 4-minute period. They were administered a slightly shortened version of the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A); before the posthypnotic suggestion and amnesia suggestion they experienced another 4-minute silent period during which they were told to 'continue to experience the state you are in right now.' After the HGSHS:A they completed PCI, Form 2, in reference to the silent period during the HGSHS:A, before they completed the 11-point questionnaire on the HGSHS:A.

Subjects who did not have reliable PCI response forms were removed from the sample, leaving 173 Ss who were divided into high, medium, and low Absorption groups, and high, medium, and low hypnotizability groups. The statistical analysis employed MANOVA on intensity scores for first the major PCI dimensions and then the 14 subdimensions using Conditions (eyes closed, hypnosis) and Groups. There were significant main and interaction effects. Subsequent ANOVAs for each (sub)dimension, Conditions by Hypnotizability Groups (2 x 3) were then performed. Hypnosis "was associated with significantly less positive affect (joy, sexual excitement, love); negative affect (anger, sadness); visual imagery (amount, vividness); self-awareness, internal dialogue, rationality, volitional control, and memory; and significantly more altered experience (time sense, perception) and altered state of awareness.

"Significant main effects for Hypnotizability Groups were found for positive affect (joy, love); altered experience (body image, time sense, perception, meaning); attention (direction, absorption); self-awareness; altered state of awareness; rationality; volitional control; and memory.

"Post-hoc comparisons for the eyes-closed condition revealed that high relative to low, hypnotizables reported significantly greater alterations in body image, time sense, meaning, and altered state of awareness. Medium hypnotizable Ss, compared

to low hypnotizables, reported significantly increased alterations in body image and state of awareness.

"Post-hoc comparisons for the hypnotic induction condition revealed that high, viz-a-viz low, hypnotizables reported significantly increased absorbed attention; greater altered experience (body image, time sense, perception, meaning); and increased alterations in state of awareness. High hypnotizables also reported significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. Medium hypnotizable Ss, vis-a-vis low hypnotizables, reported significantly more altered experience (body image, time sense, perception, meaning); absorbed attention; and altered state of awareness; and significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. High hypnotizable Ss, relative to medium hypnotizables, reported significantly more altered experience (perception, meaning) and absorption, and significantly less rationality, volitional control, and memory.

"Concerning the significant interactions ( $\alpha = .01$ ), graphs of the means indicated significant ordinal interactions between Conditions and Hypnotizability Groups for altered experience (perception), imagery (vividness), self-awareness, altered state of awareness, rationality, volitional control, and memory. For all of the PCI (sub)dimensions, the hypnotic induction condition (compared to eyes-closed) was associated with a significantly greater increase in altered experience (perception), and altered state of awareness; and a significantly greater decrease in imagery (vividness), rationality, volitional control, and memory for the high (and medium) hypnotizable groups relative to the low hypnotizable group.

"Significant disordinal interactions were found for absorption and unusual meanings. Whereas high hypnotizable Ss reported a more absorbed attentional focus and more unusual meaning during hypnosis, low hypnotizable Ss reported being less absorbed (or more distracted) during the induction than eyes-closed. Low hypnotizables reported more unusual meanings in reference to eyes closed" (pp. 84-85).

Correlations among the major PCI dimensions, absorption, and hypnotizability differ between the two conditions. In hypnosis, the hypnotizability correlations that reached the .001 level were: --Self Awareness -.55 --State of Awareness .60 --Altered Experience .56 --Inward Absorbed Attention .44 --Rationality -.41 --Volitional control -.65 --Memory -.41 --Arousal -.28

In the eyes closed condition, the only PCI variables that Hypnotizability correlated with, at the .001 level, were: --Positive Affect .26 --Altered Experience .32

MANOVAs and ANOVAs were computed for Absorption groups in a similar fashion. Main effects but not interaction effects were significant. Results are not abstracted here.

In their Discussion, the authors note that "The three hypotheses were supported by the results. Several of the absorption group comparisons obtained in previous research (Pekala et al., 1985) involving alterations in subjective experience (body image, perception, meaning); state of awareness; and volitional control were replicated in the present research" (p. 85).

Malone, M.; Strube, M. (1988). Meta-analysis of non-medical treatment for chronic pain. Pain, 34, 231-234.

Conducted a meta-analysis of 109 published studies which assessed the outcome of various nonmedical treatments for chronic pain, 48 of which had sufficient information to calculate effect sizes. The remainder were examined according to proportion of patients rated as improved. Mood and number of subjective symptoms consistently showed greater responses to treatment than did pain intensity, pain duration, or frequency of pain, indicating the importance of using a multidimensional framework for pain assessment. Effect sizes for treatments were 2.74 for autogenic training, 2.67 for hypnosis, 2.23 for pill placebo, 1.33 for package treatments that allowed patients to choose from diverse pain management strategies, .95 for biofeedback, .76 for cognitive therapy, .67 for relaxation, .55 for operant conditioning, and .46 for TENS units. However, the largest numbers of studies were in the area of biofeedback, a treatment package, and relaxation, and we must be cautious in interpreting the effect sizes due to the small number of studies in the sample.

Nash, Michael R. (1988). Hypnosis as a window on regression. Bulletin of the Menninger Clinic, 52, 383-403.

Examines the empirical evidence for temporal and topographic regression during hypnosis--which Freud explicitly defined as regressive. A review of more than 100 studies spanning 60 years of research found no convincing evidence that developmentally previous psychological structures are reinstated during hypnosis (temporal regression). In contrast, there is evidence that hypnosis enables subjects to elicit more imagistic, primary process, and affect-laden material (topographic regression). The author recommends a careful reexamination of two core assumptions underlying the concept of temporal regression: (1) that early structures in human development are imperishable, and (2) that regression necessarily involves reinstatement of infantile psychological structures.

Nathanson, Donald L. (1988). Affect, affective resonance and a new theory for hypnosis. Psychopathology, 21, 126-137.

Suggests new theory of hypnosis based on recent experimental and theoretical work on emotion that shows neurological systems (including structural effectors and chemical mediators affecting specific sites of action). Tomkins' nine innate affects are organizers of the other moieties, genetically determined prewritten subcortical programs that convert quantitative stimuli into qualitative experience. Emotion in the adult involves subtle and complex combinations of innate affect with associations to previous experiences of affect provided by neocortical mechanisms. The infant initially expresses affect in an all-or-none fashion, while the caregiver, usually mother, acts as an external modulator of infantile affect display. All the techniques by which the mother learns to achieve affect mutualization and interaffectivity are analogues of what later may be seen as the techniques of

hypnotic induction. Hypnosis may be viewed as the intentional alteration of neocortical cognition made possible by the state of primitive interaffectivity achieved when the hypnotic operator enters the central assembly system of the adult by techniques reminiscent of maternal modulation of infantile affect display.

Robins, Clive J. (1988). Development of experimental mood induction procedures for testing personality-event interaction models of depression. Journal of Clinical Psychology, 44 (6), 958-963.

Developed 2 mood induction procedures for use in testing personality- event interaction hypotheses with regard to the onset of depressed mood of clinical depression. In these inductions, Ss listened to audiotapes depicting either a series of social rejections or achievement failures and were instructed to imagine themselves as the main character. Both tapes were found to produce a strong increase in reported depressed affect in 119 normal undergraduates. These effects were large in comparison to those elicited by commonly used mood induction procedures. Women reported greater mood shifts than men in response to both tapes. It is concluded that the present procedures have the advantage of content specificity, which permits test of personality-event interaction hypotheses.

Singer, Jefferson A.; Salovey, Peter (1988). Mood and memory: Evaluating the network theory of affect. Clinical Psychology Review, 8 (2), 211-251.

Discusses G. H. Bower's (see PA, Vol 66:11724) Network Theory of Affect, which specified 4 ways in which mood can have an observable effect on memory: (a) Memory is facilitated when mood state at learning matches mood state at recall; (b) material with affective tone that is congruent with current mood is most easily retrieved from memory; (c) material with affective tone that is congruent with current mood is most easily learned; and (d) affectively intense material is learned best. Empirical literature that addresses each of these predictions by looking at studies that manipulate mood in the laboratory as well as those that utilize occurring moods is discussed. Each prediction was supported, although congruency during learning (Prediction "c") yielded the most consistent findings.

Van Der Hart, O. (1988). An imaginary leave-taking ritual in mourning therapy. International Journal of Clinical and Experimental Hypnosis, 36 (2), 63-69.

One form of mourning therapy is the therapeutic leave-taking ritual, the essence of which is that by parting with symbols connected with the deceased, patients take their leave of the deceased and can start a new life of their own. In the case described in the present paper, the patient performed such a ritual in her imagination while under hypnosis. Her extreme grief response is explained in terms of Janet's theory of emotions. It is emphasized that successfully performing the ritual necessarily involved a change in attitude towards the deceased, and it is argued that the specific characteristics of hypnosis--involuntariness and

effortlessness--add an extra dimension to guided imagery approaches to unresolved mourning.

1987

Boswell, Louis K. (1987). Abstract imaging: Abstract imaging as a mode of personality analysis and adjustment. Medical Hypnoanalysis Journal, 2, 175-179.

Describes the use of abstract imaging during hypnosis to circumvent defense mechanisms and arrive at the initial sensitizing event behind a patient's emotional problems. Case examples illustrate how abstract imaging is also used to explore how the patient relates to the world on a conscious level and forms an idealized self-image to work toward.

De Pascalis, Vilfredo; Marucci, Francesco; Penna, Pietronilla M.; Pessa, Eliano (1987). Hemispheric activity of 40 Hz EEG during recall of emotional events: Differences between low and high hypnotizables. International Journal of Psychophysiology, 5, 167-180.

This study evaluates individual differences in hypnotizability as reflected in waking-state hemispheric engagement during recollection of 3 positively and 3 negatively valenced personal life events. The State-Trait Anxiety Inventory, Maudsley Personality Inventory, Tellegen Absorption Scale and Harvard Group Scale of Hypnotic Susceptibility (Form A) were administered. Electromyogram (EMG) and bilateral electroencephalogram (EEG) activities within the 40-Hz band were recorded during rest and task conditions in 22 high and 21 low hypnotizable women. Self-report rating scores for vividness of visual imagery and emotional feeling of the material recalled were evaluated. The 40-Hz EMG amplitude and both hemisphere 40-Hz EEG densities were obtained. A 40-Hz EEG ratio, as a measure of hemispheric asymmetry, and a hemispheric specificity index were also computed. High hypnotizables showed significantly lower 40-Hz EEG density than low hypnotizables in all experimental conditions. The relationship between lateralization of 40-Hz EEG and emotional processing was moderated by hypnotizability. High hypnotizables, with respect to rest condition, showed an increase of density over both left and right hemispheres during two of the three positive emotional tasks, while they showed a depressed activity over the left and an increased activity over the right during negative emotional tasks. Low hypnotizables, on the other hand, did not exhibit differential hemispheric patterns that could be attributed to different emotional valences. The high group showed greater hemispheric specificity in the predicted direction than the low group. High subjects exhibited greater ratings of absorptive ability and emotional feeling than low subjects. Anxiety and EMG levels did not differ between groups. EMG was dependent on the type of emotion which showed greater activity in the negative emotion condition compared with the positive one.

Holroyd, Jean (1987). How hypnosis may potentiate psychotherapy. American Journal of Clinical Hypnosis, 29, 194-200.

Hypnotherapy is defined as doing psychotherapy in the hypnotic state. This article reviews cognitive, affective, and motivational changes associated with hypnotic trance, attempting to demonstrate how the hypnotic state might influence ordinary psychotherapy processes. Nine characteristics of trance probably potentiate psychotherapy: (1) changes in attention and awareness, (2) imagery enhancement, (3) increase in dissociation, (4) decrease of reality orientation, (5) increase in suggestibility, (6) increased accessibility of mind-body interactions, (7) diminution of initiative resulting in a sense of nonvoluntariness, (8) increased availability or manipulability of affect, and (9) development of a fusional relationship (rapport). This article touches upon the psychotherapeutic implications of these hypnosis attributes.

Makarec, K.; Persinger, M. A. (1987). Electroencephalographic correlates of temporal lobe signs and imaginings. Perceptual and Motor Skills, 64, 1124-1126.

Significant correlations (0.50) were observed between scores for the Wilson-Barber Inventory of Childhood Memories and Imaginings and the experiences that are indicative of temporal lobe lability. In addition, positive correlations (0.42) occurred between temporal lobe EEG measures (scalp electrodes) and numbers of temporal lobe signs. The numbers of alpha seconds per minute from the occipital lobes were correlated (0.57) with the Wilson-Barber cluster that indicated interests in 'altered states'. Scores on the childhood imaginings section of the Wilson-Barber Inventory were correlated (0.44) with the numbers of spikes per minute over the temporal lobes when the eyes were closed.

#### NOTES

1:

Persinger and DeSano (1986) found that people who display temporal lobe signs were also more likely to have more imaginings (as defined by Wilson and Barber's (1983) Inventory of Childhood Memories and Imaginings) and to be more suggestible as indicated by Spiegel's Hypnosis Induction Profile" (p. 1124).

Subjects in this investigation were 12 male and 18 female students, ages 18-39 (M = 25 years) Bipolar measures were taken from just above the ears (approximately T3-T4) and the occipital lobe (O1-O2). Number of alpha seconds per minute and number of spikes per minute from each lobe was taken for 10 minutes (5 successive pairs of 1 minute eyes- open, 1 minute eyes-closed).

"The total Wilson-Barber score was significantly ( $p < .01$ ) correlated ... with the major (0.46) and minor (0.50) temporal lobe clusters but not with two clusters of control items: normal psychological experiences (0.21) and mundane proprioceptive experiences (0.29). These correlations are similar to those in the Persinger and DeSano study (0.60, 0.50, 0.13, and 0.14, respectively). Like the first study (0.53), the items that were most associated with dissociation (depersonalization) were best correlated with the Wilson- Barber scores (0.60). The Wilson-Barber subcluster: adults' extreme experiences (Items 44 through 52, that indicate physiological changes associated with thinking) was again most strongly correlated with the major (0.55) and minor (0.65) temporal lobe clusters; these values were 0.42 and 0.52 in the first study" (p. 1125).

"The only statistically significant ( $p < .01$ ) correlations between the Wilson-Barber scales and the EEG measures were between the number of alpha seconds from the occipital lobe (with the eyes closed) and the [Wilson-Barber] 'altered state' cluster ( $r = 0.57$ ; Items 33, 41, 42, 43). A weaker correlation (0.36) occurred between the number of alpha seconds per min. (eyes closed condition) and childhood vestibular experiences (items 1, 2, 3, 10, 24)" (p. 1126).

1986

Cerny, M. (1986). Hypnosuggestive interventions in emotional stress and in stress disorders. Activitas Nervosa Superior, 2, 141-143.

This paper represents a review of results using the PSA technique (Posthypnotic Suggestion evoked by Autostimulation) as a means of protection against stress. The best results were obtained in Ss with high susceptibility. This fact limits the practical use of the PSA method. However, this method can serve as a model approach in another more exact study of psychophysiological self-regulatory mechanisms in relation to coping with stress.

Holroyd, Jean (1986). Hypnosis applications in psychological research. Imagination, Cognition and Personality, 5, 103-115.

It is proposed that hypnosis leads to altered cognition, affect, or motivation as reflected by changes in 1) reality orientation, 2) attention and awareness, 3) imagery, 4) dissociation, 5) suggestibility, and 6) mind-body interaction. Hypnosis may be used as an experimental method to effect such cognitive, affective and motivational changes in order to pursue research in learning, personality, physiological, and social psychology. Examples of possible applications of hypnosis are provided. The influence of individual differences in hypnotic responsivity on research also is discussed.

NOTES

1:

The author concludes, "Contributions of hypnosis to research in psychology may have been diminished by the confusion inherent in searching for main effects while giving insufficient attention to interaction effects between personality variables and experimental manipulations. As psychology becomes more cognitive in orientation, the phenomena of hypnosis may seem less bizarre and more amenable to inclusion in psychological research. However great care must be taken not to confuse the contributions of hypnosis with the contributions of the hypnotically responsive personality" (p. 109).

Madigan, R. J.; Bollenbach, A. K. (1986). The effects of induced mood on irrational thoughts and views of the world. Cognitive Therapy and Research, 10 (5), 547-562.

Sixty college students participated in an experiment concerning the influence of somatic mood induction statements on measurements of irrationality as defined by Ellis. Subjects were randomly assigned to depression, elation, and neutral mood

induction groups. There were significant differences between groups on mood and irrationality. Results are discussed in terms of the Ellis and Beck cognitive models of depression, the Isen cognitive loop model, and the relationship between irrationality and depression. This study added irrational thinking as defined by Ellis to the growing list of cognitions that have been manipulated by mood, and it supports a body of findings that demonstrate the reciprocal influence of cognition and mood in depression. The study also has implications for the Beck and Ellis hypothesis that cognitions are the dominant causes of depression.

Pereira, Robert Peter (1986, July). The role of organismic involvement in hypnotic emotional behavior (Dissertation, Wayne State University). Dissertation Abstracts International, 47 (1), 385-B. (Order No. DA8605027)

Two hundred college undergraduates were pretested via the Harvard Group Scale of Hypnotic Susceptibility: Form A. Fifty subjects scoring in the range 7-12 were designated as Reals, while 25 subjects scoring in the range 0-4 were designated as Simulators. Reals and Simulators were given differential instructions before the administration of a second hypnotic induction procedure, which was accompanied by a task in which subjects were asked to relive each of three emotional experiences, i.e., fear, anger, and happiness. Reals were given instructions encouraging cooperation, while Simulators were instructed to try to convince a group of experienced hypnotists that they were deeply hypnotized, when, in fact, they would not be. "Physiological, overt-behavioral, and cognitive measures taken either during or following the relived-emotions task served as indices of Sarbin's organismic involvement construct. A post-experimental measure of the realness of subjects' relived emotional experience was regressed on these organismic indices in order to test Sarbin's assumption of a positive linear relationship between organismic involvement and belief-in imaginings, using data from the Real group only. Results indicated that, across all three emotions, the linear composite of organismic indices shared statistically significant amounts of variance with the criterion of experiential realness. Obtained amounts of shared variance ranged from 22% (during anger) to 55% (during happiness). These findings were interpreted as offering clear and robust support for Sarbin's theory of hypnosis. Suggestions for further research were offered. "The question of Real-Simulator differences was explored through several multivariate analyses of variance and covariance, using the organismic indices as dependent variables. These analyses were performed on the original sample of Reals and Simulators, and on two subsamples of Reals/Highs and Simulators/Lows which were created through the use of pre- and/or post-experimental exclusion criteria. Reals/Highs showed statistically higher levels of effort than did Simulators/Lows during all three emotions, as well as higher levels of skin conductance and finger temperature during anger. These findings were interpreted as being of theoretical and practical significance. Multiple replications of the physiological findings were recommended in order to assess the extent to which the skin conductance and finger temperature variables might be used in practical, i.e., forensic contexts" (p. 385-B).

**Strosahl, K. D. (1986). Imagery assessment by self report: A multidimensional analysis of clinical imagery. Cognitive Therapy and Research, 187-199.**

**Conducted 2 studies to test the theory that emotive-abstract, sensory modality, and control imagery are functionally distinct abilities and that emotive-abstract imagery and image control are directly related to the quality of in-therapy imagery. In Study 1, 199 undergraduates completed self-report measures of sensory modality, molar imagery, and image control and completed an analog clinical visualization task. In Study 2, 53 undergraduate test-anxious covert behavior therapy participants completed the self-report battery and provided ratings of in-therapy image clarity. Results suggest that emotive/abstract imagery, sensory modality imagery, and image control are factorially distinguishable abilities. A cross-sample factor analysis revealed some instability; however, a theoretically consistent pattern of results emerged. Regression analyses demonstrated that emotive-abstract imagery abilities were the best predictors of performance on the analog task, whereas both image control and emotive imagery were related to the clarity of in-therapy imagery. Results illustrate the qualitative difference between low- and high-order image processes and the possible interaction between emotive imagery and image control.**

**Brown, Daniel P. (1985). Hypnosis as an adjunct to the psychotherapy of the severely disturbed patient: An affective development approach. International Journal of Clinical and Experimental Hypnosis, 33 (4), 281-301.**

**An affective development approach to the psychotherapy of severely disturbed patients is presented. A review of nonhypnotic psychotherapies of such patients is given, and contemporary trends in psychoanalytic-developmental approaches to the treatment of severe disturbances are described. These approaches are designed to foster structuralization of the ego. A primary deficit in severe disturbance, however, lies in the awareness of the visceral changes accompanying genuine affective experience and the related subjective sense of aliveness. Related deficits occur in affective expression and tolerance. Target symptoms (e.g., hallucinations and disordered thinking) are secondary phenomena. Hypnosis can be used as an adjunct to psychotherapy for severely disturbed patients who are in a stable therapeutic relationship and who are also hypnotizable. During trance such patients are able to focus on internal events without distraction so as to enhance their awareness of visceral changes normally out of their awareness and to link these with images and memories. They are taught to develop a sense of aliveness and genuine affective experience. Target symptoms may diminish. Several case illustrations are given along with a theoretical discussion of the stages of affective development.**

**Gottschalk, Louis A. (1985). Hope and other deterrents to illness. American Journal of Psychotherapy, 39, 515-524.**

Reviews animal and human research demonstrating that events during early development influence vulnerability to physical and mental illness. In addition, effectiveness of coping methods used to deal with problems of living can affect susceptibility to illness. The intervening mechanisms between stressful life experiences and illness appear to involve physiological homeostasis and immune competence

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott; Frauman, David; Rhue, Judith (1985). Hypnotic age regression and the importance of assessing interpersonally relevant affect. International Journal of Clinical and Experimental Hypnosis, 33, 224-235.

The present study was undertaken to replicate an earlier experiment and to clarify which factors in this previous experiment (Nash, Johnson, & Tipton, 1979) were responsible for the obtained child-like behaviors of hypnotically regressed Ss. As in the previous study, 3 characteristics of the transitional object relationship (spontaneity, specificity, and intensity) were used as the primary criteria to investigate the effects of hypnotic age regression when Ss were regressed to age 3 and placed in 3 home situations. While in the previous study E suggested separation anxiety and isolation during the 3 home situations (mother-absent condition), the present study deleted all references to anxiety and isolation, and replaced them with suggestions of security and maternal proximity (mother-present condition). As expected, the mother-present versus mother-absent conditions led to similar hypnotized- simulating differences. In further accord with predictions, hypnotized Ss and simulating Ss requested a transitional object infrequently in the presence of mother. The importance of using dependent measures which index affective processes germane to interpersonal affect-laden experience is discussed.

Nichols, Michael P.; Efran, Jay S. (1985). Catharsis in psychotherapy: A new perspective. Psychotherapy, 22 (1), 46-58.

Contemporary thinking about catharsis in psychotherapy is still dominated by Breuer and Freud's work with the cathartic method. Psychoanalysts take the fact that Freud abandoned catharsis as evidence of its ineffectiveness, while the emotive therapies developed in the 1960s returned to Freud's earliest view that neurosis results from repressed affect and can be cured by cathartic uncovering. Emotional memories continue to be thought of as foreign bodies lodged in the human psyche and requiring purgation. Unfortunately, this view divorces people from responsibility for their conduct and encourages a fractionation of human experience into feeling, thought, and action. In the current presentation, emotion is construed instead as a class of blocked or partially blocked actions, and in terms of a two-stage adaptational process. Implications of this view for psychotherapeutic practice are proposed, emphasizing richer self-expression and fuller appreciation of the consequences of responsible vs. disclaimed actions.

## NOTES

1:

Provides summary of the history of associationism. Refers to Beddoes' essays (1802-03) which state that (1) emotions play a significant role in strengthening associations, and a study of emotions would be the 'chief secret for unriddling the inconsistencies of dreams,' and (2) variations could occur in associations (from very strong to very weak).

In the 19th century there was an ongoing debate about the role of the reflex in the nervous system, about how high up it could function, and whether it could still take place if it reached areas that subserved consciousness. Dr. William Carpenter postulated three levels: (1) excitomotor reflex (spinal, and maybe lower brain), (2) sensorimotor or consensual (midbrain) which was unconscious, (3) ideomotor (cerebral) - based on evidence from hypnosis in which volition appeared suspended and the subject became 'a mere thinking automaton' whose flow of ideas resulted from external suggestions only. The ideomotor response could be unconscious.

In the 1830's and 40's Thomas Laycock brought Associationism together with the concept of reflex. "By bringing the reflex into 'cerebral processes,' he proposed a model that made fast and automatic responses possible in the realm of ideas. Automatic thinking, speaking, writing, and more complex actions became topics of increasing interest to psychologists later in the century. As early as 1868, Prosper Despine had been speaking of 'psychological automatisms.' Laycock proclaimed most of these responses as being unconscious, that ideas could be charged with varying amounts of energy, and that ideas could act as causes of human disturbances, both psychological and physiological" (pp. 25- 26).

1860's - 90's saw the rise of hypnotism, with Eugene Azam using it in surgery and psychiatry; Durand de Gros's book on Braid; Liebeault publishing a book; Bernheim launching his career; Charcot shifting interest from organic neurological conditions to functional conditions; and Charcot teaching both Janet and Freud.

The author notes that "in July 1880, a bright and educated young woman of 20 started to nurse her dying father. Like the shamans before her, she had to grapple with the spectre of death and in her own fashion, she developed a creative illness. Her symptoms were myriad, but many had to do with changes in her consciousness (including 'absences,' clear-cut trances) and splits in her memory, including the loss of an entire language. At one point her current personality disappeared and another took its place: in this case it was herself but existing a year before in a state in which she lived without any apparent awareness of what had happened to her in the interim. It is this case of Anna O. and her doctor, Josef Breuer, which became important to the next epoch in our review and who had so much to do in inspiring the studies that followed" pp. 27-28.

Handelsman, Mitchell M. (1984). Self-hypnosis as a facilitator of self-efficacy: A case example. Psychotherapy, 21 (4), 550-553.

This article presents the four-session treatment of Elaine, using self-hypnosis to facilitate the mourning process. It is argued that self-hypnosis-- rather than enhancing imagery-- increases self-efficacy, a person's feeling that he/she can perform behaviors that lead to desired outcomes. Elaine's sense of self-efficacy was increased by allowing her to choose scenes from her life to be explored in the context of the use of imagery. Elaine imagined events surrounding her father's death, and "rewrote history" in an attempt to permit herself the direct expression of emotions.

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott (1984). The direct hypnotic suggestion of altered mind/body perception. American Journal of Clinical Hypnosis, 27, 95-102.

Attentional and emotional shifts are examined following a hypnotically suggested out-of-body experience (OBE). Two hypotheses were tested: 1) that the OBE is maintained by blocking the perception of body-relevant stimulation at a sensory level; 2) that a hypnotically produced OBE is an emotionally neutral or even pleasant experience. Fourteen hypnotic subjects and 15 simulating Ss were administered a standardized induction followed by suggestions for an OBE. Geometric figures were then presented to the body but not to the "awareness." Although hypnotic Ss reported that they could not see the information, they still correctly "guess" the identity of the figures beyond chance levels. Thus, body-relevant information was obviously not blocked at a sensory level, but was kept out of awareness by some other mechanism. In addition, a significantly greater number of hypnotized than simulating Ss reported the OBE to be troubling and unpleasant, despite explicit suggestions for a positive experience. The potentially disturbing nature of OBEs and ways to minimize risk of negative affect are discussed.

Pekala, Ronald J.; Kumar, V. K. (1984). Predicting hypnotic susceptibility by a self-report phenomenological state instrument. American Journal of Clinical Hypnosis, 114-121.

In an attempt to predict hypnotic susceptibility (as measured by the Harvard Group Scale of Hypnotic Susceptibility, HGSHS) the phenomenological experiences of an hypnotic induction (HI) procedure and a baseline comparison condition (eyes closed, EC, sitting quietly) were assessed. After each experience the subjects (n=217) completed the Phenomenology of Consciousness Inventory (PCI), a self-report phenomenological state instrument, dealing with that condition. Step-wise multiple regression and discriminant analyses were then performed on data using the subject's HGSHS score as the dependent variable and the PCI (sub)dimensions as the independent variables. Regression analyses that held up under cross-validation during HI suggest that the PCI may be an appropriate instrument for predicting susceptibility. The possible clinical usefulness of this approach is discussed.

## NOTES

1:

Scientific study of multiple personality disorder (MPD) began with single cases. As of yet, there is no study of incidence in the general population ( though Bliss, in 1983 American Journal of Clinical Hypnosis, has begun study of incidence in defined psychiatric populations). Some find symptoms overlap with borderline personality (Clary et al., 1984; Kluft, 1984; Horevitz & Braun, 1984). Others with temporal lobe epilepsy (Mesulam, 1981; Schenck & Bear, 1981). Until Kluft (1984) defined criteria for "fusion," no standard existed for successful treatment. Virtually all researchers agree that childhood trauma is antecedent. "The research questions that investigators find the most intriguing, however, are the mind/body issues raised by the alternate personalities." p. 114 "The relatively large number of reports of physiologic changes across alternate personalities compared to the total number of reported cases in the literature suggests that indeed something unusual is happening with these patients" pp. 114-115.

Models of Multiple Personality Disorder: 1. trance state 2. temporal lobe dysfunction 3. state dependent learning

Schare, Mitchell L.; Lisman, Stephen A.; Spear, Norman E. (1984). The effects of mood variation on state-dependent retention. Cognitive Therapy and Research, 8 (4), 387-407.

Examined the notion that when the affective states accompanying learning and remembering are the same, information will be retained better than when they differ. In 3 experiments, with 198 undergraduates, self-statements developed by E. Velten (1968) were used to influence Ss to feel somewhat depressed or elated or to experience no mood change. A 2 x 2 experimental design, incorporating a single word list and varying the mood conditions present during learning and later testing, was used in each of the 1st 2 experiments, neither of which revealed state dependence. However, a significant effect was found in Exp II, which employed an interference paradigm. In terms of free recall, items learned and tested under the same mood were recalled with 30% greater accuracy than items learned and tested under different moods. Methodological issues and clinical implications of these findings are discussed, and it is suggested that behavior change in therapy is most likely to be implemented during heightened affective arousal that simulates characteristics of the actual problem behavior. 1981

Bower, Gordon H. (1981). Mood and memory. American Psychologist, 129-148.

This article describes experiments in which happy or sad moods were induced in subjects by hypnotic suggestion to investigate the influence of emotions on memory and thinking. One result was that subjects exhibited mood-state-dependent memory

in recall of word lists, personal experiences recorded in a daily diary, and childhood experiences; people recalled a greater percentage of those experiences that were affectively congruent with the mood they were in during recall. Second, emotion powerfully influenced such cognitive processes as free associations, imaginative fantasies, social perceptions, and snap judgments about others' personalities (e.g., angry subjects generated angry associates, told hostile stories, and were prone to find fault with others). Third, when the feeling-tone of a narrative agreed with the reader's emotion, the salience and memorability of events in that narrative were increased. Thus, sad readers attended more to sad material, identified with a sad character from a story, and recalled more about that character. An associative network theory is proposed to account for these several results. In this theory, an emotion serves as a memory unit that can enter into associations with coincident events. Activation of this emotion unit aids retrieval of events associated with it; it also primes emotional themata for use in free association, fantasies, and perceptual categorization.

## NOTES

1:

### Mood and hypnotizability

Zuckerman, Persky, & Lind (1967; *Journal of Consulting Psychology*) used the Zuckerman-Lubin MAACL to test the hypothesis that affect states just prior to hypnosis induction are related to subsequent hypnotizability, while affect traits are not so related (P. 464). The mood states of subjects in two treatment conditions (either small and highly motivated groups or large and less motivated groups) were measured just before trance induction, while the MMPI affect-trait measures were administered afterwards. The MAACL hostility scale was found to have a significant negative correlation with hypnotizability, but the affect-trait measures were unrelated.

In an attempt to determine the 'real relationships between personality traits and hypnotizability, Silver (1973) tested 40 male students on the Byrne (1964) Repression- Sensitization Scale, and in a following session the Wessman-Ricks PFS and a short form of the Nowlis MACL. Hypnotizability was also assessed using the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & Hilgard, 1962). While repression was not found to be related to hypnotizability, mood was, both on the PFS and the MACL, with bright affective states being positively related and dark states showing the opposite relationship. (Factor analysis revealed that the Nowlis measured emotional energy or buoyancy overall, whereas the Wessman-Ricks measured life satisfaction). Silver (1974) found that the surgency scale of the Nowlis MACL predicted hypnotizability as well or better than the MACL's overall mood index. This suggest (sic) that, although the overall mood may determine one's susceptibility to hypnotic induction, those who are in a surgent mood will be the ones most readily hypnotized.

Case, David B.; Fogel, David H.; Pollack, Albert A. (1980). Intrahypnotic and long-term effects of self-hypnosis on blood pressure in mild hypertension. International Journal of Clinical and Experimental Hypnosis, 28, 27-38.

Self-hypnosis using the method of Spiegel (1974) was evaluated in 15 patients with labile or mild essential hypertension who were equally hypnotizable and adhered to a regimen of 6-10 daily exercises for a 4-month period. During the hypnotic state, there were consistent rises in both systolic and diastolic pressures in hypnotizable patients, but not in non-hypnotizable controls. Similar but smaller changes were also observed in normotensive subjects. Pressure rose immediately with hypnosis and subsided gradually over 15 minutes. However, the long-term effects of the daily practice of self-hypnosis were variable: ambulatory diastolic pressure fell in 5 patients, was unchanged in 7 patients, and rose in 3 patients. The changes in blood pressure could not be specifically attributed to the daily practice of self-hypnosis; however, all patients experienced improvement in well-being, mood, and behavior patterns during the 4-month period. The study indicates that self-hypnosis can produce changes in behavior and mood which may be beneficial to cardiovascular health, although paradoxically, the act of hypnosis by this technique is pressor. Aside from its therapeutic potential, self-hypnosis may provide useful information about central mechanisms of blood pressure regulation.

#### SUMMARY

Contingent negative variation behavior was studied in 12 voluntary normal subjects in basal conditions and in the hypnotic trance state under different emotional suggestions. A CNV voltage decrease and the appearance of a PINV were observed in the hypnotic state. Furthermore 12 nonhypnotizable control subjects were tested under the same experimental conditions and no CNV modification was found" (p. 505).

Stam, Henderikus J.; Radtke-Bodorik, Lorraine; Spanos, Nicholas P. (1980). Repression and hypnotic amnesia: A failure to replicate and an alternative formulation. Journal of Abnormal Psychology, 89 (4), 551-559.

In an attempt to replicate and extend a study by S. R. Clemes, 2 groups of 10 undergraduate hypnotic Ss learned a list of 18 words and were given an amnesia suggestion telling them they would be able to remember only 10 of these words. Half of the list words were critical (i.e., considered to be related to repressed conflictual material) and half were neutral (unrelated to conflictual material) as determined by Ss' responses to a word association test. Experimental Ss received their own critical and neutral words and yoked control Ss received the critical and neutral words of experimental Ss. Neither the experimental nor the yoked control group exhibited

selective amnesia in favor of critical words, thus constituting a failure to replicate Clemes's result. However, variables affecting the degree to which words were initially learned (e.g., imagery value, serial position) predicted their resistance to amnesia. These findings are inconsistent with a repression hypothesis but congruent with an inattention hypothesis of suggested amnesia. (41 ref).

1977

Chertok, Leon; Michaux, D.; Droin, M. C. (1977). Dynamics of hypnotic analgesia: Some new data. Journal of Nervous and Mental Disease, 164, 88-96.

Following two surgical operations under hypnotic anesthesia, it was possible, during subsequent recall under hypnosis, to elicit a representation of the past operative experience. It would seem that under hypnosis there is a persistence of the perception of nociceptive information and of its recognition as such by the subject. From an analysis of these two experiments in recall, it is possible to formulate several hypotheses concerning the psychological processes involved in hypnotic analgesia. In consequence of an affective relationship, in which the hypnotist's word assumes a special importance for the subject, the latter has recourse to two kinds of mechanism: a) internal (assimilation to an analogous sensation, not, however, registered as dangerous-- rationalization); and b) external (total compliance with the interpretations proposed by the hypnotist), which lead to a qualitative transformation of nociceptive information, as also the inhibition of the behavioral manifestations normally associated with a painful stimulus.

Novaco, Raymond W. (1977). Stress inoculation: A cognitive therapy for anger and its application to a case of depression. Journal of Consulting and Clinical Psychology, 45 (4), 600-8.

Clinical interventions for anger disorders have been scarcely addressed in both theory and research in psychotherapy. The continued development of a cognitive behavior therapy approach to anger management is presented along with the results of its application to a hospitalized depressive with severe anger problems. The treatment approach follows a procedure called "stress inoculation," which consists of three basic stages: cognitive preparation, skill acquisition and rehearsal, and application practice. The relationship between anger and depression is discussed.

1976

Coe, William C.; Baugher, R. J.; Krimm, W. R.; Smith, J. A. (1976). A further examination of selective recall following hypnosis. International Journal of Clinical and Experimental Hypnosis, 24, 13-21.

29 Ss were tested for posthypnotic amnesia on SHSS:C. They rated each item for emotional tone (pleasant-unpleasant) and judged whether or not they had passed or failed it. There was some support for the notion that failed items are judged more

unpleasant than passed items, but the emotional tone of an item was not related to its being recalled posthypnotically. There were minimal findings to suggest that Ss recall items which stand out in their experience. Discrepancies with earlier findings and the possible role of processes associated with normal memory are discussed.

1974

Galin, David (1974). Implications for psychiatry of left and right cerebral specialization: A neurophysiological context for unconscious processes. Archives of General Psychiatry, 31 (4), 572-583.

A brief review is presented of hemispheric specialization for different cognitive modes, and of the symptoms that follow disconnection of the two hemispheres by commissurotomy. Our present knowledge of the hemispheres' cognitive specialization and potential for independent functioning provides a framework for thinking about the interaction of cognitive structures, defensive maneuvers, and variations in awareness. Parallels are noted between some aspects of the mental processes of the disconnected right hemisphere and some aspects of primary process thinking and repression. The hypothesis is proposed that in normal intact people mental events in the right hemisphere can become disconnected functionally from the left hemisphere (by inhibition of neuronal transmission across the cerebral commissures), and can continue a life of their own. This hypothesis suggests a neurophysiological mechanisms for at least some instances of repression and an anatomical locus for the unconscious mental contents.

1970

Podolnick, Edward E.; Field, Peter B. (1970). Emotional involvement, oral anxiety, and hypnosis. International Journal of Clinical and Experimental Hypnosis, 18 (3), 194-210.

48 undergraduates were randomly assigned to either a high or low emotional arousal manipulation and then underwent a tape-recorded hypnotic induction and test of depth. The high-arousal group was exposed to infantile oral objects and were led to believe that they would have to suck on them as part of a physiological psychology experiment in which the cutaneous sensitivity of the human mouth was being mapped. The low-arousal group believed they only had to blow on whistles or pipes. While both groups were anticipating these experiences, hypnosis was induced. Ss in the high-arousal group were significantly more hypnotizable ( $p < .001$ ) than their counterparts in the low-arousal group. Ss in the high-arousal group were significantly less anxious after hypnosis than they were before hypnosis, while the low-arousal Ss did not show a reduction in anxiety. The groups did not differ on several background personality tests given as checks on the randomization. (Spanish & German summaries) (22 ref.) **Barber, Theodore Xenophon (1965). Physiological effects of 'hypnotic suggestions': A critical review of recent research (1960-64). Psychological Bulletin, 201-222.**

**Recent studies are reviewed which were concerned with the effectiveness of suggestions given under "hypnosis" and "waking" experimental treatments in alleviating allergies, ichthyosis, myopia, and other conditions and in eliciting deafness, blindness, hallucinations, analgesia, cardiac acceleration and deceleration, emotional responses, urine secretion to sham water ingestion, narcotic-like drug effects, and other phenomena. The review indicates that a wide variety of physiological functions can be influenced by suggestions administered under either hypnosis or waking experimental treatments, and direct and indirect suggestions to show the particular physiological manifestations are crucial variables in producing the effects.**

**Bernstein, Norman R. (1965). Observations on the use of hypnosis with burned children on a pediatric ward. International Journal of Clinical and Experimental Hypnosis, 13 (1), 1-10.**

Several cases are described and observations made about the interplay of forces between staff, patient, and therapist, as well as the expectations of the patients to assess how these factors influenced the use of hypnosis. Hypnosis appears to be a particularly useful means for reaching isolated and depressed children with burns and for improving the morale of the staff team working with these children. The results may be along specific lines in terms of pain tolerance and improved eating, or in general improvement of cooperativeness and mood on the part of the child. Davison, Gerald C. (1965, June). Anxiety under total curarization: Implications for the role of muscular relaxation in the desensitization of neurotic fears. [Paper] Presented at the annual meeting of the Western Psychological Association, Honolulu.

#### NOTES

I began by describing the Jacobson-Wolpe position on the use of deep muscular relaxation as an anxiety-inhibitor: these writers assume that the considerable reduction in proprioceptive feedback from muscles which are in a relaxed state is incompatible with a state of anxiety. Then I mentioned the evidence that at least modern neuromuscular blocking-agents operate solely at the myoneural junction, with no direct central effects. I went on to discuss the various studies which have used paralytic drugs, primarily d- tubocurarine chloride, to show the learning of fear-responses under complete striate muscle paralysis: the fact that these animals are able to acquire classically-conditioned fear-responses under curare was taken as evidence inconsistent with the views of Jacobson and Wolpe. Several studies were then reviewed which purport to furnish confirmatory evidence for the Jacobson position: these studies showed considerable central depression during curare paralysis. I re-interpreted these studies in the light of the over-riding importance of exteroceptive stimulation, stressing that the animals in the curare learning experiments were likewise deprived of proprioceptive feedback and yet were hardly non- anxious: the important difference was that the animals in the conditioning experiments were stimulated frequently from the environment while curarized, this stimulation maintaining an alert, often anxious state. Finally, two hypotheses were put forward as to why training in muscular relaxation does, in fact, inhibit anxiety: the one suggested that relaxing one's muscles generates strong positive affect states, which in turn inhibit anxiety; the other hypothesis called attention to the fact that the states of muscular relaxation under curare versus under self-induced relaxation differ in the important respect that only with self-induced relaxation is there a reduction in efferent activity--perhaps this elimination of efferents, rather than afferents, inhibits anxiety.

1962

English, O. Spurgeon (1962). Some dynamic concepts of human emotions in relation to hypnosis. American Journal of Clinical Hypnosis, 4, 135-140.

**NOTES**

**1:**

He describes characteristics of the human personality as having a need for being dependent, tendency to obey or cooperate, need to avoid pain, tendency toward retreating into solitude and silence away from the stimuli of every day living, wish to avoid tension or anxiety; and therefore having a need to regress, in hypnosis.

Rosenberg, Milton J.; Hovland, Carl I.; McGuire, William J.; Abelson, Robert P.; Brehm, Jack W. (1960). An analysis of affective-cognitive consistency. In Hovland, Carl I.; Rosenberg, Milton J. (Ed.), Attitude organization and change (pp. 15-64). New Haven, CT: Yale University Press.

**NOTES**

**1:**

It was ... predicted that a strong and irreversible alteration of an attitudinal affect would eventuate in reorganization of the person's associated cognitions." In two experiments, deeply hypnotized subjects were commanded to feel differently toward an attitude object than they normally did. Examination of the subjects' attitudes indicated extensive changes in cognitive structure, making it consistent with the newly held affects. The changes in cognitive structure were shown to persist as long as the reversed affect persisted. Evidence bearing on the preferred modes of cognitive reorganization was discussed.

Schneck, Jerome M. (1960). Special aspects of hypnotic regression and revivification. International Journal of Clinical and Experimental Hypnosis, 8, 37-42.

**NOTES**

**1:**

Author's Summary: "This report delineates a type of hypnotic revivification without the usually expected dramatic behavioral attributes and use of the present tense in verbalization. On the contrary, motor involvement is at a minimum, manifestations of acting out are devoid of dramatic channels, yet emotion is intense and verbalization is absent. Awareness of the existence of such revivification in the hypnotic setting is important for adequate understanding by the therapist and incorporation into hypnotherapeutic or hypnoanalytic procedure. Considerable alteration of temporal and spatial orientations take place and should be appreciated fully. The revivification under discussion was observed in hypnotic settings involving regressions to preverbal age levels. These observations permitted better recognition of similar occurrences for later age periods. Revivification without verbalization may be disclosed subsequently by the patient in spontaneous comments or explored by the therapist when it has been suspected. The discussion of this phenomenon has centered on the hypnoanalysis of a fifty-four year old woman. The ingredients have been encountered often with others. Additional details pertaining to the revivifications have been described. The psychodynamic implications of the above-mentioned patient's reference to her hypnotic involvements as "vivification" events owing to intensity of the emotional components, have been outlined and linked to previously presented views on emotional insight preceding intellectual insight. The

transference elements in revivifications have been given attention and shown to be consistent with a proposed concept of dynamic hypnotic age regression in contrast to chronological hypnotic age regression. The data presented have been correlated with views of a hypnotic-waking state continuum" (p. 41).

Duncan, Irma W.; Dressler, Robert L.; Lyon-James, Sara; Sears, Alden B. (1958). The search for an index of hypnosis. Journal of Clinical and Experimental Hypnosis, 6 (2), 95-108.

#### Summary

"Blood and urine samples were obtained from 18 university students at the beginning and end of two experimental sessions, one with and one without hypnosis. Some of the subjects relaxed during the sessions; others imagined or hallucinated a traumatic experience.

"Of a variety of measurements made, urinary volumes and 17-ketosteroids, the eosinophil count and psychogalvanometer recordings appear to give useful information about any changes due to the hypnosis. The biochemical changes caused by the experimentally produced emotions seem to depend on the individual and his past experience rather than the hypnosis. The data suggest that if the experience hallucinated is known to the subject, the biochemical changes indicate a relaxed state during the hypnosis. The psycho-galvanometer recordings may indicate an agitated state while the biochemical indices suggest a relaxed state" (pp. 106-107).

1956

Solovey, Galina; Milechnin, Anatol (1956). Concerning a theory of hypnosis. Journal of Clinical and Experimental Hypnosis, 4, 37-45.

#### NOTES

"The essential attributes of the hypnotic condition may be understood to derive from three sources:

- 1) The hypnotic emotional state per se
- 2) The resultant motivation of the 'subject' to comply with the desires of the 'operator' (reinstating a child-like responsiveness).
- 3) The RETROGRESSION to an earlier form of psychological functioning that takes place under a hypnotic state of growing intensity" (p. 43).

"Although the retrogressive process is a general response to emotions and probably exists in some toxic states as well, it has a remarkable feature in the hypnotic state: THE COALESCENCE OF MOTIVATION AND RETROGRESSION, which exists in hypnotized people, permits a peculiar manipulation of the retrogressed condition. The peculiar responsiveness of the subject may be tested and molded by means of propositions which act as suggestions. In this manner, the so-called HYPNOTIC PHENOMENA are elicited" (p. 44).

1955

Hart, Hornell (1955). Measuring some results of autohypnosis. Journal of Clinical and Experimental Hypnosis, 3 (4), 229-242.

NOTES

1:

The author developed self ratings for mood (euphoria-dysphoria) and alertness-fatigue, which were administered to college students in neutral conditions and after self-hypnosis conditions. The self hypnosis, or "auto-conditioning" usually involved deep relaxation self suggestions followed by other suggestions. The suggestions involved using the word 'you' to be able to re-instate the autoconditioning more and more effectively; suggestions for attitude change (e.g. that 'No matter what comes, we will grapple with it courageously'); and euphoria auto-suggestions (e.g. that 'you will come out of this deep relaxation, feeling rested, alert, cheerful and courageous'). In both single session experiments, as with a class of nurses who experienced an 8 minute auto-conditioning procedure, and in experiments extending over time, depression decreased. He noted that "for various reasons, the students who participated in autoconditioning experiments between February and May, 1955, were in many respects less successful than some of the previous experimental groups had been" (p. 235).

Increased alertness and diminished fatigue was also observed.

Many students chose to give themselves suggestions to correct the habit of procrastination. Two-thirds of the participants reported complete success, up to the level specified, and only one of 43 experiments on correcting procrastination was a "flat failure."

Stokvis, Berthold (1955). Hypnosis and psychoanalytic method. Journal of Clinical and Experimental Hypnosis, 3, 253-255. (Abstracted in Psychological Abstracts, 57: 1157)

NOTES

1:

The author distinguishes between hypnosis/psychoanalysis and 'hypno-analysis' which Hadfield previously described as a combination of hypnotic catharsis and re-educative suggestions.

At the Leyden Clinic the author uses one of several methods to "apply hypnosis together with the utilization of psychoanalytic principles. ... [It] consists in a cathartic-analytic treatment of the patient in the waking state, while endeavouring to re-enact repressed psycho-traumatic events of the past, in the hypnotic state. The experiences in question are subsequently discussed with the patient and elucidated" (p. 253).

1953

Beigel, Hugo B. (1953). Hypnosis as an instrument in psychological experimentation. Journal of Clinical and Experimental Hypnosis, 1, 13-17. (Abstracted in Psychological Abstracts, 53: 6385)

Author's Summary - In this paper various areas of psychological research were pointed out in which experimentation with hypnotized subjects has been or could be

employed to advantage. It is held that there are several problems which offer no point of attack unless hypnosis is used and several others which, in view of their complexity, cannot be effectually approached by the classic method of experimentation. Specifically mentioned were the areas of thinking, learning, perception, apperception, imagination, and emotion, in which the hypnotic experiment proves valuable when either amnesia for preceding experiences, isolation from concomitant influences, or the introduction of an as-if situation is necessary. While it is undeniable that some of the experiments cited need improvement if their results are to be considered reliable -- a remediable shortcoming they share with most first experiments -- it is also evident that the use of hypnosis in experiments offers an approach to some areas that have thus far been inaccessible. Needless to say, hypnosis should not be used when similar results can be as readily obtained by the customary experimental method, but as Gidro-Frank and Bull (10) state, our scant knowledge of the nature of the hypnotic state should not bar it from use as a scientific tool. Still the only one available technique to solve a problem. It must be added, however, that the experimenter must be thoroughly familiar with the technique but also to their physical and mental health.

Guze, Henry (1953). Posture, postural redintegration and hypnotherapy. Journal of Clinical and Experimental Hypnosis, 1, 76-82. (Abstracted in Psychological Abstracts 53: 6559)

**SUMMARY**The use of postural analysis, and directives regarding posture and their importance in hypnotherapy are discussed. Theoretically, it is indicated that a chronic postural condition may act to elicit an emotional state with which it was originally associated. Such an emotional condition may have caused the posture in the first place, and then established a feed-back relationship with it. The breaking of feed-back mechanisms of this kind depends largely upon postural change when a chronic situation is established in the absence of realistic cause for the emotion. Posture may also act redintegratively, when directly suggested, in rearousing traumatic memories. Several clinical cases are reported.

## **ENURESIS**

**1993**

Banerjee, Sanjay; Srivastav, Anita; Palan, Bhupendra M. (1993). Hypnosis and self-hypnosis in the management of nocturnal enuresis: A comparative study with imipramine therapy. American Journal of Clinical Hypnosis, 36, 113-119.

Various therapeutic modalities have been used for treating enuresis due to the lack of a single identifiable cause. We carried out a comparative study of imipramine and direct hypnotic suggestions with imagery used for the management of functional nocturnal enuresis. Enuretic children, ranging in age from 5 to 16 years, underwent 3 months of therapy with imipramine (N = 25) or hypnosis (N = 25). After termination of the active treatment, the hypnosis group continued practicing self-hypnosis daily during the follow-up period of another 6 months. Of the patients

treated with imipramine, 76% had a positive response (all dry beds); for patients treated with hypnotic strategies, 72% responded positively. At the 9-month follow-up, 68% of patients in the hypnosis group maintained a positive response, whereas only 24% of the imipramine group did. Hypnosis and self-hypnosis strategies were found to be less effective in younger children (5-7 years old) compared to imipramine treatment. The treatment response was not related to the hypnotic responsivity of the patient in either group.

1987

Olness, Karen N.; Libbey, Patricia (1987). Unrecognized biologic bases of behavioral symptoms in patients referred for hypnotherapy. American Journal of Clinical Hypnosis, 30, 1-8.

Twenty patients referred for hypnotherapy had organic conditions which explained their symptoms. Each had been evaluated previously by physicians. Eleven had also been in psychotherapy; two of these had been hospitalized on child psychiatry inpatient units. Presenting symptoms included five with nocturnal enuresis, four each with headaches and recurrent abdominal pain, three with recurrent headaches, two with anxiety, and one each with sleep problems and tics. Diagnoses included hyperthyroidism, diabetes, diastometamyelia, partial oxalotranscarbamyase deficiency, sinusitis, carbon monoxide poisoning, vitamin overdose, food allergy, amebiasis, constipation, urinary tract infection, paroxysmal atrial tachycardia, and seizures. Each child had complete remission of symptoms with treatment of his/her underlying disease. Morbidity related to delayed diagnoses included parental anxiety and guilt, child anxiety, growth delays, family financial difficulties, loss of parental work time, loss of school days, and loss of confidence in child health professionals by families.

ERICKKSON

1999

Rodriguez Sanchez, Rodriguez Rodriguez, Santana Mariqo, Piqueras Hernandez, Alvarez Ramirez (1999). Current tendencies and future directions of hypnosis in Cuba. Newsletter of the Erickson Foundation, Vol 2, 6.

Reviews the history of hypnosis in Cuba and the main tendencies and trends. There were no influences from Ericksonian hypnosis till recently when the first group of Ericksonians came to teach for the first time in Manzanillo, Granma Medicine University. The main approach is still the so called traditional hypnosis in which there is a development mainly in surgery and in some medical conditions. There are some strong places: Santiago de Cuba, where HipnoSantiago Hypnosis Workshop is held regularly, Manzanillo, where there is a Hypnosis Research group with publications in the country and abroad and experience in teaching hypnosis. The Hypnosis Society is located in Habana.

The group from Manzanillo is working in a Clinic Project with such themes as hypnoanesthesia in major surgery, models of groups learning under hypnosis, and some other therapies.

## NOTES

Hypnosis as the only anaesthetic procedure in major surgery. (Thesis)

Wilson, R. Reid (1999, August). Brief strategic treatment of panic disorder and OCD. [Paper] Presented at the annual meeting of the American Psychological Association, Boston, Massachusetts.

The symptoms, prevalence, and social/economic costs of Panic Disorder, Obsessive-Compulsive Disorder, and other anxiety disorders are reviewed. Cognitive-behavioral therapy (CBT) has demonstrated efficacy for these disorders. Ericksonian and strategic principles of therapy have a number of points of contact with CBT. Taking Panic Disorder and OCD as illustrative models, this paper demonstrates how Ericksonian methods can be fruitfully combined with CBT. Examples include paradoxical intervention, hypnosis and visual rehearsal, reframing, the fractional approach, and pattern disruption.

1997

Fourie, D. P. (1997). 'Indirect' suggestion in hypnosis: Theoretical and experimental issues. Psychological Reports, 80 (3, Pt 2), 1255-1266.

"Indirect" suggestion is conceptualized in two distinct ways in the literature. From an Ericksonian perspective "indirect" suggestions are theoretically approached as suggestions which can circumvent the censorship of consciousness to reach the "unconscious" where they can activate dormant potentials. In contrast, from a research perspective "indirect" suggestion is operationally defined as a technique. Based on Ericksonian theory, it was claimed that "indirect" suggestion was more effective than traditional, "direct" suggestion. However, this claim could not be empirically substantiated. In this paper it is shown that the theoretical claim is based on questionable assumptions about the existence of the "unconscious" as a reified entity and about the direct and lineal influence of certain suggestions on this entity. Also, it is argued that traditional research strategies which emphasize strict

controls are unable to verify or unambiguously refute the Ericksonian claim because these strategies are biased toward "direct" suggestion. Finally, the paper provides a different, contextual perspective on "indirect" suggestion, thereby placing the theoretical and experimental issues in a different context of meaning. [PubMed Abstract]

1996

Rosenbaum, Robert & Dyckman, John (1996). No self? No problem! Actualizing empty self in psychotherapy . In Hoyt , Michael F. (Ed.), Constructive therapies (2, pp. 238-274). New York NY: Guilford.

In this book chapter, Rosenbaum and Dyckman (1996) argue that \_self has no permanently fixed, defining, \_thing-like\_ characteristics\_ (p. 270). They thus dispute the classical notion--commensurate with the position of \_philosophical realism\_ -- that the self is a substance, with fixed qualities and measurable qualities. The authors refer to this classical self as a \_full\_ self, contained inside the skin and delimited by its participation in linear time. Instead, they propose an \_empty self,\_ not to be construed as a void, but as a fluid, connected, relational self that overflows the traditional boundaries of the skin and is open to greater possibilities for change. To support their view of an empty self, the authors include several case examples of working with hypnosis and strategic/narrative therapy with clients experiencing a variety of psychological and physical symptoms. The authors further contend that \_self is not unitary, but the product of multiple drafts\_ (p. 248)[Editor note: See Dennett, 1991, in this database]. In the narrative-constructivist tradition, they argue, \_if we speak in terms of multiple contextual selves for us all...[then, people diagnosed with MPD/DID] are not so \_different\_ from the rest of us\_ (p. 249). The chapter draws from western & Buddhist philosophy, strategic/systemic and narrative therapies, Ericksonian hypnosis, and, cognitive science theories regarding memory, consciousness, embodiment, and language, to support their alternative view of, and treatment for, the \_self.

1995

Holroyd, Jean (1995). Handbook of clinical hypnosis, by Judith W. Rhue, Steven Jay Lynn, & Irving Kirsch (Eds.) [Review]. International Journal of Clinical and Experimental Hypnosis, 43 (4), 401-403.

#### NOTES

This is a book for the thinking clinician" (p. 401). "The editors are to be congratulated for making this volume much more coherent than most edited books" (p. 402). "My impression is that the book is best suited for an intermediate or advanced course on hypnotherapy, or for people who are already using hypnosis in treatment. Although there is some material on the basics of hypnotic inductions and a few introductory sample scripts for inductions, a beginners" course should probably use a different book, or this book could be accompanied by an inductions manual. ... I recommend it very highly" (p. 403).

1993

Lynn, Steven Jay; Neufeld, Victor; Mare, Cornelia (1993). Direct versus indirect suggestions: A conceptual and methodological review. International Journal of Clinical and Experimental Hypnosis, 31, 124-152.

The article reviews the literature on the effects of direct versus indirect hypnotic suggestions. A conceptual and methodological analysis of direct versus indirect suggestions is also provided. Three conclusions follow from the review: (a) Contrary to views of Ericksonian hypnotists, suggestion style has little effect on objective responding to hypnotic test items; (b) studies of clinical- and laboratory-induced pain and other measures of subjective experience have yielded contradictory results- however, the best controlled studies have not indicated that indirect suggestions are superior to direct suggestions; and (c) there is insufficient evidence to conclude that hypnotizability level and suggestion wording interact, such that low hypnotizable subjects are particularly responsive to indirect suggestions. Methodological and conceptual problems in defining and studying hypnotic communications, the lack of rigorous experimental controls, and research issues and directions are highlighted.

#### NOTES

1:

Although this article is primarily concerned with the nature of suggestion, the review also mentions several studies comparing hypnosis with other interventions for pain, in passing:

Crowley (1980)

Snow (1979)

Omer, Darnel, Silberman, Shuval, & Palti (1988)

Stern (1982)

Bassman (1983)

"Like the clinical studies using the RIA [Rapid Induction Analgesia], pain studies that did not use the RIA lack appropriate control groups: Neither Bassman's (1983) nor Stern's (1982) research explicitly compared direct and indirect suggestions. What our review does suggest is that studies (e.g., Crowley, 1980; Snow, 1979; Van Gorp et al., 1985) that imposed the greatest degree of methodological control yielded the outcomes least favorable to the hypothesis that indirect suggestions are effective and account for the pain relief achieved, above and beyond factors common to placebo treatments" (p. 132).

"Lynn and his colleagues' studies indicate that whereas indirect suggestions enhance archaic representations of the hypnotist, direct suggestions facilitate involvement in the events of hypnosis, as measured by subjective involvement and involuntariness" (p. 136).

1992

Kirmayer, Laurence J. (1992). Social constructions of hypnosis. International Journal of Clinical and Experimental Hypnosis, 40 (4), 276-300.

Both clinical and experimental views of hypnosis are social constructions that reflect the biases and interests of practitioners and scientists. Each perspective offers useful

metaphors for hypnosis. Underlying clinical uses of the term hypnosis are states of mind associated with imaginative reverie and automatic behavior based on procedural knowledge. Social discourse and narratives shape hypnotic experience, but they are themselves influenced by mechanisms of attention and automaticity. Study of hypnosis must proceed on both social and psychological fronts to account for the experience and clinical efficacy of hypnosis.

#### NOTES

1:

In accord with Coe, Sarbin, and other social-psychological theorists, I will argue that hypnosis, like all higher mental phenomena, is fundamentally social in nature. To accept this, however, does not obviate the role of distinctive processes of attention, imagery, and imagination. Hypnosis is a socially constructed context and ritual for evoking imaginative enactment and involuntary of "automatic" modes of experience and behavior. Contemporary social-psychological theorists have failed to sufficiently explore the nature of enactment. A satisfactory account of hypnosis must go much deeper into the cognitive and social construction of experience; only then can involuntary behavior be properly distinguished from self-deception and self-authorship from cultural construction" (p. 277).

1991

Brown, Peter (1991). The hypnotic brain: Hypnotherapy and social communication. New Haven, CT: Yale University Press.

#### NOTES

Notes are taken from a review of this book: Diamond, Michael (1993). Book review. *Bulletin of the Menninger Clinic*, 57 (Winter), 120-121.

Brown "posits that because the fundamental matrix of the human brain is metaphoric, hypnosis results from skillful matching of metaphorical communication with the brain's biological, rhythmic alterations. The most significant feature of trance experience is thereby located in the hypnotist-subject interaction" (p. 120).

"The middle section [of the book is comprised largely of] literature reviews in support of Rossi's (1986) ultradian rhythm theory of hypnosis and Lakoff and Johnson's (Johnson, 1987; Lakoff & Johnson, 1980) experientialist theory of conceptual thought" (p. 120). The final section includes "research evidence on medical uses of hypnosis, a theory of dissociation and multiple personality disorders, and an uncritical discussion of Milton Erickson's naturalistic hypnotherapeutic approach ... [and also] a brief discussion of the social-cultural functions of possession states among the Mayotte culture" (p. 120).

Goran, D. K. (1991, February). The effects of hypnosis and hypnotizability testing on chronic pain (Dissertation, Case Western Reserve University). Dissertation Abstracts International, 52 (8), 4466-4467.

This study evaluated the effectiveness of Ericksonian-oriented hypnosis in the treatment of chronic pain and the value of the Stanford Scale of Hypnotic Susceptibility in preselecting pain patients for hypnosis. Chronic pain patients were

assigned to one of three treatments: a one-hour session of Ericksonian hypnosis with suggestions for pain control, suggestions with no hypnotic induction, or an interview about their pain condition. It was discovered that during the treatment hour hypnosis was more successful in reducing both pain and emotional distress than was suggestion alone, and both were superior to the interview control treatment. Of particular interest, those patients who were not given the Stanford Scale of Hypnotic Susceptibility until the end of the study improved more than those who were tested with it prior to treatment. Scores on the Stanford Scale did not correlate with improvements in pain or distress. Thus, it is possible that formal hypnotic susceptibility testing may be detrimental to a pain patient's chances of being successfully treated with hypnosis" (pp. 4466-4467).

Shutty, Michael S.; Sheras, Peter (1991). Brief strategic psychotherapy with chronic pain patients: Reframing and problem resolution. Psychotherapy.

There is currently a paucity of literature concerned with the delivery of psychological services to chronic pain patients in an outpatient setting where patient contact is limited to one or two consultations. Yet, the role of psychological consultation to patients with pain problems has expanded greatly in the past decade. This article describes the application of brief strategic interventions that can promote behavior change in patients who have not adhered to medical recommendations for conservative treatment of chronic pain. Strategic interventions embody a here-and-now problem-solving perspective that facilitates integration of medical and psychological treatment goals for pain patients.

#### NOTES

1:

Pain is a significant problem for many people--8% of the general population (Von Korff, Dworkin & Le Resche, 1990), accounting for most of the money paid for health care, compensation, and early retirement (Anderson, 1981). Linton (1986) reported that only 35-45% of chronic low back pain patients can work a year after pain treatment, and Gallon (1989) reported that 2/3 of chronic low back pain patients did not show improvement 4-6 years after a pain management program.

In the past, outpatient treatment has included diagnosis and short-term treatment, but now they are providing more physical therapy, vocational retraining, and psychotherapy. Behavioral treatments focus on reducing pain behavior, use of medication, exercise, and stress management. They are labor intensive and the authors state that they are not readily adapted to outpatient settings.

Among psychological treatments would be included 'brief strategic therapy' which has a here-an-now problem-solving focus and clearly specified behavioral or attitude change goals. This type of therapy has been associated with Milton Erickson's hypnotherapy strategies. It has been described by Fisch et al. (1982) and Watzlawick et al. (1974). Erickson and these other therapists stress altering the patient's frame of reference (reframing) in order to provide an opportunity for change. Brief strategic therapy includes such things as paradoxical intention, negative practice, and symptom prescription.

The authors note that since complete pain relief is not a realistic goal for chronic pain, it is important to focus on teaching patients better coping skills. They note that Rybstein-Blinchik (1979) and Rybstein-Blinchik & Grzesiak (1979) have demonstrated that reformulation of the pain experience (reframing) is beneficial for chronic pain patients. In their research, pain patients were taught to somatize (focus on specific sensations), divert attention (think of important events in their lives) or reframe their experience (reinterpret it in cognitive terms inconsistent with pain complaint, e.g. as numbness or warmth). Those who were taught reframing reported that their pain was less intense, and they exhibited fewer pain behaviors. This is taken as supportive for using cognitive interventions that teach patients to reinterpret pain, rather than focusing on its somatic sensations or diverting attention.

1990

O'Hanlon, W. H.; Hexum, A. L. (1990). An uncommon casebook: The complete clinical work of Milton H. Erickson, M.D.. New York: W. W. Norton & Co.. (Reviewed by Elgan Baker, *American Journal of Clinical Hypnosis*, 34, 137)

NOTES

1:

According to the review by Elgan, cases are organized into sections by the presenting problems of the patients treated and include a wide range of psychopathology. Each case is given an identifying number for ease of cross-referencing and is presented in a standard form: case summary, presenting problem, age group, modality of treatment, problem duration, treatment length, result of treatment, follow-up (if available), a summary of techniques used, and sources for the case description.

Sherman, S. J.; Lynn, S. J. (1990). Social-psychological principles in Milton Erickson's psychotherapy. *British Journal of Experimental and Clinical Hypnosis*, 7, 37-46.

In this article we will suggest that social-psychological principles may be used to understand M. H. Erickson's psychotherapeutic approach. In addition to using an array of indirect suggestive approaches, Erickson exploited clients' reactance, increased their perceptions of control and mastery, altered the accessibility of thoughts and memories, and modified thoughts and behaviours. To accomplish these therapeutic goals, Erickson used the following techniques: seeding, priming, confusion, script enactment, framing, explanation, and perspective modification.

1988

NOTES

1:

This is the introduction to a special issue of *International Journal of Clinical and Experimental Hypnosis*, which is devoted to the contributions of Milton Erickson. "The conclusions of these analyses are sometimes surprising. The usual understanding of Erickson's work and the hallmarks of the Ericksonian tradition emphasize such parameters as indirect suggestion; naturalistic or permissive trance

induction; confusional strategies; 'unconscious learning'; and the focal use of metaphor, analogy, anecdote, and storytelling. These authors suggest, however, that Erickson's work frequently did not entail the use of hypnotic trance in any conventional sense and attribute many of the crucial variables in his therapeutic work to a variety of nonhypnotic phenomena" (p. 126).

Several consistent themes emerge, which Baker refers to as perhaps the "essence" of Erickson's contributions: "(a) the charismatic power of Erickson's personal presentation and style; (b) the marked influence of social variables; (c) consideration of primitive, unconscious relationship variables; (d) the evocative use of language, symbolism, and nuances of communication; (e) the ingenious tailoring of therapeutic interventions to the perceived uniqueness of each patient; and (f) the central influence of nonhypnotic variables rooted in social learning and cognitive-behavioral paradigms" (p. 126).

**Diamond, Michael Jay (1988). Accessing archaic involvement: Toward unraveling the mystery of Erickson's hypnosis. International Journal of Clinical and Experimental Hypnosis, 36, 141-156.**

The "essence" underlying Milton Erickson's unique style and uncommon technical maneuvers inheres in his uncommon skill at eliciting patients' archaic involvement. Archaic involvement, as characterized by perspectiveless overevaluation, is explicated and America's beloved tale, *The Wonderful Wizard of Oz*, is used to evoke further perspectives. The importance of such regressive object-representations are noted. Erickson's uncanny ability to access archaic involvement and thereby profoundly influence his client is analyzed in terms of his: (a) relationship style; (b) therapeutic "persona"; (c) theoretical orientation; and (d) specific micro-techniques and interventions. Clinical findings derived from a case transcript and videotaped work are employed throughout to substantiate the argument that Erickson fosters regressive interpersonal shifts. Implications of this skill are discussed, and further avenues for investigation are suggested.

#### NOTES

1:

Shor (1959, 1962, 1979) introduced the concepts of archaic involvement, trance (fading of the generalized reality orientation or altered state of consciousness) and nonconscious involvement (or fulfillment of the role of hypnotic subject, dissociated role taking) to account for experienced hypnotic depth. Shor (1979) defined archaic involvement as "'the extent to which at any given moment in time there are archaic, primitive modes of relating to the hypnotist that echo back to the love relationships of early life [p. 126]' (p. 143)."

Archaic involvement develops as a hypnotist actively encourages the subject to regard the hypnotist with the role of parent, teacher, guru. Charismatic authority, protector, etc. Erickson fostered these attitudes in his patients, and his apparent magical expertise can be attributed to his ability to tap into these archaic ties, which are 'ubiquitous.' "Freud (1919/1955) long ago noted that human beings' irresolution and craving for authority should never be underestimated. Fenichel (1945) stressed the universal yearning for 'omnipotent beings whose help, comfort, and protection

he could depend on [ p. 491].' Kaiser (1965) considered the 'universal psychopathology' of attempting to create in real life the fantasy of fusion. Still others (Kohut, 1971, 1977; Kriegman & Solomon, 1985; Newman, 1983) suggested that the motivation to yield to or to create such charismatic leaders stems from the desire to lose all boundaries and become lost within a greater whole--an experience elsewhere termed a fusional or symbiotic alliance (Diamond, 1987). This 'search for oneness' (cf. Silverman, Lachman, & Milich, 1982) is engaged by charismatic leaders as we become enticed by our own archaic wishes to avoid uncertainty, ambivalence, and the complexities of maturation, perhaps even creating such leaders to save us from ourselves" (p. 145). There remains the question of how archaic involvement facilitates or impedes psychotherapy.

In addition to archaic involvement, Erickson's behavior as a hypnotherapist during the later years of his career stressed the evocation of nonconscious role-playing, while underplaying the evocation of the trance dimension. He relied on his reputation and interventional skills, stressing 'naturally occurring trance' of everyday life. (In his earlier years he spent more time on developing profoundly altered states of consciousness.)

"Erickson's therapeutic 'persona' and style of engaging were consistently parental and authoritative, albeit frequently permissive, supportive, flexible, and benevolent. He always remained in control and typically insisted that his orders be carried out strictly and without question (Hilgard, 1984). ... Archaic wishes are further gratified by Erickson's gentle and soothing parental tone and stance, while control is maintained as he invites his patient to 'enjoy being irritable with me'" (pp. 147-148). To further psychotherapeutic goals, he sometimes assumed the role of surrogate parent, in hypnosis, to supply the patient with needed (childhood) experiences, as in the famous case referred to as the 'February Man.'

Erickson's implicit theory of an autonomous and omnipotent unconscious further encouraged "more primitive modes of perceiving and construing consensual and historical reality" (p. 148). "For example, he tells his patient in the Lustig (1975) videotape that: 'Your unconscious knows all about it; it will inform the conscious mind when it is ready to know'" (p. 149).

Regarding his technical maneuvers (intonation, wording, nonverbal communication, indirect suggestion, metaphor, and anecdote), "contrary to popular belief, he frequently spent long periods of time thinking about and planning his interventions (Hammond, 1986). In addition to using these patterns to evoke both patient resources and archaic alliances, he adopted an exceptionally confident manner, even when prescribing unusual assignments (McCue, 1984). Thus, patient faith and positive expectation in the efficacy of his interventions were maximized" (p. 149).

Erickson's pacing of his speech was slow, at the same rate as President Reagan's speeches. He was tone deaf, which may have contributed to the arrhythmia and unusual intonation observed in his speech. He used the patient's language, typically, which "undoubtedly provides a narcissistically gratifying identification with a hypnotist felt to be inside one's own psychic system (Diamond, 1987)" (p. 150). When he would say to patients, "My voice will go with you," he was inviting a "bodily-level incorporation" (p. 150). When he created mental confusion through his maneuvers, he increased the likelihood that the patient would "respond to

subsequent direction in order to bind anxiety" (p. 150). "Thus, an archaic object relationship is recapitulated by an invoked regression to earlier, primary phases of cognitive processing, and in turn, Erickson provides a safe, 'holding environment' (cf. Winnicott, 1965) for his now regressed patient" (p. 150).

Erickson used what Watzlawick (1978) has called 'the language of change'--puns, metaphors, indirect communication, analogies. He finessed the defensive functions of secondary processes (Kalt, 1986) by allying himself with the patient's secondary processes, as when he used anecdotes and teaching tales in the role of a 'Dutch uncle' giving advice. The teaching tales usually affirmed basic American values (common sense, pragmatism, self-sufficiency, resiliency, achievement; Diamond, 1983). However, this kindly grandfather approach "recreates an archaic relational situation wherein adult-level defenses and secondary processes are realigned while Erickson the storyteller permits expression and oftentimes symbolic gratification of instinctual drives. This archaic recapitulation occurs as a result of the relaxing of defenses through metaphorical communication (cf. Schafer, 1983), in addition to the revival of opportunities for mastery within this safe and often enchanting context (cf. Bettelheim, 1977)" (p. 151).

The author concludes by addressing clinical issues pertaining to an Ericksonian approach that relies on archaic involvement. "An essential question for clinicians concerns the long-term effects on the patient of the therapist's fostering such regressive involvement. There are both pluses and minuses of therapeutic relationships which maximize archaic involvement. Consequently, we need to empirically determine the efficacy of Ericksonian interventions both in offering short-term relief from suffering, and in potentiating developmental maturation in the long run. Not only must we ascertain how much archaic involvement is required for lasting change, but what is done with the regressive involvement (i.e., is it merely evoked, managed, utilized, or ultimately worked through?) is critical in assessing the value of Erickson's contribution" (p. 152).

Edgette, John H. (1988). 'Dangerous to self and others': The management of acute psychosis using Ericksonian techniques of hypnosis and hypnotherapy. In Lankton, Stephen R.; Zeig, Jeffrey K. (Ed.), Ericksonian Monographs: No. 3. Treatment of special populations with Ericksonian approaches (pp. 96-103). New York: Brunner/Mazel.

#### NOTES

1:

Edgette shows how several agitated psychotics were hypnotized using an Ericksonian approach. His inductions were bold attempts to introduce hypnosis in a setting where drugs and restraints are often the only available tools. He offers some ideas concerning the myth that hypnosis will not work with such a population.

Hammond, D. Corydon (1988). 'Will the real Milton Erickson please stand up?'. International Journal of Clinical and Experimental Hypnosis, 36, 173-181.

Disciples of Erickson are overaccentuating some aspects of his work and are thereby neglecting others. Current training predominantly focuses on indirection, confusion,

esoteric metaphors, paradox, and magical expectations of instant success via superficial trances. Therapists are sometimes encouraged to simply go into trance themselves and "trust the unconscious," instead of following Erickson's model of hard work and careful treatment planning. It is time for a new law in the field of hypnosis: the Law of Parsimony. Interviews with numerous long-time associates of Erickson present him as being much more diverse in his approach. Erickson's true legacy is eclectic hypnotherapy, not a dogmatic and restrictive cultism.

## NOTES

1:

This article appeared in a special issue of the journal devoted to an evaluation of the contributions of Milton H. Erickson, who had died eight years earlier. The author begins with a statement that he has deep respect for Erickson's work and ideas, but wishes to deal with many myths that have evolved regarding Erickson's therapy approach. He notes several factors that have contributed to current confusion: 1. Few clinicians are sufficiently skillful to use the panoply of techniques employed by Erickson, so they gravitate to a few with which they feel comfortable. 2. Some of Erickson's techniques are unique, thereby drawing special attention. 3. The Erickson observed in seminars in his senior years was very different from the man during mid-life, in terms of therapy style.

The author devotes considerable attention to discussing two techniques critically: indirection, and interspersal of suggestions within metaphors (multiple-level communication). These were developed to bypass resistance, but Erickson himself did not use them if the hypnotic Subject was receptive. The author also takes issue with followers' assumption that Erickson worked spontaneously, without planning his interventions.

(1) Indirect suggestion. Erickson reportedly told a long-time student and associate, Herbert Lustig, "if a person were desirous of changing and accepting of the therapist's input, then direct suggestions were the most efficient form of treatment" (p. 176). The author indicates that there are numerous examples in his collected works of Erickson giving suggestions "with compelling, progressive, rapid, emphatic, insistent intensity ... [Erickson, 1980c, Vol II, p. 281]." Several examples are cited in this article, e.g. "Now listen to me. These are the things you must do. Do them you must, and without fail [Erickson, 1980, Vol. IV, p. 359]" (p. 175). Erickson's use of direct suggestions was substantiated by another long-term associate, Kay Thompson, who is quoted as saying, "Many of the patients who came to Erickson did not have a need for indirection. They were ready and able to utilize trance. ... Sometimes people need the excuse of being ordered to do what they wanted to do, and Erickson complied with that need in a totally intimidating and authoritarian fashion. I would venture to say that his indirect therapy was successful principally because of his extensive work with direct therapy" (p. 176).

(2) Metaphors as suggestions. Regarding the use of metaphors (into which suggestions are imbedded), the author quotes other Erickson colleagues (e.g. Robert Person, Florence Sharp) in support of the position that contemporary followers of Erickson overemphasize his use of them. Many of his stories were not even meant to be metaphors. He seemed to fill in time with stories to allow patients time for deepening or to integrate previous material. "Metaphors were not the core of his

therapy and every comment by Erickson did not have three levels of meaning. Pearson said, Erickson 'told me within the last year before he died that one of the things that disgusted him was that so many people in trying to imitate him with embedded metaphor and parables were hiding behind that obscurity. He was very careful in what he told and why he told them.'

"When Erickson did use metaphors, they were generally not stories constructed on the spot (Erickson, 1983, p. 78), and they usually had obvious relevance rather than being so highly indirect as to be incomprehensible. In fact, most long-term associates recalled Erickson frequently using bridging associations, making direct connections between metaphoric stories and patient problems, rather than refusing to answer patient questions about the possible meanings" (pp. 177-178).

(3) Treatment Planning. Many contemporary followers of Erickson assume that he advocated simply going into a trance themselves and "trusting the unconscious." However, "Erickson himself said, 'I have found that I often spend more time analyzing a patient's resistance--going over and over it, phrasing and rephrasing what I could say in response--than I spend with the patient during the actual interview [Erickson, 1983, p. 245]. Over and over again, after a patient has left your office, you ought to review in detail every item of behavior. You ought to make notations of the types of behavior, and then perhaps even practice out loud to yourself so that you learn how to phrase your remarks [p. 240]. I think you all ought to write out your suggestions and then carefully analyze them to see what they really mean [p. 242]. When a patient comes into my office [for a scheduled appointment], I usually have a rather clear idea of what I want to do' [p. 125].

"It was this compulsive preparation and writing and rewriting of suggestions for over 40 years that allowed him at the end of his life to have the appearance of spontaneity. He could trust his unconscious after putting something into it" (p. 178). "Late in his life, Erickson instructed Rossi (cited in Erickson & Rossi, 1979): 'I want you to notice how connected everything is even though it's all impromptu. It is a language I've learned, a careful study. ... Because I learned it carefully, I can speak it easily [p. 295].' His widow and many others emphasized his time consuming, compulsive preparation" (pp. 178-179).

The author notes that Erickson also took a considerable amount of time in training patients to use trance before doing hypnotherapy with them. He quotes Ernest Rossi as writing, "'Erickson rarely gives therapeutic suggestions until the trance has developed for at least 20 minutes, and this only after hours of previous hypnotic training' [Erickson, 1980, p. 89, Vol III]."

The references cited in this paper are usually one of the volumes of Erickson, M. H. (E. L. Rossi, Ed.) *The collected papers of Milton H. Erickson on hypnosis*, published in New York by Irvington Publishers, 1980.

**Hilgard, Ernest R. (1988). Milton Erickson as playwright and director. International Journal of Clinical and Experimental Hypnosis, 36, 128-140.**

Milton Erickson in his therapeutic practice can be characterized as a playwright who plans a little play for each patient and then leads that patient to accept and enact the assigned role. This arrangement permits him to be authoritarian as

playwright and director by providing the staging and the strategy, while the patient then provides the tactics by carrying out the assignment in his or her own way. Several examples are given from published cases. The first is a case of enuresis in both husband and wife, selected because in this instance no mention is made of hypnosis as Erickson sets the circumstances and gives direct orders for carrying out the instructions. 3 pairs of cases are described to indicate how differently Erickson has treated cases with similar symptoms. Finally, 1 case is discussed more extensively because the treatment extended over a 6-year period. Its interpretation shows how difficult it is to distinguish what belongs to the strategic drama and what to hypnosis. All cases had successful outcomes.

## NOTES

1:

The essence of Erickson's therapy lay in the unexpectedness of his comments or instructions, the shock element, the surprises, and the tasks that he assigned the patient to carry out in the real space-time world or in fantasy. There was often doubt whether other than light hypnosis was involved" (p. 129).

As an example, Hilgard reports on a published case in which both the husband and wife had enuresis and Erickson treated them in a very authoritarian fashion. Erickson told them that he "would make a bargain with them: If they got well, they would not have to pay; if they did not benefit from the therapy, they would have to take full financial responsibility for the time he gave to them. He obtained their promise that they would do what he told them, and then he proceeded to tell them: 'This is what you are to do.' He then laid out the scenario. The most important part was that they were to take fluids frequently, drink a glass of water 2 hours before going to bed, and then lock the bathroom door. At bedtime, they were to get into their pajamas, kneel side by side on the bed and deliberately and jointly wet the bed. Wetting the bed would then be over for the night, and they could sleep through the night in the wet bed. They must do this every night for 2 weeks; on the Sunday night to follow, they may lie down and sleep in a dry bed. If the bed is wet the next morning, they will have to kneel and wet the bed each night for another 3 weeks.

"You have your instructions. There is to be no discussion and no debating between you about this, just silence. There is to be only obedience, and you know \_and will know what to do\_. I will see you again in five weeks' time. You will then give me a full and amazing account. Goodbye! [Volume IV, 1954, p. 100, emphasis in original].

"When they reported--cured after the first 2 weeks--they asked whether Erickson had used hypnosis. He dodged their question by saying that they were entitled to full credit for what they accomplished" (p. 130).

Hilgard makes the point that Erickson's authoritarianism might seem to contradict claims made that he had a high degree of respect for patients, their autonomy, and their responsibility for solving their own problems. "There need be no contradiction, if it is recognized that the planned behavior may not in itself be the cure, but may only be the occasion that leads to patient to reorient and solve the personal problems that led to the seeking of therapy. Another way of putting this is that the \_strategy\_--that is, the plot of the drama--was entirely Erickson's, although the \_tactics\_--that is, beyond the fixed actions required by him, how the part was played--were left to the resources of the patient. This is not the permissiveness of

Rogers (1951) with respect to the patient's responsibility for his or her own life, nor does it have the freedom of expression of Moreno's (1946) spontaneity theater" (p. 131).

Kirmayer, Laurence J. (1988). Word magic and the rhetoric of common sense: Erickson's metaphors for mind. International Journal of Clinical and Experimental Hypnosis, 36 (3), 157-172.

Milton Erickson did not produce a systematic theory of psychotherapy. His talent was as a storyteller, inventing metaphors and more extended healing fictions for his patients. A great many of Erickson's cases did not involve hypnosis in any conventional sense of the term. He used a wide range of persuasive rhetorical forms to encourage behavioral change in his patients. Nevertheless, taken together his work represents a significant shift in paradigm from prevailing schools of psychotherapy. Erickson captured the power of word magic in the language of common sense. This coupling of magical power with folk psychology accounts for much of his current popularity. Attempts to experimentally test his techniques are likely to be unsuccessful because these techniques were unique inventions tailored to the individual idiosyncrasies of patient and context. Although regularities in his work can be found, Erickson's most important contributions are not techniques but changes in the values or ethos under which psychotherapy is conducted.

#### NOTES

1:

This paper focuses Erickson's implicit models of mind and the values they carry. "It is here that Erickson made his most significant contribution to the general practice of psychotherapy . Erickson avoided systematization. His writing is unusually anecdotal, even for psychotherapy (Erickson, 1980; Vol IV, passim). Erickson's writing format consists of 'thin' case descriptions, freely recycled in parable or homiletic form to serve his immediate rhetorical purpose. ... For Erickson, flexibility and eclecticism were not signs of a lack of coherence but a spirited rejection of rigid dogma that needlessly limited therapeutic possibilities" (pp. 158-59).

Erickson used language of the common man rather than a technical vocabulary, even when speaking of 'hypnosis' or 'trance' or 'the unconscious.' He called his approach 'naturalistic' and viewed hypnotic phenomena as an extension of normal experience and behavior. His common sense descriptions of events and techniques are easily understood in general terms. "Erickson took magic and dressed it in the familiar clothes of common sense. Some of his less critical followers, however, seem intent on taking common sense and dressing it in the cloak of magic" (p. 163).

Erickson used metaphors as a way of actively involving the patient in conceptual, affective, and sensory qualities of experiences, i.e. as a "tool for thought" (p. 164).

In attempting to understand Erickson's psychotherapy, one must note his "elastic use of the word 'hypnosis.' Sometimes Erickson uses the term narrowly with a focus on the elicitation of trance or dissociative phenomena, but more often he uses it broadly to mean any state of absorption" (p. 165). For him, this was "\_a state of special awareness characterized by a receptiveness to ideas\_" [Erickson, 1985, p. 223, emphasis in original]. By this he does not mean exclusively the classic

suggestion effect where motor acts are experienced as involuntary (Evans, 1967). ... The hypnotic subject exhibits a "\_special willingness to examine ideas for their inherent values\_" [p. 224, emphasis in original]. ... For Erickson, any move in the direction of increased absorption is an instance of hypnosis. Dissociation accounts for a great deal but not all of hypnotic behavior" (p. 165). That is why he used the word hypnosis to describe heightened attention that might occur when someone is surprised. But in fact, his published cases include many other kinds of interventions, such as reframing, symptom prescription, etc.--forms of influence and persuasion used by many therapists who do not consider themselves working with hypnosis. Erickson also emphasized that hypnosis enables one to work with 'the unconscious.' "Ordinarily, we view our consciousness as the causal agent of doing while our unconscious is the place where things just 'happen to us.' Erickson reversed this attribution, emphasizing the unconscious as the agent of active control working for the benefit of the patient while consciousness adopts the attitude of 'wait and see.' This leads consciousness into reverie--the state where images and events move of their own accord, animated by emotion, before the 'passive audience' of consciousness" (p. 167). So Erickson viewed hypnosis as liberating the unconscious. There was healing potential in helping the ego to relinquish "rigid control over the creative and benevolent processes of the unconscious" (p. 168). From this theoretical position, the patient and therapist are seen as allies and psychotherapy is a collaboration; there is no need for the Freudian concepts of resistance and defense. "Erickson's metaphors for hypnotherapy link it with normal processes of learning and imagining. His image of the unconscious as a storehouse of creative potential supports a non-pathologized view of man amid all his troubles and craziness. In contrast to psychiatry's current preoccupation with nosology, and the emphasis of psychoanalysis on the dimensions of human frailty, Erickson adopted a non-pathologizing attitude. He did not deny his patient's difficulties but neither was he excessively fascinated by them. He recognized that healing depends not on cataloguing deficiency but on fully mobilizing the person's intelligence, imagination, and integrity. This message of therapeutic optimism was balanced by his own example of the benefits and limitations of hypnotherapeutic practice" (p. 170).

McCue, Peter A.; McCue, Elspeth C. (1988). Literalness: An unsuggested (spontaneous) item of hypnotic behavior? A brief communication. International Journal of Clinical and Experimental Hypnosis, 36, 192-197.

Milton Erickson claimed that the large majority of hypnotized individuals respond in a peculiarly literal way to questions/requests such as, "Would you mind telling me your name?" and he viewed this behavior as a manifestation of the 'hypnotic state.' In the present study, numerous Ss were exposed to hypnotic induction procedures and tested for literalness. Since it is possible that Erickson obtained literal responses by inadvertent cueing, some of these Ss were asked questions in a 'distorted' manner that was thought likely to elicit literal responses. A minority of the latter Ss gave literal responses, but with Ss who were asked questions in a normal manner, no clear-cut literal responses of the type described by Erickson were noted.

Omer, H.; Darnel, A.; Silberman, N.; Shuval, D.; Palti, T. (1988). The use of hypnotic-relaxation cassettes in a gynecologic-obstetric ward. In Lankton, S. R.; Zeig, J. K. (Ed.), Research, comparisons and medical applications of Ericksonian techniques (pp. 28-36). New York: Brunner-Mazel.

#### NOTES

1:

They did three studies in which they gave women having gynecologic procedures tapes with a Rapid Induction Analgesia hypnosis experience.

STUDY 1. Women heard tapes before a painful Fallopian tube procedure (salpingography). The patients reported less pain, tension, anxiety, and fear than control patients. (N.B. Physicians' ratings did not show that difference.)

STUDY 2. Women practiced with the tapes at home before labor and delivery. One day after delivery, there was no difference in pain report or experience report between treated and control patients.

STUDY 3. Women used the tapes during labor. They reported worse pain and labor experiences than the control patients.

The authors conclude that their research does not support the hypothesis that Rapid Induction Analgesia is useful for acute pain.

Spinhoven, Philip; Baak, Diana; Van Dyck, Richard; Vermeulen, Peter (1988). The effectiveness of an authoritative versus permissive style of hypnotic communication. International Journal of Clinical and Experimental Hypnosis, 36, 182-191.

The differential effectiveness of an authoritative versus permissive style of hypnotic communication was investigated, with locus of control as a moderator variable. 44 Ss received in counterbalanced order both the more authoritatively worded Harvard Group Scale of Hypnotic Susceptibility, Form A and the Wexler-Alman Indirect Hypnotic Susceptibility Scale (WAIHS), which is a more permissive scale with the same item content as HGSHS:A. Permissively worded suggestions did not enhance the level of hypnotic responsiveness. Locus of control did not predict the response level on one of the scales. Unexpectedly, significantly more female Ss preferred the WAIHS, and more male Ss preferred HGSHS:A. It is concluded that Ss' characteristics (i.e., hypnotizability) are more important for hypnotic responsiveness than variations in style of hypnotic communication or scale preference."

Lynn, Steven Jay; Neufeld, Victor; Matyi, Cindy L. (1987). Inductions versus suggestions: Effects of direct and indirect wording on hypnotic responding and experience. Journal of Abnormal Psychology, 96 (1), 76-79.

This study examined the effects of direct wording (authoritative language, specific responses) versus indirect wording (permissive language, choice of responses) of hypnotic inductions and suggestions in measures of behavioral and subjective responding. Subjects experienced suggestion-related involuntariness and suggested effects to a greater degree in response to direct-word suggestions (Harvard Group

Scale of Hypnotic Susceptibility; Form A; Shor & Orne, 1962) than in response to indirect-worded suggestions (Alman-Wexler Indirect Hypnotic Susceptibility Scale; Pratt, Wood, & Alman, 1984). No difference in behavioral responding was observed. Furthermore, induction wording did not have an effect on these measures, nor did the wording of the induction and the wording of the suggestion types interact with each other. Female subjects attributed less of their responsiveness to their own efforts when they received direct suggestions, and male subjects were less likely to attribute their responsivity to the hypnotist's ability when they received indirect suggestions. Rapport with the hypnotist did not vary as a function of induction or suggestion wording.

1986

Woolson, Donald A. (1986). An experimental comparison of direct and Ericksonian hypnotic induction procedures and the relationship to secondary suggestibility. American Journal of Clinical Hypnosis, 29 (1), 23-28.

Recent studies reporting the disparate effects of direct and indirect suggestion upon hypnotized subjects have indicated that standardized, direct hypnotic susceptibility tests may not accurately predict the suggestibility of subjects exposed to an indirectly worded, albeit similar, test. Historically, primary suggestibility correlates highly with hypnotizability, while secondary suggestibility does not and has been reported to be a subject's response to indirect suggestion. In this study 56 volunteers for self-hypnosis training were first tested for secondary/indirect suggestibility, then each singly received either a direct standardardized [sic] induction or an Ericksonian (indirect) version. While susceptibility scores between groups were close, a greater number of the Ericksonian group subjects were rated as medium or highly susceptible. This occurred regardless of their type of suggestibility. Also, the Ericksonian group subjects appeared to be less aware of their depth of trance, as judged by a comparison of their susceptibility scores and their self-report depth scores. - Journal Abstract

Yapko, Michael D. (1986). What is Ericksonian hypnosis?. In Zilbergeld, B.; Edelstien, M. G.; Araoz, D. L. (Ed.), Hypnosis - questions & answers (pp. 223-231). New York: Norton.

#### NOTES

1:

Author presents the principles of Ericksonian hypnosis (the Utilization Approach) as:

- "1. Each person is unique. ...
2. The client's experience is valid for him. ...
3. Each person relates to ongoing experience from his own frame of reference. ...
4. Join the client at the client's frame of reference. ...
5. The unconscious mind is rich in resources, positive in nature, and patterned from experience. ...
6. Trance is naturalistic. ..." (pp. 224-225).

1985

Stone, Jennifer A.; Lundy, Richard M. (1985). Behavioral compliance with direct and indirect body movement suggestions. Journal of Abnormal Psychology, 94 (3), 256-263.

Investigated the effectiveness of 2 types of suggestions in eliciting body movement by presenting 96 high-, medium-, and low-susceptible undergraduates, in hypnotic or nonhypnotic conditions, with either of 2 series of body movement suggestions. The indirect suggestions were designed to represent the approach of M. H. Erickson (see PA, vol 60:11116 and 12262) and resulted in greater compliance in the hypnotic condition. Direct suggestions resulted in greater compliance in the nonhypnotic condition. Susceptibility to hypnosis was related to compliance in the hypnosis condition, but no interactions were found between susceptibility and type of suggestion. Sense of volition in responding was unrelated to the major findings. Discussion of the results includes a call for the accurate reporting of the wording of hypnotic suggestions in future research.

1984

Nugent, William R.; Carden, Nick A.; Montgomery, Daniel J. (1984). Utilizing the creative unconscious in the treatment of hypodermic phobias and sleep disturbance. American Journal of Clinical Hypnosis, 26 (3), 201-205.

An Ericksonian hypnotherapeutic procedure is designed to access and direct creative unconscious processes toward the creation and implementation of satisfactory solutions to recurrent problem behaviors. The use of the procedure is described in 3 cases. Two of the cases involve treatment of severe hypodermic needle phobias. The third case involves use of the procedure in treatment of a somnambulistic sleep disturbance. Possible curative forces tapped by the procedure, suggestions for its continued use, and suggestions for further investigation of the procedure are also discussed.

NOTES

1:

The procedure involved: 1. Pretrance discussion of unconscious mental processes 2. Hypnosis, followed by "Now your unconscious mind can do what is necessary, in a manner fully meeting all your needs as a person, to insure that [desired therapeutic outcome], and as soon as your unconscious knows that you will [desired therapeutic outcome] it can signal by [appropriate ideomotor signal]" 3. Post-ratification.

Example: "'Now your unconscious mind can do what is necessary, in a manner fully meeting all your needs as a person, to insure that you remain comfortably awake and alert anytime you receive an injection in the future, and as soon as your unconscious knows you will remain comfortably awake and alert when receiving an injection it can signal by lifting your right hand into the air off the chair.' This suggestion was [their] communicative effort to access and direct unconscious processes to the creation and implementation of altered behavioral responses to injections. Three minutes after the suggestion, B's right hand lifted jerkily into the

air. She was then awakened and experienced a complete amnesia for the trance period" (p. 203).

"[They] then carried out a procedure to ratify the therapeutic change. This process presumably further develops expectancy of change, confirms change at the unconscious level, and puts doubt into any conscious beliefs contrary to positive change. This step is standardly carried out as was done with B. [They] had B sit with her hands resting on the arms of the chair. [They] told her they would ask her unconscious mind a question that only it would know the answer to. It could answer 'yes' to the question by lifting her left hand, 'no' by lifting her right hand, and 'I don't know' or 'I don't want to answer' by lifting both hands. Then the question was asked, 'In the future, will B remain comfortably awake and alert anytime she receives an injection or a blood test?' After a few minutes her left hand jerked momentarily into the air. After some discussion about the ideomotor response and her trance experience they dismissed her with the prescription to 'await the surprising results'" (p. 203).

The authors cite as a source for their work two books: Erickson, Rossi, and Rossi, *Hypnotic Realities*, 1976, pp. 226-230; also Erickson & Rossi, *Hypnotherapy*, 1979.

**1983**

Bassman, S. (1983). The effects of indirect hypnosis, relaxation and homework on the primary and secondary psychological symptoms of women with muscle contraction headache (Dissertation). Dissertation Abstracts International, 44, 1950-B.

**NOTES**

**1:**

Compared the effects of indirect hypnosis (e.g., metaphors, stories, vague suggestions, and implied directives) on muscle contraction headaches with a relaxation and a no-treatment control condition. Both hypnosis and relaxation conditions reduced symptoms more than did the no-treatment condition. Unlike relaxation, indirect hypnosis did not reduce the intensity and duration of headaches, although it did reduce the amount of medication and also benefitted sleep.

**1979**

Snow, Lorraine L. (1979). The relationship between 'rapid induction' and placebo analgesia, hypnotic susceptibility, and chronic pain intensity (Dissertation, University of Rhode Island). Dissertation Abstracts International, 40 (n2-B), 937.

**NOTES**

**1:**

Found that the RIA [Rapid Induction Analgesia] was no more effective than oral placebo analgesia in relieving the pain of 30 paraplegics suffering from chronic pain syndrome. Although Snow found that the RIA was unrelated to hypnotizability when the effect of chronic pain experience was controlled, Crowley (1980) did find that hypnotizability was related to multiple chronic pain indices.

**1977**

Beahrs, J. O. (1977). Integrating Erickson's approach. American Journal of Clinical Hypnosis, 20, 55-68.

More than any other psychotherapist, Milton Erickson epitomizes the flexibility needed to do most skillfully what he feels is necessary for any psychotherapy: first, meet the patient at the patient's level and gain rapport; second, modify the patient's productions and gain control; third, use this control to help the patient change in a desirable direction. Several adjectives often used and misused to describe Erickson are discussed; how they sometimes apply, sometimes do not. His concepts of hypnosis and the unconscious are briefly set forth. Four major and seemingly divergent frameworks for formulating and treating human behavior are presented. My thesis is that, semantics considered, they may often be saying the same thing. The semantics is yet of vital importance, as each framework carries its own different all-important pragmatic implications for how one should work. Erickson is again notable in his uncanny ability to function within all of these modes, and possibly others, with great skill, and the flexibility which allows him to adapt totally to each patient's own individualized system. Finally, a personal experience of my own is recounted, with a speculative hint on how it might shed some light on the mechanism of how this amazing psychotherapist might do his magic.

**1976**

Erickson, Milton H.; Rossi, Ernest L. (1976). Two level communication and microdynamics of trance and suggestion. American Journal of Clinical Hypnosis, **18**, 153-171.

The authors provide the transcript and commentaries of an hypnotic induction and an effort to achieve automatic writing. An unusual blend of Erickson's approaches to two level communication, dissociation, voice dynamics and indirect suggestion are made explicit in the commentaries. The junior author offers a 'context theory of two level communication' that conceptualizes Erickson's clinical approaches in terms consonant with Jenkins' (1974) recent contextual approach to verbal associations and memory. A summary of the microdynamics of Erickson's approach to trance induction and suggestion is outlined together with a utilization theory of hypnotic suggestion.

Jenkins, J. J. (1974). Remember that old theory of memory? Well, forget it! American Psychologist, **29**, 785-795.

**1971**

Beahrs, J. O. (1971). The hypnotic psychotherapy of Milton H. Erickson. American Journal of Clinical Hypnosis, **14**, 73-90.

The principles of hypnosis and suggestion permeate most of Milton Erickson's psychotherapy, although formal trance induction is used in less than ten percent. Characteristic of Erickson's style is his indirect manner of phrasing suggestions or interpretations. They come not as outside impositions, but as subtle manipulations leading the patient to institute constructive behavior from within, often without full conscious awareness. Usually Erickson first attempts to meet the patient at the patient's level, thereby gaining rapport. As trust is developed, he modifies the patient's productions by covert suggestions, thereby gaining control. In this manner, he is able to convert a chaotic psychotic hallucination into an orderly hypnotic one,

or the desperate cries of a terminal cancer patient into hypnotic anesthesia. As interpreted here, Erickson's therapeutic approaches can be divided into three categories. First are techniques resembling modern behavior therapy, with frequent use of desensitization. Second, uncovering or abreactive techniques are only rarely used for rigidly resistant and severe symptom patterns. With these, extreme care is taken to protect against too rapid a disclosure to conscious awareness. Third and most important, are techniques enabling the patient to shift or displace large amounts of emotional cathexis from his original problem to some new constructive outlets, usually involving the development of trusting interpersonal relationships. These techniques are the cornerstone of Erickson's therapeutic technique.

**1964**

Erickson, Milton H. (1964). The confusion technique in hypnosis. American Journal of Clinical Hypnosis, 6, 183-207.

**NOTES**

**1:**

The confusion technique is "a play on words or communications of some sort that introduces progressively an element of confusion into the question of what is meant, thereby leading to an inhibition of responses called for but not allowed to be manifested and hence to an accumulating need to respond. ... [Added to the play on words] are the modification of seemingly contradictory, or irrelevant unrelated concepts, non sequiturs and ideas, variously communicated, and each of which out of context is a simple reasonable assertion, meaningful and complete in itself. In context, such communications given in a meaningfully emphatic manner become a medley of seemingly valid and somehow related ideas that leads the subject to try to combine them into a single totality of significance conducive to a response, literally compelling a response. But the rapidity of the communications inhibits any true understanding, thereby precluding responses and resulting in a state of confusion and frustration. This compels a need for some clear and understandable idea. As this state develops, one offers a clearly definite easily comprehensible idea which is seized upon immediately and serves to arouse certain associations in the subject's mind. The medley is then continued and another comprehensible idea is offered, enhancing the associations of the previous clear understanding. And in the process, one throws in irrelevancies and non sequiturs as if of pertinent value, thereby enhancing the confusion" (p. 256 in the article as reprinted in Jay Haley).

**1954**

Erickson, Milton H. (1954). Special techniques of brief hypnotherapy. Journal of Clinical and Experimental Hypnosis, 2, 109-129. (Abstracted in Psychological Abstracts 55: 2508)

**NOTES**

**1:**

Author describes techniques used with patients who aren't able, for internal or environmental reasons, to undertake comprehensive therapy, "Intentionally utilizing neurotic symptomatology to meet the unique needs of the patient" (p. 109). He provides 8 case reports.

Patient 1 was reassured, in hypnosis, that his arm paralysis was due to "inertia syndrome" which he would continue to have, but it wouldn't interfere with his work.

Patient 2, also with arm paralysis had another comparable, non-incapacitating, symptom substituted.

Patients 3 and 4, for whom restrictions on therapy were the limits of time and situational realities, had their symptoms transformed (e.g. by introducing in hypnosis the obsessional thought or worry that he would NOT have the symptom for which he sought help).

Patients 5 and 6 were helped, through hypnosis, to symptom amelioration. (Patient 5 had an IQ of 65.)

Patient 7 "Therapy was achieved ... by a deliberate correction of immediate emotional responses without rejecting them and the utilization of time to palliate and to force a correction of the problem by the intensity of the emotional reaction to its definition" (p. 121)

Patient 8 "the procedure was the deliberate development, at a near conscious level, of an immediately stronger emotion in a situation compelling an emotional response corrective, in turn, upon the actual problem" (p. 121).

## **ETHICS/STANDARDS OF CARE**

**1997**

**Karlin, Robert (1997). Illusory safeguards: Legitimizing distortion in recall with guidelines for forensic hypnosis - two case reports. International Journal of Clinical and Experimental Hypnosis, 45, 18-40.**

Two amnesic automobile accident victims remembered the information needed for their ongoing lawsuits during hypnosis. Meeting the recording requirements of the Hurd safeguards led to the admission of hypnotically influenced testimony in court in one case, whereas failure to record led to exclusion in the other. In both cases, closed-head trauma almost certainly prevented long-term memory consolidation. Thus adherence to guidelines for forensic hypnosis legitimized distortions in recall instead of preventing them. Hypnosis used to facilitate hypermnesia alters expectations about what can be remembered, makes memory more vulnerable to postevent information, and increases confidence without a corresponding increase in accuracy. Distortion of recall is an inherent problem with the use of hypnosis and hypnotic-like procedures and cannot be adequately prevented by any set of guidelines.

**Barber, Joseph (1995, November). When hypnosis causes trouble. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.**

**NOTES**

**1:**

**NOTES: Sexual acting out occurs, even with highly trained and responsible clinicians. But other problems occur, and it is the same qualities of hypnosis that**

make it useful that also make for problems. I found 20 publications that exhibited problems in therapy, and they all discussed only the mental illness of the patients.

1995

Frischholz, Edward J. (1995, November). A critical evaluation of the 1985 AMA Report on hypnosis and memory. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

#### NOTES

JAMA 1985 concluded that hypnotically refreshed memories are less reliable than nonhypnotic recall. There are two problems with their conclusion: 1. No consensually validated definition of 'hypnosis' is identified. They talk about administration of induction, and differences in hypnotic susceptibility. 2. Empirical criteria for discriminating the unique and/or moderating effects attributable to hypnosis are not specified.

For example Loftus showed that memory errors can be created without hypnosis. You should not just add hypnosis to that model.

The criticisms have not led to remedial practices. No research has been done to show how to minimize errors or how to facilitate accuracy.

'What is Hypnosis?' Something that is done vs. something that happens? A procedure or responsivity? Questions like this are relevant to research on whether hypnotically refreshed memories are less reliable than ordinary recall.

Hypnosis is not a 'valid therapeutic modality' (i.e., 'hypnotherapy' is a misnomer). Hypnosis can be used adjunctively with many different types of therapeutic modalities: --psychodynamic therapies --behavior modification treatments --cognitive restructuring strategies --systematic desensitization --flooding --direct suggestion

There is a specious communality: hypnosis is used in a different kind of way with each approach.

If hypnosis is defined in terms of whether an hypnotic induction procedure was administered to the subject, then hypnosis is a universal phenomenon (i.e., everyone can be administered an hypnotic induction procedure). This, in the AMA report, permitted the courts to define it this way, which leads to a number of ridiculous results.

We need to highlight 'What are the variables that are the source of the errors?' The sources are not hypnosis. We can minimize the sources by the way we ask questions, instruct the subjects, etc.

If hypnosis is defined in terms of the nature of the subjects' response to the procedures, then hypnosis is not a universal phenomenon (i.e., there are wide individual differences in hypnotic responsivity). I have shown that it is possible to alter memories, using the Loftus model, in people who are both low and high hypnotizable.

We need to take into account induction procedure, hypnotizability, type of memory, and the retrieval/influence procedure. The demand characteristics re forced responding, expectancies about memory (e.g. video recorder model), expectancies about hypnosis (e.g., everyone remembers) must be accounted for.

Dependent variables in this type of research include memory accuracy, memory errors, and subjective confidence.

1994

Barber, Joseph (1994, October). How to use and abuse boundaries with hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco. Keywords: abuse, ethics/standards of care, hypnotherapy, hypnotist, psychodynamic, relationship/transference, suggestion

#### NOTES

(for only part of the presentation) I would like to focus on how we can productively use boundaries. Hypnosis experience reactivates archaic experiences with parents; if therapist can evoke trust, the patient can feel increasingly that they can relax into the experience.

Beahrs, John O. (1994). Why dissociative disordered patients are fundamentally responsible. International Journal of Clinical and Experimental Hypnosis, 42 (2), 93-96.

The author was asked to respond to the question, "To what extent should patients with multiple personality disorder (MPD) be held fundamentally responsible for their actions?"

Bloom, Peter B. (1994). Clinical guidelines in using hypnosis in uncovering memories of sexual abuse: A master class commentary. International Journal of Clinical and Experimental Hypnosis, 42 (3), 173-178.

"Joan," a clinical psychologist, requested a psychiatric consultation to determine whether hypnosis could recover accurate memories of suspected child abuse by her still living father. Are there clinical guidelines in using hypnosis in uncovering such possible memories of sexual abuse? We asked Dr. Peter B. Bloom to share his views with us.

#### NOTES

Gives case example and clinical guidelines for using hypnosis in uncovering memories of sexual abuse. 1. In medical practice, "Primum non nocere," i.e. "First do no harm." 2. "No therapist should ever, either directly or indirectly, suggest abuse outside of a specific therapeutic context--certainly not to a client who is on the phone making a first appointment!" 3. "A therapist must not jump quickly to the conclusion that abuse occurred simply because it is plausible." 4. "A therapist should never simply assume that a client who cannot remember much from childhood is repressing traumatic memories or is in denial." 5. "Remember 'a client is most vulnerable to suggestion and the untoward influence of leading questions when therapy begins to delve into painful life situations from the past, particularly from childhood.'" 6. "Therapists ... should be cautious about suggesting that clients cut off communication with their families." 7. "Therapists should reconsider the 'no

pain, no gain' philosophy of treatment." 8. "The context of therapy is as important as the content." 9. "Tolerate ambiguity." (Sincerity and conviction on the part of the patient reporting abuse are not in and of themselves reason to believe the material.) 10. "Respect the current science of memory." 11. "Maintain responsibility for making the diagnosis and choosing the treatment." 12. "Pursue alternative diagnoses to account for the symptoms." 13. "Historical and narrative truth: Understand the difference."

#### COMMENT

The tenet that insight is necessary for change and growth is not true. Change can occur without insight, although insight may be helpful in maintaining change once it has occurred.

#### SUMMARY

These guidelines are presented to enhance safe practice, however, clinicians should use their own judgement to determine the best path to follow with each patient.

#### NOTE

Guidelines 1, 8, 9, 10, 11, 12, and 13 are those of Peter B. Bloom. Those labeled as Guidelines 2, 3, 4, 5, 6, and 7 were taken with permission from Yapko, M. (1993 September/October). "The seductions of memory. The false memory debate." *Family Therapy Networker*, 17, pp. 30-37. All discussions, however, are those of Peter B. Bloom.

Bloom Peter (1994, October). Training boundaries that enhance responsible therapy: Using hypnosis creatively in one's own discipline. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

Presented three cases that he elected not to treat, to illustrate the principle that we should only treat cases we would be professionally trained to treat without hypnosis. (1) a hemorrhoidectomy patient, where he elected not to do hypnosis because he is not trained specifically in anesthesiology and didn't know how to do anesthesia procedures; (2) conversion hysteria in 12 year old girl, because he isn't trained in child psychiatry and doesn't know child development; (3) to confirm the supposed existence of unidentified flying objects, or UFOs (when a woman tried to get him to hypnotize her so the "truth" would emerge). We must free ourselves from treatment of patients who retreat from reality, when we can't find commonality in goals.

Ganaway, George K. (1994, October). The thin line: Reality and fantasy in hypnotically facilitated memory retrieval during psychotherapy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

**Historical review: Every hundred years there has been a peak in interest in altered states--a fin de siècle zeitgeist. It is the Brigadoon effect, i.e. something materializing for one day every 100 years. The theories developed then suffer from "paradigm grandiosity." In hypnosis, we can refer back to:**

**1694 Salem witch trials**

**1790s Gausssner's exorcism (see Ellenberger); in a 1775 showdown between him and Mesmer, there occurred the turning point between exorcism and psychotherapy.**

**1880s Charcot at Salpêtrier 'demonstrated' that hypnosis was an organic, pathological condition. Ultimately this contributed information about the plasticity of hypnotized people. (In the 1880s Bernheim thought it wasn't pathological and thought that suggestion was the important element in hypnosis.)**

**Recent historical contributions have influenced our views of MPD. Spiegel and Kardiner published book about hypnosis and war neuroses. Cheek & LeCron developed ideomotor questioning, which ignores the contribution of unconscious fantasy. Jacob Arlow's metaphor for MPD is two movie projectors aiming at a screen from two different sides. The subjectively known experiential world thereby combines external reality and the person's internal, motivated perceptions. The author presented a case study of female therapist, who had been previously diagnosed as MPD, who presented with dissociative symptoms that she thought were due to abuse by her grandmother. She fabricated the memories in order to get the holding and physical nurturing from her therapist for being courageous and remembering the abuse.**

**Maintenance of professional boundaries is very important in treatment.**

**Lynn, Steven Jay; Nash, Michael R. (1994). Truth in memory: Ramifications for psychotherapy and hypnotherapy. American Journal of Clinical Hypnosis, 36, 194-208.**

**In this article we address a number of issues relevant to the practice of psychotherapy and hypnotherapy: How reliable is memory? How are therapists' and clients' beliefs and expectancies related to pseudomemory formation? Are certain clients particularly vulnerable to pseudomemory creation? Does hypnosis pose special hazards for pseudomemory reports? What are the variables or factors that mediate hypnotic pseudomemories? In addition to reviewing the literature on these topics, we intend to sensitize the clinician to the potential pitfalls of critical reliance on the patient's memories, as well as uncritically accepted clinical beliefs and practices.**

**1993**

**London, Ray William (1993, October). Refreshed adult memories: Abuse survivor or therapeutic victim?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.**

**NOTES**

The author addresses four areas: 1. public policy 2. psychological issues 3. legal issues (evidence) 4. how to properly deal with it

A definition of sexual abuse is being applied to behaviors that for years were not considered out of bounds (e.g. entering a bathroom where someone else is). Furthermore, using the word "survivor" for abused people equates patients with survivors of concentration camps, who do not present with repressed memories typically. National incidence of child abuse remains unclear estimates are 6 to 60% of females. In Florida, only 13% of cases reported are confirmed.

Some therapists who specialize in this area in surveys indicate that they have false beliefs regarding memory and effects of trauma.

Stolar, Donald Sigmund (1993). History of hypnosis in court. [Lecture] UCLA Hypnosis Seminar.

#### NOTES

Disclaimer--The following information is not intended to substitute for professional legal advice and should not be used as such.

The following events led up to our current situation in California, regarding the use of hypnotically elicited information in court:

1968 - Harding vs. the State of Maryland. First case in which the state prosecution requested use of hypnosis. (Prior to this hypnotically refreshed memory was not used in court testimony because the memory was regarded as unreliable.) Police hypnotized a state's witness, and a man was convicted of rape. Hypnosis in this case was considered no different from other memory jogging techniques (Like showing a witness pictures.)

1978 - Reiser published "Hypnosis and it's use in law enforcement." In it he stated that 60% of witnesses hypnotized by police gave important information that helped the case. Reiser is a psychologist working in the Los Angeles Police Department.

1976 - Chowchilla kidnaping case, the driver of the bus was hypnotized, and remembered enough of a license plate to catch the kidnappers.

1980 - Reiser, Handbook of Investigative Hypnosis \_ N=384 cases were investigated using hypnosis. In 67% of these cases, hypnosis was thought to have led to valuable information. Where external corroboration was possible, 90% of the new pieces of information were accurate. The Society for Investigative and Forensic Hypnosis was established by Reiser.

During this same period, courts were pulling back from permitting hypnotically refreshed memories to be given in court testimony.

1979 Martin Orne (in the *International Journal of Clinical and Experimental Hypnosis*) proposed safeguards for the use of hypnosis for forensic purposes. 1. Licensed psychologist or psychiatrist does the hypnosis. 2. Hypnotist is independent of prosecution, defense, and investigator. 3. Any information regarding a crime given to the hypnotist before hypnosis must be written down. 4. The hypnotist writes everything the witness says. 5. All interviews, including the pre-hypnosis interview, are recorded. 6. Only the hypnotist and witness are in the room, and 7. independent verification is very important.

Inasmuch as Reiser had been training detectives to do investigative hypnosis, he countered the Orne requirements by noting that: 1. Therapists are not trained investigators; detectives typically work with trauma victims. 2. Reports of adverse side effects following investigative hypnosis are exaggerated 3. Confabulation and fantasy are no more prevalent in hypnosis than in waking state.

Herbert Spiegel, in addressing the reliability of hypnotically refreshed memories, said hypnosis can make an "honest liar" out of a person. That is, they can be personally convinced that they have remembered something that in fact did not happen.

1980 - Bernard Diamond, M.D. (psychiatrist and law professor) wrote an article in the *California Law Review*, noting that: 1. Hypnotically refreshed testimony is full of fantasy and confabulation. 2. A hypnotist cannot tell if the subject is simulating. 3. A hypnotized subject cannot discriminate between fact and fantasy. 4. A hypnotized subject could become hardened against cross examination because with hypnosis he becomes more confident.

Courts began using the Frye Rule: in order for expert testimony to be admissible, it must be what is generally accepted to be true, in the scientific research literature.

1982 - The Shirley Decision (California Supreme Court) A woman who was raped was hypnotized before the trial. The accused, a man named Shirley, admitted having sex but said it was not forced. The Supreme Court used the Frye Rule to exclude any testimony from either side from anyone who had been hypnotized. (This rule applied to any hypnosis, including hypnotherapy.) Later the Court revised it to say that the defendant could be hypnotized (but not the plaintiff) because nothing should impede their defense.

1982 - Proposition 8 passed (Victim's Rights bill) and allowed hypnotically refreshed testimony to be used.

1986 - Three Justices, including Justice Rose Bird, were removed from the California Supreme Court (by election) and the legislature wrote Section 795 (which represented a middle ground). Hypnotically refreshed memory is allowed if the court testimony is limited to pre-hypnotic recall.

Weissberg, Michael (1993). Multiple personality disorder and iatrogenesis: The cautionary tale of Anna O.. *International Journal of Clinical and Experimental Hypnosis*, 41, 15-34.

An examination of Breuer's treatment of Anna O. Illustrates some of the controversies surrounding the recent rise of case reports of multiple personality disorder. Anna O., the first patient of the cathartic method, psychoanalysis, and dynamic psychiatry, fits current criteria for multiple personality disorder. Breuer's treatment, however, may have contributed to her states of absence; the timing, type, and intensity of Breuer's interventions make it possible that he unwittingly encouraged and amplified Anna's dissociations, reified her ego fragments, and then explained Anna's symptoms with the pseudomemories and confabulations recovered from Anna while she was hypnotized. A review of Breuer's treatment highlights some of the controversial aspects of multiple personality disorder, specifically its possible vulnerability to iatrogenesis via suggestion and unconscious collusion and other factors. The current stance of some multiple personality disorder enthusiasts, opaque to their participation in interactions that may lead to certain patient productions, resembles the older psychoanalytic stance exemplified by the early Breuer and Freud. The dialectic of the therapist as a neutral observer versus as an influential participant continues to be a focus of controversy, both within psychoanalysis and psychotherapy and in the understandings of the etiology and treatment of multiple personality disorder.

1992

Crawford, Helen J.; Kitner-Triolo, Melissa; Clarke, Steven W.; Olesko, Brian (1992). Transient positive and negative experiences accompanying stage hypnosis. Journal of Abnormal Psychology, 101 (4), 663-667.

Frequency of positive and negative experiences accompanying stage hypnosis was assessed in follow-up interviews with 22 participants of university-sponsored performances. Most subjects described their experience positively (relaxing, interesting, exciting, satisfying, illuminating, and pleasurable), but some described it negatively (confusing, silly, annoying, and frightening). Five subjects (22.7%) reported partial or complete amnesia; all were highly responsive to the stage hypnosis suggestions. One subject was completely unable to breach amnesia and felt annoyed and frightened. Five subjects (22.7%) believed the hypnotist had control over their behavior. Participants (n=15) tested subsequently on the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & Hilgard, 1962) were mostly moderately to highly hypnotizable ( $M = 7.07$ ), and the scores correlated significantly ( $r = .68$ ) with the percentage of passed stage hypnosis suggestions.

#### NOTES

Echterling and Emmerling (1987, American Journal of Clinical Hypnosis) conducted a follow-up of 18 people who participated in stage hypnosis at a university, within a month after the experience. Referring back to the hypnosis itself, 39% reported positive experiences, 39% reported both positive and negative experiences, and 22% (four people) reported 'strongly negative' experiences. The present study contacted subjects immediately after the stage hypnosis experience, either in person or by telephone. They completed both objective questions and open-ended questions referring to three time periods: after the hypnotic induction, during

the hypnotic suggestions, and after the stage hypnosis had been terminated. Subjects were invited to come to the laboratory to be tested for hypnotizability, and 15 of the 22 did return for testing.

Of the 22 Ss, 4 had previously participated in stage hypnosis, one in laboratory hypnosis, and one had been hypnotized by her father. Of the 15 tested with the Stanford Hypnotic Susceptibility Scale, Form C: 7 were high hypnotizables (scoring 9-12), 7 were medium hypnotizables (scoring 4-8), and one was a low hypnotizable (scoring 0-3). Several people reported that they 'went along with' the hypnotist's suggestions, role playing rather than actually experiencing the suggestions.

"Most of the subjects found the experience positive: 86.4%, relaxing; 86.4%, interesting; 77.3%, exciting; 59.0%, satisfying; 54.6% illuminating; and 54.6%, pleasurable. Negative experiences were also reported: 36.4%, confusing; 36.4%, silly; 9.1%, annoying; and 9.1%, frightening. Only 1 subject reported the stage hypnosis experience as entirely negative.

"The stage hypnotists told the participants about the suggestions at the end of the stage hypnosis performance and supposedly lifted amnesia. Despite this, some participants continued to experience partial or full amnesia for the suggestions. ...

"One participant reported complete amnesia even after the interview and was distraught, permitting only a telephone interview and not accepting an offer to be hypnotized at a later time to help recall what had been forgotten. ...

"... The interviewer told her what had been observed and attempted to breach the amnesia. The subject continued to report complete amnesia.

"Two other participants continued not to remember many of the suggestions but showed no major concern. Waking suggestions to breach amnesia were given, but no further information was obtained.

"Five participants reported feeling that the hypnotist had complete control over their behavior and that they could not resist the hypnotist's suggestions" (p. 664).

In their Discussion, the authors note that in general, when negative experiences occur, they tend to be mild and transient. None of the subjects in this investigation reported some of the negative sequelae reported in earlier literature (headaches, nausea, drowsiness). The few subjects who had strong cognitive distortions following hypnosis were highly hypnotizable, which also was observed in an earlier study published by the first author and her colleagues (Crawford, Hilgard, & Macdonald, 1982, *International Journal of Clinical and Experimental Hypnosis*).

Spontaneous post hypnotic amnesia is one example of cognitive distortion. The authors remarked on the rather high incidence of spontaneous amnesia for some specific suggestions (22.7%), which was discovered when friends of the subjects described to them what they had done on stage. In an experimental study by Hilgard and Cooper (1965), only 7% of student subjects had spontaneous amnesia (though 35% had amnesia following suggestions for posthypnotic amnesia). Furthermore, in the Hilgard and Cooper study, hypnotizability correlated with suggested amnesia but not with spontaneous amnesia. Cooper (1972) reviewed the literature on posthypnotic amnesia and observed that spontaneous occurrence is less frequent than suggested amnesia.

Explanations of spontaneous amnesia include ideas that high hypnotizables who experience it are significantly different from those who do not (Chertok, 1981;

Weitzenhoffer, 1989); or that it is due to expectancy (Kirsch, 1985); or that it is found in people with a tendency for dissociation in and out of hypnosis, or people who may be prone to repression or dissociative and post-traumatic stress disorders. For reviews of these issues, see Kihlstrom, 1987; Kihlstrom & Hoyt, 1990; Frankel, 1990; Nemiah, 1985; Spiegel, 1990; Spiegel & Cardena, 1991).

The authors note that stage hypnotists, while they may otherwise be ethical, do not provide information to subjects to correct misperceptions about hypnosis. For example, in this study 22.7% of the subjects believed, after the stage hypnosis experience, that the hypnotist had control over their behavior and they couldn't resist the suggestions. "Appropriate guidelines for stage hypnosis (see also Crawford et al., 1982) include screening out participants who are in therapy or counseling, correcting misperceptions about hypnosis among the participants before the hypnosis begins, screening subjects prior to hypnosis, avoiding embarrassing or upsetting suggestions, providing dehypnosis instructions to those who do not remain in hypnosis (or are asked to leave the performance), terminating fully the hypnotic experience, removing all amnesia suggestions and reviewing the events at the end of hypnotic experience, and remaining available afterward for further questions" (p. 666).

Deutch, James A. (1992, October). Ethics in clinical social work. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

[Introductory comments by the Moderator Dr. Sam Migdall from Beverly, Mass.: Insurance may not cover you if you are practicing outside the scope of your practice. How do internists bill for treating a phobia with hypnosis?

In training sessions we hear about single session cures, but usually we need to work much longer (and using the same methods we would use not using hypnosis).

How do we initiate and decide on hypnotic treatment? Is there a solid diagnosis, treatment plan? Or do we accept the patient's opinion of what is going on?]

Deutch's paper presented the following information:

Article 7 of socialwork ethics says people who use hypnosis must abide by our ethics plus those of SCEH (and ASCH if they belong). In my opinion, though different, the ethics all have the goal of providing to the consumer the best service they can render.

All are focusing on practicing within one's level of competency. [Details of talk not recorded.]

Recommends hypnotically facilitated psychotherapy as the treatment of choice for MPD and to accelerate case-finding. Twenty-one categories of hypnotic interventions with MPD patients are summarized.

**Lynn, Steven Jay; Rhue, Judith W. (1992, October). Memory. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.**

#### **NOTES**

[Author presented a dramatic case report of patient who recalled specific events that subsequently he and the patient investigated and disproved. What the patient thought they saw could not possibly have been seen.]

The experimental literature on memory gives us some things to think about. Therapy relies highly on memory, and the therapist shapes the contours of the memory by validating the memories, which are rarely doubted. Tacit acceptance of memories as historical facts is part of the contract of therapy.

Memory studies challenge the idea of accurate storage. Some people are unduly confident of their memory. Bartlett's research demonstrated distortion according to schema, interpretations, embellishments, etc. Jacobi et al indicate people's theories about what happened shape memory.

One theory is that trauma leads to amnesia, repression, dissociation. But research does not show inability to recall early life events indicates presence of a traumatic history. Repression is not prima facie evidence of abuse. The *Courage to Heal* book states that merely thinking you were abused is evidence that you probably were.

How do vague ideas crystallize? Loftus finds if inability to remember isn't attributed to ordinary forgetting, the person may look for memories, thereby creating them.

Studies of persons who confess to crimes, unsure whether they did or didn't do them, indicate that these people are easily coerced. Doubt in a memory's accuracy can be reframed by a therapist.

Hypothesis: Therapists who confidently state a view risk implanting pseudomemories. Therapists must be cautious.

Clients can confuse sources of information that they receive. Different sources of information can be integrated into a single memory (e.g. what occurred to them and what occurred to siblings can be integrated into a pseudomemory). Some limited evidence that early life experience memories could be implanted has been presented by Loftus.

Certain client characteristics contribute to false memories: 1. Present mood state (mood congruent memory). This effect is reliable when people are clinically depressed. Though clinicians may say it indicates early childhood abuse, the

memory might be selective or biased. 2. History of fantasy-proneness. In childhood this type of person might have had problems distinguishing fantasy from reality. LaBelle et al found absorption made it difficult to distinguish sounds in hypnosis from what really occurred, creating pseudo- memories. With this population it is essential to avoid suggesting abuse.

Lynn was successful in implanting an idea of abuse in an alter called Person. He used the Orne technique (from the BBC film "Hypnosis on Trial") to ask a patient what she had told him about her dog during the hypnosis; he did this to convince her of the importance of exploring her amnesic episodes.

Does hypnosis foster a literal re-experiencing of childhood events? NO. Nash, in an exhaustive review, failed to find correspondence between information from hypnotic age regression and childhood events. He notes that literal reliving is not possible. It is possibly an expression of primary process thinking. Hypnosis doesn't ameliorate memory problems; and it may exacerbate memory problems.

Lynn views primary process thinking observed in hypnosis as due to the demand of hypnosis to fantasize and relinquish critical thinking or objectivity. This plus Therapist and Patient expectancies may foster tenacious beliefs that events occurred.

Many hypnotic suggestions may interfere with memory. The AMA 1985 report suggests that hypnosis can influence confidence in a 'memory' with no actual improvement in accuracy.

The effects aren't limited to hypnosis however. Simulators and controls also generate pseudomemories. Repeated questioning of Ss who are led to believe that questioning helps distinguish memories from fantasies, actually diminishes the accuracy of memories.

Hypnotizability is correlated with pseudomemory occurrence. We should evaluate a client's hypnotizability when evaluating for pseudomemories.

Perceived verifiability rate is important, as pseudomemories are higher where you can't verify the reported memory, it is thought. Therefore, approach with caution. Make every effort to corroborate memories.

Subjective reports may tell narrative truths even though inconsistent with the historical record, and could be useful independent of historical accuracy. I agree that those 'memories' could be important, just as age progression or past life regression material could be useful in therapy. But should we base our interpretations or conclusions on events that are not confirmed? A patient's belief in abuse by their parent has enormous implications for a family.

Therapists should understand the dynamics of a request for using hypnosis to recall forgotten memories before using uncovering techniques. Ask yourself, "Why is this being requested?" Also ask other questions: 1. Is the person fantasy prone, dissociative, suggestible, a high hypnotizable? 2. Is the person stabilized enough to focus on an abreaction? 3. Is there conscious or unconscious motivation to avoid responsibility for one's own behavior? 4. Is there a wish to arrive at a facile solution, a magic cure, the royal road to the unconscious; or is there an attempt to control the treatment hour, to avoid issues, to test the therapist? 5. Is therapy stalled, not moving forward? 6. Am I angry with the client because they expect to uncover more?

Instead of using hypnosis to retrieve memories, I may focus on the issues to which I answer 'Yes' in the forgoing list.

I do not believe current research is sufficiently persuasive to throw out hypnosis for retrieving memories. The dangers of pseudomemory are endemic to therapy. Incorporating hypnosis into a broader frame of therapy depends on the skill of the clinician. However, we must use hypnosis with great caution

#### COMMENTS FROM AUDIENCE

Joseph Dane: In 75% of cases that could be verified, they found corroborating evidence: what should you look for as an index that the memory recalled in hypnosis is more likely to be accurate?

Lynn: Many instances of abuse are corroborated. No one questions the veracity of all memories. To my knowledge there are no ways of corroborating genuine from false memories. We know subjective conviction is not sufficient, and clients' affective experience can be very misleading. Since my experience [in the case study reported at the beginning of this presentation] I have talked with many therapists who have had similar experiences.

David Spiegel - the problem is not the hypnosis: patients go in and out of hypnosis all the time, momentarily. The problem is, how do I explore the material in psychotherapy? There is no substitute for corroboration if you can get it. But you have to be sensitive to the vulnerability of those people.

Howard Hall: What is a genuine memory? No memory is undistorted. More importantly, can we verify significant events that might have had long term consequences, like abuse? We should try to verify memories when we base treatment programs on them. The only memories in the literature that have a reputation of being accurate are highly traumatic events that stand out, and these reports are anecdotal in nature.

Strauss, Billie S. (1992, October). What's in a name: Use and presentation of hypnotherapy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

Psychologists have standards of ethical and professional conduct for clinical and research endeavors. Several guidelines which have particular relevance for the use of hypnosis are (1) issue of informed consent, (2) issues of training, and (3) consultation with another professional.

New Guidelines have been published by APA. 1. Informed consent is required. This raises the issue of whether we [invariably] should use the term hypnosis. What if we use hypnotic techniques in a non-hypnotic context? Or conversely, if a patient doesn't go into a hypnotic state, are we bound to tell them so? Bauman (1988) thought, with respect to psychotherapy, that we don't need to explain about "interpretation" or "behavior modification." (I tend to tell patients about these, however, as much as the patient can understand.) Euphemisms for hypnosis (guided imagery, relaxation) are also used. If a patients say they don't want to use hypnosis, it should not be used, even under the guise of guided imagery.

Does informing patients of potential hazards result in a self-fulfilling prophesy?

One needs to pay attention to the implications when the hypnotist also may be interacting with students and colleagues in a non hypnotic setting, e.g. setting up double binds when asking them to do something. Think carefully about role implications, especially if you have perceived status. 2. A second issue has to do with training. APA adopted a resolution that hypnosis should not be taught to lay people. New guidelines require that hypnosis and projective techniques only be taught to people with adequate training. 3. A third issue is consultation (e.g. when hypnosis is used by one professional, and the patient is being treated by someone else in psychotherapy). The patient should give permission for the two to communicate. This raises issues of countertransference, especially of omnipotence and control and of splitting.

Patterson, David R. (1991, August). Why hypnosis is not taken more seriously as a form of pain control. [Paper] Presented at the annual meeting of the American Psychological Association, San Francisco.

Despite the backing of laboratory studies and numerous clinical case reports, hypnotically based pain control is infrequently used in pain programs and lacks respect in the scientific community. It is argued that this is a situation that could be remedied by 1) delineating more often whether hypnosis is to be used as facilitator for other techniques or as an analgesic in itself, 2) improving the quality of clinical research, 3) resolving the issue of the significance of hypnotizability in pain control, and, 4) integrating hypnotic interventions with a better understanding of the nature of pain.

1990

Page, Roger A.; Handley, George W. (1990). Psychogenic and physiological sequelae to hypnosis: Two case reports. American Journal of Clinical Hypnosis, 32 (4), 250-256.

Two cases of hypnotic sequelae occurring in a research context (with a non-clinical college population) are reported. Case 1 was a male who experienced retroactive amnesia following hypnosis: He was unable to recall familiar telephone numbers later that day. This was not a continuation of an earlier confusion or drowsiness (as is often found) since he indicated he was wide awake following hypnosis. Two parallels exist with previous reports: unpleasant childhood experiences with chemical anesthesia and a conflict involving a wish to experience hypnosis but a reluctance to relinquish control. Case 2 was a female who, while in hypnosis, experienced an apparent epileptic seizure that had characteristics of both petit mal and grand mal seizures. Although having a history of epilepsy, she had not had a seizure in 7 years. We suspect that the seizure was psychogenic and may have been triggered by wording used in the hypnotic scale or other similarities. Possible mechanisms are discussed and preventative recommendations are made.

1989

**Gibson, H. B. (1989). The Home Office attitude to forensic hypnosis: A victory for scientific evidence or for medical conservatism?. [Comment/Discussion] .**

**NOTES**

The author is in agreement with the Home Office Circular (August 1988) that advises against the use of hypnosis in police investigations. However he disagrees with the Circular statement that "'There may be danger that, in some cases, the experience of hypnosis may cause longer term harm to the mental health of the subject...' This is certainly not true if the proceedings are carried out by a competent health professional" (p. 26).

**Pinizzotto, Anthony J. (1989). Memory and hypnosis: Implications for the use of forensic hypnosis. Professional Psychology: Research and Practice, 20 (5), 322-328.**

**NOTES**

The author reviews arguments regarding hypnosis in forensic investigations, offers procedures of a nonhypnotic nature to enhance memory recall, and suggests guidelines for hypnosis in criminal cases. The effects of hypnosis on memory, as well as the concomitant dangers regarding those effects, are discussed.

**Torem, Moshe S. (1989). Iatrogenic factors in the perpetuation of splitting and multiplicity. Dissociation, 2, 92-98.**

Many dissociative patients tend to have rapidly dissociative switching from one ego-state to another. These trance-like states make the patients highly suggestible to outside influences which include the therapists' verbal and nonverbal communication. Some therapists may have an over-investment in more personalities, and thus ignore the needs of the whole person. Treating an adult patient who is in an age regressed ego-state, or alter personality, presents a particular challenge as to the patient's boundaries since violating these boundaries may perpetuate splitting and multiplicity. Therapeutic limit setting, the issue of trust, and countertransference issues are discussed.

**1988**

**Coons, P. M. (1988). Misuse of forensic hypnosis: A hypnotically elicited false confession with the apparent creation of a multiple personality. International Journal of Clinical and Experimental Hypnosis, 36 (1), 1-11.**

A case is presented in which there was flagrant misuse of forensic hypnosis. The patient, a woman in her early 30s, was accused of shooting her 2 children. During a hypnotic interview, the police hypnotist used an extremely suggestive interrogative technique, and the suspect produced an apparent secondary personality who confessed to the shootings. Subsequently the prosecutor tried to enter the "hypnotic confession" as evidence against the defendant. The evidence was dis-allowed because of the manner in which it was obtained and because of the lack of verification from other sources. The literature regarding the use of forensic

hypnosis is reviewed as is the literature regarding multiple personality and the experimental production of multiple personality-like phenomena.

Greaves, G. B. (1988). Common errors in the treatment of multiple personality disorder. Dissociation, **1**, 61-66.

Psychotherapists report widely different experiences in their attempts at treating multiple personality disorder (MPD) patients. Some have deepened their interests and developed full-time specialized practices with this clinical population. Others have declined to have any further contact with them at all, referring possible MPD patients to colleagues when they first suspect that this disorder may be present. Still others have decided against treating more than one or two MPD patients. These diverse decisions are examined with a focus upon the effects of therapists' uneven attention to the formal properties of the dyadic psychotherapeutic experiences as a possible influence upon their future work with MPD. Problems concerning the framework of psychotherapy and the countertransference conflicts which often move the therapist unconsciously and irrationally to alter the canons of psychotherapy in mutually detrimental ways appear to be crucial determinants.

#### NOTES

Discusses countertransference conflicts that often move the therapist unconsciously and irrationally to alter the canons of psychotherapy in mutually detrimental ways.

MacHovec, Frank J. (1988). Hypnosis complications, risk factors, and prevention. American Journal of Clinical Hypnosis, **31**, 40-49.

There is a substantial body of clinical and experimental research data documenting the incidence of mild to severe after effects coincident with the use of hypnosis in persons with no prior history of similar medical or mental problems. This article provides an overview of relevant clinical and experimental research and a review of pertinent literature since 1887. Subject, hypnotist, and environmental risk factors are listed, a definition and classification system for hypnosis complications is suggested, and recommended preventive practices are described.

Venn, J. (1988). Misuse of hypnosis in sexual contexts: Two case reports. International Journal of Clinical and Experimental Hypnosis, **36** (1), 12-18.

A military officer was accused by 2 young men of having used hypnosis to attempt homosexual relations. The officer denied the charges and claimed that the young men had imagined these events while they were in altered states of consciousness. The officer did admit to questionable practices such as consuming alcoholic beverages with the 2 young men and then using relaxation techniques with them in bedrooms. Subject motivation and nonhypnotic coercive tactics such as abuse of authority and alcohol seem important in understanding alleged cases of hypnotic coercion.

1987

**Olness, Karen N.; Libbey, Patricia (1987). Unrecognized biologic bases of behavioral symptoms in patients referred for hypnotherapy. American Journal of Clinical Hypnosis, 30, 1-8.**

Twenty patients referred for hypnotherapy had organic conditions which explained their symptoms. Each had been evaluated previously by physicians. Eleven had also been in psychotherapy; two of these had been hospitalized on child psychiatry inpatient units. Presenting symptoms included five with nocturnal enuresis, four each with headaches and recurrent abdominal pain, three with recurrent headaches, two with anxiety, and one each with sleep problems and tics. Diagnoses included hyperthyroidism, diabetes, diastometyelia, partial oxalotranscarbamyase deficiency, sinusitis, carbon monoxide poisoning, vitamin overdose, food allergy, amebiasis, constipation, urinary tract infection, paroxysmal atrial tachycardia, and seizures. Each child had complete remission of symptoms with treatment of his/her underlying disease. Morbidity related to delayed diagnoses included parental anxiety and guilt, child anxiety, growth delays, family financial difficulties, loss of parental work time, loss of school days, and loss of confidence in child health professionals by families.

**Patterson, David R.; Questad, Kent A.; Boltwood, Michael D. (1987). Hypnotherapy as a treatment for pain in patients with burns: Research and clinical considerations. Journal of Burn Care and Rehabilitation, 8 (3), 263-268.**

Hypnotherapy has increasingly been included in the management of burn patients, particularly in the area of acute pain. To better understand such issues as (1) overall efficacy of hypnotherapy to alleviate acute burn pain, (2) instances in which hypnotherapy is contraindicated, (3) interaction of hypnotherapy with medication, (4) standard induction techniques to use with various age groups, (5) role of nursing and other staff in facilitating hypnotic effects, and (6) future methodological directions, they examined the clinical and methodological merits of recent studies of hypnoanalgesia. A literature search found 17 studies in which hypnotherapy was applied to the management of burns. The literature generally supports the efficacy of this approach to reduce burn pain; however, little else can be concluded from these studies. Several recent studies have applied hypnotherapy to aspects of burn care other than pain using excellent experimental designs. It is suggested that future studies of acute pain management follow suit.

**American Medical Association Council on Scientific Affairs (1986). Scientific status of refreshing recollection by the use of hypnosis. International Journal of Clinical and Experimental Hypnosis, 34, 1-12.**

The Council finds that recollections obtained during hypnosis can involve confabulations and pseudomemories and not only fail to be more accurate, but actually appear to be less reliable than nonhypnotic recall. The use of hypnosis with witnesses and victims may have serious consequences for the legal process when

testimony is based on material that is elicited from a witness who has been hypnotized for the purposes of refreshing recollection.

#### NOTES

The Council finds that recollections obtained during hypnosis can involve confabulations and pseudomemories and not only fail to be more accurate, but actually appear to be less reliable than nonhypnotic recall. The use of hypnosis with witnesses and victims may have serious consequences for the legal process when testimony is based on material that is elicited from a witness who has been hypnotized for the purposes of refreshing recollection.

APA Council of Representatives (1986, December). Resolution on hypnosis. Newsletter of Division 30, Psychological Hypnosis, of the American Psychological Association, 1.

#### NOTES

The Council of Representatives adopted a motion that opposes the teaching of hypnosis to persons who are not fully trained in a health delivery profession. The motion presented by Dr. Gene Levitt, Division 30 representative to Council of Representatives, was passed by voice vote on August 24, 1986. It read as follows:

"Be it resolved that the American Psychological Association, in the interest of the public, opposes applications of hypnosis by persons who are not fully trained members or advanced students of a health delivery profession and who lack specific, in-depth training in hypnosis. Therefore, be it also resolved that APA opposes the teaching of hypnotic induction techniques or applications of hypnosis that involve treatment or assessment with patients or clients to persons who are not fully trained members or advanced students of a health delivery profession. Be it resolved further that upon passage of this resolution, its text shall be conveyed to the APA Ethics Committee to consider its incorporation in the APA Code of Ethics. We note that the resolution is consistent with the preamble of Principle 1 of the code as well as the Standards for Providers of Psychological Services (Principles and Implications of Standards, 3)"

Dr. Levitt proposed that the motion be named the "Erik L. Wright Memorial Resolution" in honor of the Division 30 Council representative who introduced the first version of it in 1980.

Judd, Fiona K.; Burrows, Graham D.; Dennerstein, Lorraine (1986). Clinicians' perceptions of the adverse effects of hypnosis: A preliminary study. Australian Journal of Clinical and Experimental Hypnosis, 14, 49-60.

Questionnaires were sent to all members of the Australian Society of Hypnosis and responses obtained from 202 members and associate members who used hypnosis clinically. Respondents' experience in the use of hypnosis and the frequency of use of hypnosis as a treatment modality varied. Overall 43.5% of respondents reported adverse effects with one or more patients over the preceding year. Most adverse effects attributed to hypnosis were transient and included development of panic or

extreme anxiety, development of excessive dependence and difficulty in terminating hypnosis. Exacerbation or precipitation of significant depression was an infrequent but serious adverse effect attributed to hypnosis. Other infrequent adverse effects included symptom substitution, acting out behaviour, fantasied sexual seduction, precipitation or worsening of psychotic illness or difficulties in the management of organic conditions. The difficulties were acknowledged of differentiating between the effects of hypnosis itself and other components of the therapeutic transaction, but the results of this survey suggested both that hypnosis be employed clinically by properly trained professionals and that further sensitive clinical research is needed in the area.

**1985**

Fellows, Brian J. (1985). Hypnosis teaching and research in British psychology departments: Current practice attitudes and concerns. British Journal of Experimental and Clinical Hypnosis, 2 (3), 151-156.

#### NOTES

The author mailed a questionnaire to 58 departments of psychology to determine the extent/nature of hypnosis teaching and research, and attitudes toward teaching and research on hypnosis. The author noted a general anxiety about teaching students how to do hypnosis (as contrasted with learning about hypnosis). "Some of the anxieties which departments have about the teaching of hypnosis seem to stem from some rather ancient and invalid conceptions about the nature of hypnosis and what it can do" (p. 153). The author also relates his personal experience teaching undergraduates "something about the procedures and phenomena which have been traditionally associated with hypnosis" (p. 153). They may use one of the standard hypnotizability scales, study a particular hypnotic phenomenon such as ideomotor action or age regression, or study an empirical issue such as facilitation of recall. He reports not meeting with "any particular difficulties," but also that he has seen two problems: the student who is anxious about doing the procedure, and an occasional subject who reports the experience was unpleasant or disturbing--e.g. during age regression. He reports teaching students to handle these events in a normalizing manner. J. Holroyd

**1984**

Allison, R. B. (1984). Difficulties diagnosing the multiple personality syndrome in a death penalty case. International Journal of Clinical and Experimental Hypnosis, 32 (2), 102-117.

The problems involved in diagnosing the multiple personality syndrome in a rape-murder suspect are illustrated by the case of Kenneth Bianchi and the Hillside Stranglings. Hypnotic investigations of his amnesia revealed "Steve," who admitted guilt for the rape-murders. "Billy" later emerged, claiming responsibility for thefts and forgeries. Attempts to evaluate Kenneth Bianchi with methods used in therapy yielded an original opinion that he was a multiple personality and legally insane. Later events showed the diagnosis to be in error. A new diagnosis was made of atypical dissociative disorder due to the effects of the examining methods themselves. Warning is given that it may be impossible to determine the correct diagnosis of a dissociating defendant in a death penalty case.

Braun, Bennett G. (1984). Hypnosis creates multiple personality: Myth or reality?. International Journal of Clinical and Experimental Hypnosis, 32 (2), 191-197.

Since before the turn of the century, multiple personality has been associated with hysteria and hypnosis. The myth that hypnosis can create multiple personality is examined in this paper by reviewing studies that have suggested or implied a casual link between hypnosis and multiple personality. While it is possible that personality fragments can appear under hypnosis, there is no evidence that personalities with separate life histories and a full range of affect can be created with hypnosis. The author concludes that hypnosis is a valuable tool in diagnosing and treating multiple personalities.

Kleinhaus, Moris; Beran, Barbara (1984). Misuse of hypnosis: A factor in psychopathology. American Journal of Clinical Hypnosis, 26, 283-290.

Six cases of posthypnotic trauma are presented to illustrate possible psychopathologic symptoms that may be exhibited in Ss following the misuse of hypnosis, particularly for a stage performance. Medical professionals must be made aware of the possibility of immediate as well as long-term deleterious effects that may follow misuse of hypnosis so that those cases which come to the attention of the physician will be properly diagnosed and treated.

## NOTES

This is a modified version of a policy brief prepared for the National Institute of Justice. The Conclusions read:

**"The use of guidelines is designed to permit the subsequent evaluation of a hypnosis session by independent experts, in order to determine whether undue suggestiveness was present. Nonetheless, even when hypnosis has been used appropriately in a forensic situation and when the session has been monitored and conducted in a manner that is likely to minimize undetected biasing, inadvertent distortions of memory may still occur. Although the recommended guidelines for conducting the hypnosis session help determine what was done during the session, they do not prevent (nor is there any reliable way to prevent) subjects from confounding distorted hypnotic memories with prior and subsequent nonhypnotic recall or from placing undue confidence in these distorted recollections. Thus, the use of the results of hypnosis applied in forensic situations, as well as the use of the procedure itself, demands extreme caution.**

**"'Hypnotically refreshed' memories cannot be used to 'verify' facts for which no adequate evidence exists, especially when subsequent investigation has failed to produce any substantial independent corroboration and the individual did not recall the fact or was not confident of it prior to hypnosis. As long as the detail recalled is verified by independent physical evidence, the utility of hypnosis can be considerable and the risk attached to the procedure - if properly conducted - minimal. There is no way, however, by which anyone (including an expert with extensive experience in hypnosis) can for any particular piece of information obtained in hypnosis determine whether it is an actual memory or a confabulation. For these reasons, hypnotically induced testimony is not reliable and ought not be permitted to form the basis of testimony in court" (pp. 210-211).**

**Gruenewald, Doris (1982). Problems of relevance in the application of laboratory data to clinical situations. International Journal of Clinical and Experimental Hypnosis, 30 (4), 345-353.**

**Advantages and disadvantages of measuring hypnotic susceptibility in clinical settings are presented. The argument for standardized methods of measurement in the interest of scientific advancement is balanced against clinical considerations and counterindications. The question of identity of hypnotic processes in the laboratory and in the clinical situation is addressed.**

**1982**

**Sacerdote, Paul (1982). A non-statistical dissertation about hypnotizability scales and clinical goals: Comparison with individualized induction and deepening procedures. International Journal of Clinical and Experimental Hypnosis, 30 (4), 354-376.**

**Researchers and theoreticians in the field of hypnosis have insisted for some time that reports of clinical applications of hypnosis should include the patients' classification based on their responses to standardized hypnotizability scales. Accordingly, clinical scales (Barber & Wilson, 1978/79; Cooper & London, 1979; J.R. Hilgard & E.R. Hilgard, 1979; Morgan & J.R. Hilgard, 1979; Wilson & Barber, 1978) have been developed or adapted from pre-existing standardized scales. For**

the same purpose, the Hypnotic Induction Profile (HIP) of Spiegel (1978), which claims reliability in classifying patients according to hypnotizability and psychopathology, has been developed and utilized.

Additionally, tailored scales which include specific qualitative items have been proposed (E.R. Hilgard, Crawford, P. Bowers, & Kihlstrom, 1979). According to a few clinical investigators (Frankel, Apfel, Kelly, Benson, Quinn, Newmark, & Malmaud, 1979) no disadvantage does ensue from routinely subjecting patients to hypnotizability scales. The positive results are: accumulation of reliable information about the validity of hypnotic intervention in various clinical conditions; differentiation between results of hypnosis and results of psychotherapy; and also a determination of whether hypnotizability is a fixed talent or whether it can be improved with training. With the individual patient the use of hypnotizability scales would rapidly indicate if his score will be high enough for certain specific applications and in general to determine whether therapy with hypnosis should even be attempted. The present author recognizes the rationale for the use of scales in the therapeutic realm, especially if the results are to be reported. The present author notes, however, that the generally accepted hypnotizability scales give disproportionate weight to some categories of hypnotic responses, but they are not comprehensive enough to tap all the possible capabilities of individual patients. Standardized scales of hypnotizability rely almost entirely upon written or spoken instructions and therefore miss the opportunities of nonverbal communication. Also, most hypnotizability scales implicitly seem only to recognize hypnosis obtained by progressive relaxation as "the typical hypnosis." Some examples are presented to clarify how the use of standardized scales or of HIP (Spiegel, 1978) would wrongly classify a considerable minority of patients as nonhypnotizable or poorly hypnotizable, thus depriving them of potential therapeutic benefits.

1981

Gruenewald, Doris (1981). Failures in hypnotherapy. International Journal of Clinical and Experimental Hypnosis, 29 (4), 345-350.

Failures in hypnotherapy are discussed in the context of considerations applying to treatment in general. Emphasis is given to the principle that hypnotherapy must be structured according to patients' personality and needs. When treatment fails, therapists should examine carefully what may have led to an unsatisfactory outcome.

Kleinhaus, Moris; Beran, B. (1981). Misuses of hypnosis: A medical emergency and its treatment. International Journal of Clinical and Experimental Hypnosis, 29 (2), 148-161.

Hypnosis is an intense interpersonal relationship requiring 2-way respect and involvement. Inadequate understanding of this dynamic relationship, and a consequent inability to cope with its potential dangers, may result in posthypnotic trauma. Unless treated carefully by a hypnotherapist who is experienced in both the techniques of dehypnotization and the utilization of psychotherapy, such traumas

may persist for a very long time. In this paper, one striking case illustrates mishandling of the hypnotic event and immediate posthypnotic treatment and details the procedure by which successful treatment was eventually determined.

Zelig, Mark; Beidleman, William B. (1981). The investigative use of hypnosis: A word of caution. International Journal of Clinical and Experimental Hypnosis, 29 (4), 401-412.

The purpose of the present experiment was to determine the efficacy of hypnosis for enhancing the recall of Ss exposed to a stress provoking motion picture. This stimulus, which vividly displayed several workshop accidents, was selected to provide an analog to witnessing an actual crime. After viewing the film, Ss were questioned in either hypnosis or in a waking state and responded to a questionnaire which contained leading and nonleading questions. Dependent measures included the number correct, number of errors, and the average confidence rating given to their responses. Analyses of these data revealed that waking Ss were significantly more accurate on leading questions. No significant differences were observed when Ss' responses to nonleading questions were examined. Post hoc correlational analyses across both hypnotic and waking conditions revealed that hypnotic susceptibility and confidence ratings were positively correlated while susceptibility and the number of correct responses were not significantly correlated. These findings are compared with previous research and the resulting implications for hypnotically conducted interrogations are discussed.

1980

Fromm, Erika (1980). Values in hypnotherapy. Psychotherapy: Theory, Research and Practice, 17 (4), 425-430.

Hypnosis is an altered state of consciousness characterized by a regression in the service of the ego along with increased access to the unconscious. This makes it possible to achieve lasting therapeutic results faster in hypnosis than in the waking state. Hypnosis is also a state of decreased vigilance, a vulnerability that involves dangers if a patient is in the hands of a poorly trained, incompetent, or unscrupulous therapist. In general, the same human and moral values that guide responsible therapists with patients in the ordinary waking state must guide them with patients in hypnosis, only more so. Contemporary permissive hypnotherapists do not superimpose their own wills or personalities onto patients but provide support, help patients face the frightening parts of the unconscious, and thus aid them in coping with conflicts and gaining full autonomy and freedom from fear. (11 ref).

Reiser, Martin; Nielson, Michael (1980). Investigative hypnosis: A developing specialty. American Journal of Clinical Hypnosis, 23, 75-84.

## NOTES

Author describes his involvement with the Los Angeles Police Department, using

hypnosis for "enhancing the recall of key witnesses whose memories of the crime were poor" (p. 75). In 1975, the author and other experts in hypnosis trained 11 lieutenants and 2 captains to use hypnosis. The author describes the training program and a one-year demonstration project, during which volunteer witnesses and victims were interviewed by the hypnotist investigators. "In 77% of cases, important information was elicited that had not been available by routine interrogation. Approximately 16% of cases were solved with the aid of hypnosis" (p. 76). "Follow-up with the involved witnesses and victims has not revealed any instance of ill effects stemming from the hypnosis program, while 39.8% of the hypnosis subjects reported some relief or benefit resulting from the hypnosis session" (p. 77). Jean Holroyd

1979

Ault, R. L. Jr. (1979). FBI guidelines for use of hypnosis. International Journal of Clinical and Experimental Hypnosis, 27 (4), 449-451.

The Federal Bureau of Investigation uses hypnosis as a tool for investigative purposes in selected cases where further leads are needed and witnesses or victims are willing to participate in a hypnotic interview. All sessions are tape recorded, preferably by video. A hypnotic interview cannot necessarily provide accurate leads, and therefore careful investigative work is done to verify the accuracy of any information obtained in hypnosis. Psychiatrists, psychologists, or physicians specially trained in hypnotic techniques have been employed to add protection for the witnesses or victims being questioned under hypnosis.

Frankel, Fred H.; Apfel, R. J.; Kelly, S. F.; Benson, H.; Quinn, T.; Newmark, J.; Malmaud, R. (1979). The use of hypnotizability scales in the clinic: A review after six years. International Journal of Clinical and Experimental Hypnosis, 27 (2), 63-73.

This is a review of the use, after 6 years, of the Stanford Hypnotic Susceptibility Scale, Forms A and B (Weitzenhoffer & E. R. Hilgard, 1959); the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962); the Hypnotic Induction Profile (Spiegel & Bridger, 1970); and the Stanford Hypnotic Clinical Scale (Morgan & J. R. Hilgard, 1975) in the clinical situation. The great majority of over 300 patients found their experience with the scale to be a positive one, despite the authors' initial hesitancy about exposing them to the probability of failure on at least some of the items. The standardized scales were administered as specific tests, not as part of therapy.

The data on responsivity has not only contributed to clinical strategy in individual cases, but has also added to our understanding of hypnosis, of psychopathology, and of therapeutic outcome.

Hilgard, Ernest R.; Loftus, Elizabeth F. (1979). Effective interrogation of the eyewitness. International Journal of Clinical and Experimental Hypnosis, 27 (4), 342-357.

Eyewitness reports have been investigated in the psychological laboratory from time to time ever since 1900. Specimen studies from the early period and from the last decade indicate that free reports are consistently more accurate but less complete than reports obtained through specifically directed inquiry. The optimal combination is free report followed by the asking of specific questions. The wording of those questions, however, can have a substantial effect on the answers given. Furthermore, the wording of questions put to a witness can distort the witness's memory for the previously experienced event. These techniques and findings have implications for the study of other "retrieval" techniques such as hypnosis. Although laboratory-type control cannot be expected in practical settings, scientific validation of interrogation methods as practiced can be obtained if recording is complete and accurate, if processes of memory restoration or amplification are studied as they occur in the course of interrogation, and if outcome studies are fully reported, including both successes and failures to gain new information or to substantiate existing information.

Kleinhauz, Moris; Dreyfuss, Daniel A.; Beran, Barbara; Goldberg, Tova; Azikri, David (1979). Some after-effects of stage hypnosis: A case study of psychopathological manifestations. International Journal of Clinical and Experimental Hypnosis, 27, 219-226.

Some deleterious effects of stage hypnosis are described through a case report. A middle-aged respected member of a kibbutz who became the subject of an evening's entertainment by a stage hypnotist suffered a posttraumatic neurosis. The stage hypnotist, unaware of her traumatic childhood during World War II when she and her sister were hidden by Gentiles, requested her to regress to that age. This reactivated a former successfully repressed trauma and acted as a precipitating factor to the development of a traumatic neurosis which was left untreated. She was self-referred for adequate psychiatric treatment 11 years later. This treatment successfully restored her to an adequate level of functioning.

Orne, Martin T. (1979). The use and misuse of hypnosis in court. International Journal of Clinical and Experimental Hypnosis, 27, 311-341.

The various forensic contexts in which hypnosis has been used are reviewed, emphasizing its advantages and pitfalls. The technique may be helpful in the context of criminal investigation and under circumstances involving functional memory loss. Hypnosis has no utility to assure the truthfulness of statements since, particularly in a forensic context, subjects may simulate hypnosis and are able to willfully lie even in deep hypnosis; most troublesome, actual memories cannot be distinguished from confabulations either by the subject or by the hypnotist without full and independent corroboration. While potentially useful to refresh witnesses' and victims' memories to facilitate eyewitness identification, the procedure is relatively safe and appropriate only when neither the subject, nor the authorities, nor the hypnotist have any preconceptions about who the criminal might be. If such

preconceptions do exist -- either based on information acquired before the hypnotic procedure or on information subtly communicated during the hypnotic procedure -- hypnosis may readily cause the subject to confabulate the person who is suspected into his "hypnotically enhanced memories." These pseudomemories, originally developed in hypnosis, may come to be accepted by the subject as his actual recall of the original events; they are then remembered with great subjective certainty and reported with conviction. Such circumstances can create convincing, apparently objective "eyewitnesses" rather than facilitating actual recall. A number of minimal safeguards are proposed to reduce the likelihood of such an eventuality and other serious potential abuses of hypnosis.

Perry, Campbell (1979). Hypnotic coercion and compliance to it: A review of evidence presented in a legal case. International Journal of Clinical and Experimental Hypnosis, 27 (3), 187-218.

There are 2 main positions concerning the potential of hypnosis to coerce unconsenting behavior. One position asserts that coercion is possible through the induction of distorted perceptions which delude the hypnotized person into believing that the behavior suggested is not transgressive. The other position asserts that where hypnosis appears to be a causal factor in coercing behavior, other elements in the situation -- especially a close hypnotist-client relationship -- were the main determinants of behavior. The present paper analyzes the court transcript of a recent case in Australia in which a lay hypnotist was found guilty of 3 sexual offenses against 2 female clients. The uniqueness of the case is that it pits the 2 main positions on hypnotic coercion against each other. The hypnotist admitted the acts attributed to him; his defense was that hypnotic coercion is impossible since a hypnotized person would resist immediately any transgressive suggestion. The women involved stated that they were aware of what was happening but that, because they were hypnotized, they were unable to resist. Analysis of the court transcript indicates that neither a hypothesis of hypnotically induced perceptual distortion, nor one of a close hypnotist-client relationship can account for the events that occurred. Other alternative explanations are discussed within the context of the inherent difficulties of analyzing a court transcript.

Warner, K. E. (1979). The use of hypnosis in the defense of criminal cases. International Journal of Clinical and Experimental Hypnosis, 27 (4), 417-436.

The 4 principal stages in a criminal proceeding are discussed with a view toward determining the role that hypnosis can and does play in the American judicial system. In the preliminary investigative stage, hypnosis is primarily a technique for the discovery of evidence and its use is largely unfettered by court imposed restrictions. In the pre-trial stage, however, hypno-related testimony will be screened for abuses in obtaining it. At the trial stage, hypno-related testimony is generally admissible as a basis for expressing an opinion concerning mental condition, although no opinion may be expressed concerning the truthfulness of statements made under hypnosis. Where the testimony of a trial

witness has been enhanced by the prior induction of hypnosis, the extent to which taint has occurred is usually a question for the jury to determine. In cases of flagrant suggestion during the induction process, however, such testimony will not be allowed in evidence. Learned societies in the field of hypnosis must bear the responsibility for educating the judiciary on the limits of hypnosis as an evidentiary technique.

Worthington, T. S. (1979). The use in court of hypnotically enhanced testimony. International Journal of Clinical and Experimental Hypnosis, 27 (4), 402-416.

The leading judicial decisions on the use of hypnosis on witnesses are presented. Emphasis is on the increasing use of hypnosis by the police or prosecution with witnesses in criminal cases. Hypnosis has proved to be a valuable tool to learn facts not otherwise available. There is, however, a potential for abuse when the information learned is used directly as evidence in court or when the subjective certainty of the witness is increased to the point where cross-examination becomes ineffective. Safeguards are needed to prevent abuse.

1978

Schafer, D. W.; Rubio, R. (1978). Hypnosis to aid the recall of witnesses. International Journal of Clinical and Experimental Hypnosis, 26, 81-91.

14 cases are presented of interrogation under hypnosis of witnesses and victims of crimes. Videotaping is considered essential for use of the court, if necessary. Interrogation of indicted people should be done only as an exception, if at all. The ideal case for hypnosis interrogation is with a witness or a victim where information is obtained which leads to evidence which itself will stand up in court without the need of the hypnosis interrogation to be presented as such. Guidelines for such interrogation are presented.

1976

Hodge, J. R. (1976). The contractual aspects of hypnosis. International Journal of Clinical and Experimental Hypnosis, 24, 391-399.

No generally accepted theory of the essence of hypnosis is currently available, nor are any specific responses uniquely associated with hypnosis. A necessary, though not sufficient, aspect of hypnosis involves the subject's preconceived expectations and selective attention to a series of agreements ("contracts") which are developed between patient and therapist before the induction, during the induction and deepening procedures, and during the operational phase. These contracts may be either implicit or explicit, but they can be identified in all hypnotic interactions. The skillful therapist will make the contracts explicit by defining, at least in general terms, what he expects. If the patient agrees, i.e., "sings the contract," he is likely to comply with suggestions.

1968

Sakata, Kenneth I. (1968). Report on a case of failure to dehypnotize and subsequent reputed aftereffects. International Journal of Clinical and Experimental Hypnosis, 16 (4), 221-228.

The failure of a hypnotized S to execute a suggested task may have contributed to a failure to dehypnotize, the repression of the unsuccessful task after awakening, and a prolongation or reinstatement of hypnosis 3 days later. Some interview material and procedures utilized in handling the problems encountered are presented. (French & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1965

Moss, C. Scott; Rikken, G.; Coyne, L.; Bishop, W. (1965). Some correlates of the use (or disuse) of hypnosis by experienced psychologist-therapist. International Journal of Clinical and Experimental Hypnosis, 13, 39-50.

147 psychologist-psychotherapists were compared on the basis of their attitude towards the employment of hypnosis as a technique in psychotherapy. 1 finding was the absence of extensive differences between the 2 groups in the use of most other therapy techniques, though the hypnosis-favorable group made somewhat more active use of a wider variety of approaches. Doctrine and experience level per se were not significant determinants of the behavior in question. A major finding was that those favorably disposed were inclined to represent themselves as significantly more objective (rather than clinical or intuitive) in their frame-of-reference. A number of significant biographical correlates were found which led to the advancement by speculation of vignettes of the 2 extreme attitude groups. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Orne, Martin T. (1965). Undesirable effects of hypnosis: The determinants and management. International Journal of Clinical and Experimental Hypnosis, 226-237.

Various kinds of complications arising from the use of hypnosis are reviewed. The distinction is drawn between the induction of hypnosis when it is perceived as an episodic event, as in a laboratory context, versus the effect when it is perceived as leading to permanent changes, as in a therapeutic context. An attempt is made to draw these and other distinctions in order to understand better the possible sources of difficulties. [Author Abstract]

1964

Ludwig, Arnold M. (1964). An historical survey of the early roots of mesmerism. International Journal of Clinical and Experimental Hypnosis, 12 (4), 205-217.

Many believe that Franz Anton Mesmer helped lay the foundations upon which modern hypnotic theory and practice evolved. However, as one views the history of healing through suggestion prior to Mesmer, it becomes apparent that neither his theories nor his practices showed much originality. In fact, there is good evidence

that Mesmer plagiarized the work of others. With this in mind, it appears that Mesmer's contribution to later psychological healing and theory was related more to his personality than to his originality. (Journal Abstract)

Levitt, Eugene E.; Hershman, Seymour (1963). The clinical practice of hypnosis in the United States: A preliminary survey. International Journal of Clinical and Experimental Hypnosis, 11 (1), 55-65.

A preliminary survey of 301 clinical practitioners of hypnosis who responded to a questionnaire suggests that reported success in inducing hypnosis is unrelated to claimed experience with hypnosis. Children and adolescents are reported to be more susceptible than adults, but there is no sex difference reported. Type of training is generally unrelated to reported success as a hypnotist. Reported percentages of patients who attain various levels of hypnotic depth are generally in keeping with earlier reports. Unexpected reactions to being hypnotized were reported by one out of four respondents.

Pulver, Sydney E. (1963). Delusions following hypnosis. International Journal of Clinical and Experimental Hypnosis, 11, 11-22.

Delusions occurring after hypnosis in the nonpsychotic patient are usually a result of the interplay of 3 factors. (a) the development of rapid, tense, transference reactions in hypnosis; (b) the presence of major defects in the patient's character structure; and (c) the occurrence of countertransference reactions on the part of the hypnotist which touch on a specific area of conflict within the patient. The presence of a chaperon or the use of tape recorders are not satisfactory preventive measures. Rather, the physician using hypnosis should focus upon: (a) preliminary psychological evaluation and selection of patients free from disposition to delusion formation, (b) identification of transference reactions and a willingness to discuss with patients, (c) awareness of his own emotional responses to the patient. Basic courses in psychiatry are recommended. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Marcus, Howard W.; Bowers, Margaretta K. (1961). Hypnosis and schizophrenia in the dental situation. A case report. International Journal of Clinical and Experimental Hypnosis, 9, 47-57. (In Index Medicus 61: 1228)

#### Author's Summary

A case is presented of a schizophrenic patient, paranoid type, whose phobic fear of dentistry had resulted in the development of a delusional system: he would get well if his teeth were repaired under hypnosis. In reality, his need of dental care was severe. He had lost three teeth by extraction because of painful cavities which he could not permit to be treated with conventional methods. He presented deep cavities in his front teeth. The patient was consistently unable to make rapport with several psychiatrists and dental treatment was finally discontinued because of unwillingness to proceed without psychiatric supervision. Alternative methods of handling the situation and its implications are discussed.

McCartney, James L. (1961). A half century of personal experience with hypnosis. International Journal of Clinical and Experimental Hypnosis, 9, 23-33.

#### NOTES

(Author's Summary and Conclusions). "After fifty years of experience with hypnosis, it is evident that it is not a superficial and careless technic but should be utilized only by capable, trained physicians, as are the other complex and difficult medical technics. ... In order to induce hypnosis, the patient must be perfectly willing to be hypnotized, he must have confidence in the practitioner, and he must concentrate on doing exactly as he is told. In selected cases, drugs or electrical impulses may be used for the initial induction of hypnotic sleep, but if hypnotherapy is to be continued, the physician must keep in contact with the patient by repeated suggestions. The technic used should fit the individual patient, but in most cases, verbal suggestions are all that is necessary to bring about dissociation. Hypnosis may be used to facilitate the beginning of mental catharsis, the establishment of transference, and may be easily instituted following narcosynthesis, electroshock therapy, minimum stimulus, or Sedac. Suggested activity under hypnosis may be carried out at a designated time, place, and manner after awakening. This is a result of autosuggestion and may be mistaken for psychopathic behavior. Such suggestions may be instituted by television, movies, radio, telephone, or recorded or written instruction. Hypnosis may be used to plant suggestions; if misused, it may create an obsessive-compulsive neurosis, while when properly used, it may overcome many functional symptoms and may be used to supplement other forms of psychotherapy" (p. 32).

Shaw, S. Irwin (1961). The dangers of hypnosis (the mental hypodermic) as applied to dentistry. International Journal of Clinical and Experimental Hypnosis, 9 (2), 53-58.

#### NOTES

The author expresses the opinion that there are no inherent dangers in using hypnosis in dentistry, if the dentist is well-trained (including training in the psychodynamic factors involved, counter-transference, etc.) He indicates that dentists should not use hypnodontia with patients who are in psychiatric treatment, or recently had such treatment, without consulting with the physician or psychologist involved in the mental health treatment. "The qualified practitioner of hypnosis is always alert to possible involvements on the part of the patient, and perhaps including himself, in the emotional relationship connected with trance induction. It is this knowledge and full awareness of possible dangers, which prevents harm to the dental patient, in the same way that the conscientious user of a hypodermic syringe, knowing of dangers involved, is always careful to avoid risks when making injections of drugs or chemicals into the patient" (p. 56).

Raginsky, Bernard B. (1959). Temporary cardiac arrest induced under hypnosis. International Journal of Clinical and Experimental Hypnosis, 7 (2), 53-68.

#### NOTES

##### Summary

"An experiment is described in which the symptoms of syncope and temporary complete cardiac arrest were induced under hypnosis in a patient who had been operated on for a so-called Adams-Stokes syndrome and who had, until the time of the experiment, remained free of such symptoms. An attempt is made to correlate contemporary knowledge in explaining this phenomenon.

"It is pointed out that maturity in the biological sciences takes about twice as long to achieve as does maturity in the physical sciences. This holds especially true in the use of hypnosis" (p. 66).

The authors report that in attempting to reinduce a fainting episode, "We were not at all prepared for the complete cardiac arrest which followed the hallucinated episodes" (p. 59).

**1956**

**Marcuse, F. L.; Phipps, G. T. (1956). A demonstration of dental extraction with hypnotic anesthesia. Journal of Clinical and Experimental Hypnosis, 4, 2-4.**

**NOTES**

**The authors report on a demonstration of dental extractions with two patients (of five patients with whom hypnosis was attempted). They describe successful results despite 3-minute inductions in people not pre-trained, a terse and abrupt approach by the dentist (who uses only hypnosis and refers non-responding patients elsewhere). "While the hypnotist demonstrated effectively what could be done with hypnosis, his theoretical orientaton as to why this had occurred can only be described as unfortunate. In response to questioning he stated and quite flatly: that in hypnosis there are no dangers (1); that hypnosis is essentially cardiovascular in nature; that drugs had no place along with hypnosis--despite the advice of Moss (2) that dentists should use hypnosis along with drugs routinely unless the latter is contraindicated. He expressed his attitude toward the use of local anesthetics by indicating that the package he had had was thrown away because it had become spoiled from disuse. Hypnosis was presented in effect as an all or nothing technique" (p. 3).**

**1954**

**Meares, Ainslie (1954). History-taking and physical examination in relation to subsequent hypnosis. Journal of Clinical and Experimental Hypnosis, 2 (4), 291-295.**

**NOTES**

**"Summary. The history-taking and physical examination of the initial interview can be so structured as to facilitate the subsequent induction of hypnosis. Rapport is established, and negative transference feelings are not allowed to develop. There must be no holding back or hiding of the real complaint with screen symptoms. Physical examination is a symbolic surrender and paves the way for the real surrender of passive hypnosis. If induction by an active method is anticipated, authoritative attitudes are introduced into the history-taking and physical examination" (p. 295).**

**EVENTS RELATED POTENTIAL (ERP)**

**2001**

**Jensen, Stacia M.; Barabasz, Arreed; Barabasz, Marianne; Warner, Dennis (2001). EEG P300 event-related markers of hypnosis. American Journal of Clinical Hypnosis, 44 (2), 127-139.**

**Demonstrated that when subjects are stringently selected for hypnotizability and responses are time-locked to events, robust markers of hypnotic response emerge that reflect alterations in consciousness corresponding to subjects' subjective experiences of perceptual alteration. To further test this hypothesis, the researchers obtained EEG visual P300 event-related potentials (ERPs) from 20 high- and low-**

hypnotizable subjects (7 males and 13 females, aged 19-52 years). The effects of positive obstructive and negative obliterating instructions were tested during waking and alert hypnotic conditions. High-hypnotizables showed greater ERP amplitudes in response to the negative hallucination condition and lower ERP amplitudes in response to the positive obstructive hallucination when compared to the low-hypnotizables. Contrary to socio-psychological or role play conceptualizations, the hypnotic induction resulted in specific psychophysiological responses which could not be produced by waking imagination or by the lows who were trying to mimic hypnotic responding. **1999**

Barabasz, A.; Barabasz, M.; Jensen, S.; Calvin, S.; Trevisian, M.; Warner, D. (1999). Cortical event-related potentials show the structure of hypnotic suggestions is crucial. International Journal of Clinical and Experimental Hypnosis, 47 (1), 5-22.

Electroencephalographic cortical event-related potentials (ERPs) are affected by information processing strategies and are particularly appropriate for the examination of hypnotic alterations in perception. The effects of positive obstructive and negative obliterating instructions on visual and auditory P300 ERPs were tested. Twenty participants, stringently selected for hypnotizability, were requested to perform identical tasks during waking and alert hypnotic conditions. High hypnotizables showed greater ERP amplitudes while experiencing negative hallucinations and lower ERP amplitudes while experiencing positive obstructive hallucinations, in contrast to low hypnotizables and their own waking imagination-only conditions. The data show that when participants are carefully selected for hypnotizability and responses are time locked to events, rather robust physiological markers of hypnosis emerge. These reflect alterations in consciousness that correspond to participants' subjective experiences of perceptual alteration. Accounting for suggestion type reveals remarkable consistency of findings among dozens of researchers.

NOTES

1:

In their Discussion the authors note that not all of the highly hypnotizable subjects demonstrated the changes predicted, consistent with Hilgard's (1992) observation that individual differences in response remain even among high hypnotizables. Post-experimental inquiry revealed the sources of (non-predicted) response for these two people. "One, showing only a moderate ERP amplitude attenuation in the obstructive condition, noted she pictured a cardboard box in front of the computer monitor, but 'I pictured a rather small box that didn't block the entire screen!' Another showed an apparently contradictory response, a markedly diminished amplitude in the negative hallucination that called for deafness during the auditory stimuli. This participant reported the perception of complete obliteration of all sounds and, therefore, showed no surprise ERP effect. 'It was kind of scary when he (AB) said 'deaf' the second time. I couldn't hear anything at all. I was glad when he

touched my shoulder and it was OK to hear again. I don't think I would do that again ... I mean do the hypnotic suggestion as much!" (pp. 17-18).

De Pascalis, Vilfredo (1999). Psychophysiological correlates of hypnosis and hypnotic susceptibility. International Journal of Clinical and Experimental Hypnosis, 47 (2), 117-143.

This article reviews and summarizes electroencephalographic (EEG)-based research on physiological and cognitive indicators of hypnotic responding and hypnotic susceptibility, with special attention to the author's programmatic research in this area. Evidence that differences in attention levels may account for hypnotic depth and individual differences in hypnotizability is provided with traditional EEG rhythms, event-related potentials, and 40-Hz EEG activity. The alteration of stimulus perception may be a secondary effect with respect to allocation of attentional resources. In both nonhypnosis and hypnosis conditions, high hypnotizables appeared to show greater task-related EEG hemispheric shifts than did low hypnotizables. Findings concerning cognitive and physiological correlates of hypnotic analgesia are discussed with respect to hemispheric functioning in the apparent control of focused and sustained attention. The conclusion is that although a definitive EEG-based signature for hypnosis and hypnotizability is not yet established, there are a number of promising leads.

#### NOTES

1:

The authors conclude that their results support Hilgard's (1986) hypothesis that high hypnotizables are better able to focus attention on task-relevant stimuli than low hypnotizables; "show a greater 40-Hz EEG hemispheric specificity in both nonhypnotic and hypnotic conditions" (p. 134) which suggests "greater physiological flexibility (i.e., the subjective capacity to shift from one state to another)" (p. 134); exhibit more EEG beta activity during early stages of hypnotic inductions (especially Left hemisphere) though there is hemisphere balancing later -- supporting Gruzelier's (1988, 1996) theory; show changes in ERP that can't be explained by a theory of goal directed strategies but are consistent with findings by Barabasz et al (1996) "showing that hypnotic alteration of stimulus perception operates early at the level of the detection of the signal as well as later at the level of response bias" (p. 134); and, given hypnotic analgesia suggestions, they "showed significantly smaller total, delta, and beta 1 amplitudes in the right hemisphere across all frontal, central, and posterior recordings so that a significantly more pronounced hemispheric asymmetry in favor of the left hemisphere was displayed" (p. 135).

De Pascalis, V.; Magurano, M. D.; Bellusci, A. (1999). Pain perception, somatosensory event-related potentials and skin conductance responses to painful stimuli in high, mid, and low hypnotizable subjects: Effects of differential pain reduction strategies. Pain, 83 (3), 499-508.

In this study, pain perception, somatosensory event-related potential (SERP) and skin conductance response (SCR) changes during hypnotic suggestions of Deep

Relaxation, Dissociated Imagery, Focused Analgesia, and Placebo, compared with a Waking baseline condition, were investigated. SERPs were recorded from frontal, temporal, central, and parietal scalp sites. Ten high, 9 mid, and 10 low hypnotizable right-handed women participated in the experiment. The following measures were obtained: (1) pain and distress tolerance ratings; (2) sensory and pain thresholds to biphasic electrical stimulation delivered to the right wrist; (3) reaction time and number of omitted responses; (4) N2 (280+/-11 ms) and P3 (405+/-19 ms) peak amplitudes of SERPs to target stimuli delivered using an odd-ball paradigm; (5) number of evoked SCRs and SCR amplitudes as a function of stimulus repetition. Results showed, high, mid and low hypnotizables exhibited significant reductions of reported pain and distress ratings during conditions of Deep Relaxation/Suggestion of Analgesia, Dissociated Imagery and Focused Analgesia. High hypnotizable subjects displayed significant reductions in pain and distress levels compared to mid and low hypnotizables during Dissociated Imagery, Focused Analgesia and, to a lesser degree, during Deep Relaxation. Placebo condition did not display significant differences among hypnotizability groups. High hypnotizables, compared to mid and low hypnotizables, also showed significant increases in sensory and pain thresholds during Dissociated Imagery and Focused Analgesia. High, mid, and low groups showed significant reductions in P3 peak amplitudes across all hypnosis conditions and, to a lesser degree, during Placebo. The temporal cortical region was the most sensitive in differentiating SERP responses among hypnotizability groups. On this recording area the subjects highly susceptible to hypnosis displayed significantly smaller P3 and greater N2 peaks during Focused Analgesia than did the other hypnotizable groups. In this condition highly susceptible subjects also reported the highest number of omitted responses and the shortest Reaction Times. These subjects also showed faster habituation of SCRs when compared with mid and low hypnotizables. During Dissociated Imagery and Focused Analgesia, highly hypnotizable subjects also disclosed a smaller total number of evoked SCRs than did mid and low hypnotizable subjects. The results are discussed considering possible common and different mechanisms to account for the effects of different hypnotic suggestions.

Abstract from National Library of Medicine, PubMed

Kallio, Sakari; Revonsuo, Antti; Lauerma, Hannu; Hdmldinen, Heikki; Lang, Heikki (1999). The MMN amplitude increases in hypnosis - a case study. Neuroreport, **10** (17), 3579-3582.

The neural mechanisms associated with hypnosis were investigated in a single highly hypnotizable subject by measuring the mismatch negativity (MMN) component of auditory ERP, reflecting the preattentive discrimination of change in stimulus flow, in normal baseline state and under hypnosis. It has been proposed that the frontal inhibition associated with hypnosis can be measured as a decrease in MMN. ERPs were elicited using the passive oddball paradigm with standard and deviant sine tone stimuli of 500 and 553 Hz respectively. The measurement was repeated in five separate sessions. In hypnosis the MMN was significantly larger compared to baseline. The results indicate that hypnosis can give rise to altered information

processing in the brain even at a relatively early, i.e. preattentive level and that the larger MMN measured under hypnosis does not support frontal inhibition theory.

1998

Crawford, Helen J.; Knebel, Timothy; Kaplan, Lyla; Vendemia, Jennifer M. C.; Xie, Min; Jamison, Scott; Pribram, Karl H. (1998). Hypnotic analgesia: 1. Somatosensory event-related potential changes to noxious stimuli and 2. Transfer learning to reduce chronic low back pain. International Journal of Clinical and Experimental Hypnosis, 46 (1), 92-132.

Fifteen adults with chronic low back pain (M = 4 years), age 18 to 43 years (M = 29 years), participated. All but one were moderately to highly hypnotizable (M = 7.87; modified 11-point Stanford Hypnotic Susceptibility Scale, Form C [Weitzenhoffer & Hilgard, 1962]), and significantly reduced pain perception following hypnotic analgesia instructions during cold-pressor pain training. In Part 1, somatosensory event-related potential correlates of noxious electrical stimulation were evaluated during attend and hypnotic analgesia (HA) conditions at anterior frontal (Fp1, Fp2), midfrontal (Fe, F4), central (C3, C4), and parietal (P3, P4) regions. During HA, hypothesized inhibitory processing was evidenced by enhanced N140 in the anterior frontal region and by a prestimulus positive-ongoing contingent cortical potential at Fp1 only. During HA, decreased spatiotemporal perception was evidenced by reduced amplitudes of P200 (bilateral midfrontal and central, and left parietal) and P300 (right midfrontal and central). HA led to highly significant mean reductions in perceived sensory pain and distress. HA is an active process that requires inhibitory effort, dissociated from conscious awareness, where the anterior frontal cortex participates in a topographically specific inhibitory feedback circuit that cooperates in the allocation of thalamocortical activities. In Part 2, the authors document the development of self-efficacy through the successful transfer by participants of newly learned skills of experimental pain reduction to reduction of their own chronic pain. Over three experimental sessions, participants reported chronic pain reduction, increased psychological well-being, and increased sleep quality. The development of "neurosignatures of pain" can influence subsequent pain experiences (Coderre, Katz, Vaccarino, & Malzack, 1993; Melzack, 1993) and may be expanded in size and easily reactivated (Flor & Birbaumer, 1994; Melzack, 1991, 1993). Therefore, hypnosis and other psychological interventions need to be introduced early as adjuncts in medical treatments for onset pain before the development of chronic pain.

NOTES

1:

The authors suggest that "the anterior frontal region deals with the active allocation of attention and disattention, whereas spatiotemporal aspects of the somatosensory perceptions involve the posterior cortical systems" (p. 113) They acknowledge that "other inhibitory pain systems are actively interacting with the frontal attentional system, including the limbic and thalamic systems" and mention evidence that the inhibitory processing "may extend as far as spinal cord antinociceptive mechanisms as evidenced by reductions in brief latency (Hagbarth & Finer, 1963) and R-III

amplitude (Kiernan, Dane, Phillips, & Price, 1995) of spinal reflexes" (p. 113). Both pain perception and strategies of pain control may involve the anterior cingulate cortex (Kropotov et al. 1997), which has many connections with anterior frontal cortex "and is thought to be an area that organizes responses to noxious stimuli" (p. 113).

For the chronic low back pain Ss there were reductions in reported low back pain during the experimental sessions, and significant improvements in psychological well-being and sleep quality across the three sessions. "The importance of developing self-efficacy through learning to control experimental pain and the understanding of one's own attentional and disattentional abilities was demonstrated as being a significant intervention in the modulation and control of chronic pain" (p. 123).

Danziger, N.; Fournier, E.; Bouhassira, D.; Michaud, D.; De Broucker, T.; Santarcangelo, E.; Carli, G.; Chertock, L.; Willer, J. C. (1998). Different strategies of modulation can be operative during hypnotic analgesia: A neurophysiological study. Pain, 75 (1), 85-92. Keywords: analgesia/anesthesia, autonomic nervous system, EEG, electrical stimulation, event related potential (ERP), inhibition, neurophysiology, pain, pain threshold, reflex, suggestion

Nociceptive electrical stimuli were applied to the sural nerve during hypnotically-suggested analgesia in the left lower limb of 18 highly susceptible subjects. During this procedure, the verbally reported pain threshold, the nociceptive flexion (RIII) reflex and late somatosensory evoked potentials were investigated in parallel with autonomic responses and the spontaneous electroencephalogram (EEG). The hypnotic suggestion of analgesia induced a significant increase in pain threshold in all the selected subjects. All the subjects showed large changes (i.e., by 20% or more) in the amplitudes of their RIII reflexes during hypnotic analgesia by comparison with control conditions. Although the extent of the increase in pain threshold was similar in all the subjects, two distinct patterns of modulation of the RIII reflex were observed during the hypnotic analgesia: in 11 subjects (subgroup 1), a strong inhibition of the reflex was observed whereas in the other seven subjects (subgroup 2) there was a strong facilitation of the reflex. All the subjects in both subgroups displayed similar decreases in the amplitude of late somatosensory evoked cerebral potentials during the hypnotic analgesia. No modification in the autonomic parameters or the EEG was observed. These data suggest that different strategies of modulation can be operative during effective hypnotic analgesia and that these are subject-dependent. Although all subjects may shift their attention away from the painful stimulus (which could explain the decrease of the late somatosensory evoked potentials), some of them inhibit their motor reaction to the stimulus at the spinal level, while in others, in contrast, this reaction is facilitated.

Abstract from National Library of Medicine, PubMed

1997

Barabasz, Arreed; Barabasz, Marianne (1997, August). Altered brain activity shows the structure of hypnotic suggestions is crucial. [Paper] Presented at the annual

meeting of the American Psychological Association, Chicago, IL. (Abstract was published in *Psychological Hypnosis*, Winter-Spring 1998, Vol 7, No. 1, pp. 3-4.)

Recently, Kirsch and Lynn (1995) helped to converge understandings of hypnosis and at the same time stimulated renewed consideration of the central issues. Kihlstrom (1996, p.1) reminded us that trance versus non-trance as well as persistent individual differences versus experimental manipulation "continue to divide the field." Hilgard (1992, p. 80) emphasized that the "basic reason" hypnosis theories are in disarray stems from the lack of "any truly distinguishing basis - psychological, physiological or neurophysiological - by which to distinguish sharply between the established hypnotic condition (call it 'trance' or any other name) and normal waking consciousness." Cortical event related potentials (ERPs) provide one way of shedding light on this issue.

This study tested the effects of positive obstructive and obliterating instructions on visual and auditory EEG P300 ERPs. Considering issues raised by Spiegel and Barabasz (1988), 20 participants, stringently selected for hypnotizability, were requested to perform identical tasks during waking and alert hypnotic conditions. High hypnotizables showed greater ERP amplitudes while experiencing negative hallucinations (i.e., a suggestion not to perceive stimuli) and lower ERP amplitudes while experiencing positive obstructive hallucinations (i.e., a suggestion to perceive competing stimuli instead of the presented ones) in contrast to low hypnotizables and their own waking imagination only conditions. Accounting for suggestion type reveals remarkable consistency of findings among dozens of researchers.

The findings do not contradict the real and impressive effects of hypnosis that result from immediate social influences, social context and personal abilities (Kirsch, Council, Mobayed, 1987; Lynn, Rhue & Weekes, 1990). Given the leptokurtic distribution of hypnotizability in the general population, social influence may entirely account for many of the hypnotic phenomena seen in research and clinical situations, which tap primarily those of moderate hypnotizability. However, the present study does show that when participants are very stringently selected and responses are time locked to events, robust physiological markers of hypnosis emerge that reflect alterations in consciousness and correspond to subjective experiences of perceptual alteration.

Jasiukaitis, Paul; Nouriani, Bitá; Hugdahl, Kenneth; Spiegel, David (1997). Relateralizing hypnosis: Or, have we been barking up the wrong hemisphere?. *International Journal of Clinical and Experimental Hypnosis*, 45 (2), 158-177.

Research and theory over the past couple decades have suggested that the right cerebral hemisphere might be the focus of brain activity during hypnosis. Recent evidence from electrodermal responding, visual event-related potentials, and Stroop interference, however, can make a case for a role of the left hemisphere in some hypnotic phenomena. Although hemispheric activation on hypnotic challenge may depend in large part on the kind of task the challenge might involve, several general aspects of hypnosis might be more appropriately seen as left-rather than right-hemisphere brain functions. Among these are concentrated attentional focus and the

role of language in the establishment of hypnotic reality. A left-hemisphere theory of hypnosis is discussed in light of recent findings and theories about a left-hemisphere basis for synthetic or generational capabilities (Corballis, 1991) and a neuro-evolutionary model of a left-hemisphere dopaminergic activation system for the implementation of predetermined motor programs (Tucker & Williamson, 1984). -- Journal Abstract

Barabasz, Arreed F.; Barabasz, Marianne; Jensen, Stacia (1995, November). Effects of hypnosis on cortical event-related potentials during visual and olfactory hypnotic hallucinations. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

NOTES

1:

Slotnick and London showed that different wording of suggestions led to very different results, which explains why our study on negative hallucinations and Spiegel's study had opposite results.

This study is still ongoing. Screened for highs who passed visual and olfactory hallucinations and lows who passed only motoric items on hypnotizability tests. Trained Ss with eyes open induction, and lows had instructions to simulate hypnosis. (Used the eyeroll induction, eyes open.)

Did waking administration of alternating checkerboard pattern on computer screen. Then did eyes open hypnotic induction plus a depth check to make sure they were deep (assign number; then instructed raise a finger when you double it; then again, raise a finger when you double it). Then used checkerboard design again.

Obstructive visual hallucination - "imagine traveling through space, a dark nebula" (better than imagining you are blind. Lows had no difference in waking, obstructive hallucination, and negative hallucination. The highs did--looks like they had to see it before they couldn't see it. "The dark nebula envelopes you completely, and now you can see nothing."

Schnyer, David M.; Allen, John J. (1995). Attention-related electroencephalographic and event-related potential predictors of responsiveness to suggested posthypnotic amnesia. International Journal of Clinical and Experimental Hypnosis, 43 (3), 295-315.

Higher frequency electroencephalographic (EEG) activity around 40 Hz has been shown to play a role in cognitive functions such as attention. Furthermore, event-related brain potential (ERP) components such as N1 and P1 are sensitive to selective attention. In the present study, 40-Hz EEG measures and early ERP components were employed to relate selective attention to hypnotic response. Participants were 20 low hypnotizable individuals, half assigned as simulators, and 21 high hypnotizable individuals. Each of these groups was subsequently divided into two groups based on recognition amnesia scores. The four groups differed in 40-Hz (36-44 Hz) EEG spectral amplitude recorded during preinduction resting conditions but not in EEG amplitude postinduction. The groups also differed in N1

amplitudes recorded during hypnosis. Regression analysis revealed that these effects only distinguish the high hypnotizable participants who experienced recognition amnesia from all other groups. The findings support the role of selective attention in hypnotic responsiveness, and the utility of subdividing high hypnotizable individuals is discussed.

1994

Crawford, Helen J. (1994). Brain dynamics and hypnosis: Attentional and disattentional processes. International Journal of Clinical and Experimental Hypnosis, 42 (3), 204-232.

This article reviews recent research findings, expanding an evolving neuropsychophysiological model of hypnosis (Crawford, 1989; Crawford & Gruzelier, 1992), that support the view that highly hypnotizable persons (highs) possess stronger attentional filtering abilities than do low hypnotizable persons, and that these differences are reflected in underlying brain dynamics. Behavioral, cognitive, and neurophysiological evidence is reviewed that suggests that highs can both better focus and sustain their attention as well as better ignore irrelevant stimuli in the environment. It is proposed that hypnosis is a state of enhanced attention that activates an interplay between cortical and subcortical brain dynamics during hypnotic phenomena, such as hypnotic analgesia. A body of research is reviewed that suggests that both attentional and disattentional processes, among others, are important in the experiencing of hypnosis and hypnotic phenomena. Findings from studies of electrocortical activity, event-related potentials, and regional cerebral blood flow during waking and hypnosis are presented to suggest that these attentional differences are reflected in underlying neurophysiological differences in the far fronto-limbic attentional system.

Crawford, Helen J. (1994). Brain systems involved in attention and disattention (hypnotic analgesia) to pain. In Pribram, Karl H. (Ed.), Origins: Brain and self organization (pp. 661-679). Hillsdale, NJ: Lawrence Erlbaum Associates.

Data are reviewed from regional cerebral blood flow, EEG, and somatosensory event-related potential (SERP; both scalp and intracranial) studies of attention to and disattention (hypnotic analgesia) of painful stimuli to provide further evidence for two neurophysiological systems of pain involving the cortex: (1) the epicritic, sensory system of pain associated with the parietal, posterior region, and (2) the protocritic, distress, comfort-discomfort system of pain associated with the far fronto- limbic region. Studies of neurophysiological changes accompanying suggested hypnotic analgesia support the hypothesis that the executive controller of the far frontal cortex, via the far fronto-limbic attentional system, acts as a gate against the ascent of painful stimuli into conscious awareness by 'directing' downward the inhibition of incoming somatosensory information coming from the thalamic region. In hypnotically responsive individuals who could eliminate the perception of pain, reviewed studies demonstrated increased regional cerebral blood in the frontal and somatosensory regions, shifts in hemispheric dominance of EEG

theta power, differential surface SERP topographical patterns in the anterior and posterior regions of the brain, and reduction of the intracranial SERP P160 waveform in the gyrus cingulus.

## NOTES

1:

Paradoxically, there may be physiological reactivity to pain stimuli while the hypnotized Subject reports they are not consciously aware of pain. Posner's proposal of two different attentional systems may account for why there is physiological reactivity concurrent with lack of awareness of pain. Posner suggested that the posterior brain is involved with engaging and disengaging attention while the anterior brain is involved in attention for action or effortful attention. "Thus, the posterior region is involved in space and time, the epicritic processes, whereas the anterior region is involved in comfort- discomfort, the protocritic processes (Pribram, 1991)" (p. 665).

In parallel, there appear to be two systems of pain involving the cortex, as revealed in positron emission tomography research. Also relevant is clinical data showing that "removal of the frontal or cingulate cortex in patients with intractable pain leads to the amelioration of distress while not eliminating sensory pain (Bouckoms, 1989)" (p. 665).

The author proposes a neuropsychophysiology of hypnotic analgesia based on Hilgard's (1986) neodissociation theory of hypnosis, together with Pribram and McGuinness' (1975, 1992) attention model. In this view, "Hilgard's executive control system is the far frontal cortex 'directing' the inhibition of incoming painful stimuli" (p. 666) after determining that the somatosensory signal is 'irrelevant.'

"Highly hypnotizable individuals ('highs') have greater attentional and disattentional abilities than low hypnotizable individuals ('lows'). ... Recent neuroimaging techniques (PET, SPECT, CBF) that assess regional brain metabolism have found no differences in waking conditions between low and highly hypnotizable individuals, but have consistently reported that only highs show increased cerebral blood flow during hypnosis, suggestive of enhanced cognitive effort (Crawford, Gur et al., 1993; Halama, 1989; Meyer, Diehl, Ulrich, & Meinig, 1989; Walter, 1992)" (p. 666).

The hippocampus appears to be involved as a gating mechanism in selective attention (Crowne, Konow, Drake & Pribram, 1972; Isaacson, 1982, Isaacson & Pribram, 1986; R. Miller, 1991; Pribram, 1991; Arnolds et al., 1980) This gating function may be promoted "through a cortico-hippocampal relay [that] transmits information by theta wave modulation and Hebbian synaptic modification so that there is selective disattention" (p. 667). The author suggests that hypnotic pain control may involve directing attention away from pain sensory signals.

Highly hypnotizable people generate more EEG theta than low hypnotizables whether they are hypnotized or not, and Crawford (1990) observed marked hemispheric shifts in theta when highs (but not lows) were attempting to control pain with hypnosis.

This paper reports on preliminary results of SERP studies of people given hypnotic analgesia suggestions to reduce electric shock stimulus evoked pain. The results were analyzed individual by individual, because group data obscured pronounced

shifts in SERP patterns (e.g. habituation rates differed among Subjects). For highs, the SERP tended to be reduced, and the lower amplitudes were observed as early as the N100-P200 components. This did not occur for low hypnotizables.

Different kinds of mechanisms may be operative for high hypnotizables, however. "In over half of the high hypnotizable subjects the far frontal region (Fp1, Fp2) showed strong arousal during attention to pain, but during hypnotic analgesia there was a flattening out of the SERPs to the point they are hard to measure. By contrast, the more posterior SERPs (including F3 and F4), while reduced in amplitude, were still evident. The other half of highs showed little SERP activity in the far frontal region in either attend or disattend conditions, but substantial reductions of SERPs at all locations during hypnotic analgesia" (p. 670). Additionally, some of the highs evidenced a contingent negative variation (CNV) or a late 400-500 msec negativity in the far frontal region, which author is inclined to interpret as "a preparation for a response or for an inhibition of a response" (p. 670).

Case studies of two patients with intracranial electrodes and scalp electrodes recording SERPs are presented in support of the experimental data. The two female patients were diagnosed with obsessive compulsive disorder; one was highly hypnotizable and one was not. They received 30 moderately painful stimuli to the left middle finger under sequential conditions: waking attention, hypnosis with analgesia suggestions, and hypnosis with attention instructions. The highly hypnotizable patient reported significantly less pain during suggested analgesia, and that reduction in pain was associated temporally with reduction of SERP at P160 in the gyrus cingulus (and at no other recording sites). The 'unhypnotizable' patient showed no SERP changes. As an aside, the author notes that "Subsequent to the hypnotic analgesia, when the pain was attended to again during waking this patient showed a significant enhancement of the same positivity wave at Fz, as if there was a rebound effect (something we have also observed in some of our SERP subjects at the BRAINS Center)" (p. 674).

**DePascalis, Vilfredo (1994). Event-related potentials during hypnotic hallucination. International Journal of Clinical and Experimental Hypnosis, 42 (1), 39-55.**

Event-related potentials were elicited by visual stimulation and recorded at frontal, central, and posterior scalp sites so as to study the psychophysiological process associated with hypnotic hallucination. Subjects were screened using two measures of hypnotic susceptibility (Harvard Group Scale of Hypnotic Susceptibility, Form A and the Stanford Hypnotic Susceptibility Scale, Form C). Seven high and 9 low hypnotizable right-handed females participated in the experiment. Eight intermediate hypnotizable right-handed females served as controls. Peak amplitudes and latencies of P1, N1, P2, N2, and P3 components were compared in two hypnotic conditions (obtained by means of hypnotic suggestions): stimulus enhancement and stimulus elimination. High hypnotizable subjects displayed a significant attenuation of the P1 and N1 amplitudes of the evoked response while experiencing stimulus elimination. The effect for the P1 component was greatest at the posterior sites compared to that found at the anterior and central sites. A similar trend across condition was also observed for P3 peak amplitude, even though the Group x

Condition interaction was only marginally significant ( $p < .07$ ). during negative hallucination, P3 peak latency for high hypnotizables was shorter than that obtained during stimulus enhancement. This effect was more pronounced across the right hemisphere. These results are discussed in light of previous findings.

1993

Dabic-Jeftic, Mirjana; Barnes, Graham (1993). Event-related potentials (P300) during cognitive processing in hypnotic and non-hypnotic conditions. Psychiatria Danubina, 5 (1-2), 47-61.

In this study authors investigated to find out if there were any specific changes of event related potentials in subjects before hypnosis, entering hypnosis, in deep hypnosis and leaving hypnosis, and to compare mental activities of subjects such as capability of correctly calculating and remembering the exact number of unexpected stimuli delivered by stimulator with their verbal or nonverbal reports during any of the conditions investigated. The methodology was of testing the cognitive evoked potentials elicited by auditory stimuli, using the oddball paradigm. Obtained results show that the most constant values of shortest latency and highest amplitudes of the cognitive waves, especially P300 were found during deep hypnosis. All five subjects in the investigation answered with the exact number of delivered target stimuli only after deep hypnosis. Conversely, in all other conditions their answers were approximate to the correct number of delivered target stimuli. (Author abstract.)

NOTES

1:

In this experiment, 5 adult volunteers were told to attend to one of two tones delivered through headphones. The tones were randomly delivered but one occurred 85% of the time (the 'frequent, non-target tone') and the other occurred 15% of the time (the 'rare, target tone'). The subjects were to notice, remember, and count the target tone. Measures were taken during five periods: pre-hypnosis, entering hypnosis, deep hypnosis, leaving hypnosis, and post-hypnosis.

Some subjects had extensive hypnosis experience prior to the experiment; others had little.

The EEG P300 wave was sensitive to condition. Latency of P300 was significantly shorter in deep hypnosis compared with other periods. Higher amplitude of P300 also occurred during deep hypnosis compared with other periods. (Notes taken from secondary reference, Ericksonian Newsletter.)

Jutai, Jeffrey; Gruzelier, John; Golds, John; Thomas, Martin (1993). Bilateral auditory-evoked potentials in conditions of hypnosis and focused attention. International Journal of Psychophysiology, 15, 167-176.

Brain event-related potentials (ERPs) evoked by auditory stimulation were used to study cerebral hemispheric activity during hypnosis. ERPs were recorded from bilateral central (C3 and C4) and temporal (T3 and T4) scalp locations in response to tone pips in 6 medium-high and 6 low-susceptible subjects in three conditions:

baseline (tones only), hypnosis (tones plus hypnotic induction), and a focused attention control (tones plus a newspaper story read by the hypnotist). Task asymmetries were individually adjusted for baseline asymmetries. Responses from central locations did not differentiate hypnosis from focused attention for either group. The same was true of temporal locations for the low-susceptible group. The predominant temporal lobe pattern for both conditions and groups was larger left than right responses. The exception was the hypnosis condition for the medium-high susceptible group where there was an increase in responses in the right temporal lobe.

Lyskov, E.; Juutilainen, J.; Jousmaki, V.; Hanninen, O.; Medvedev, S.; Partanen, J. (1993). Influence of short-term exposure of magnetic field on the bioelectrical processes of the brain and performance. International Journal of Psychophysiology, 14, 227-231.

The influence of an extremely-low-frequency (ELF) magnetic field on the bioelectrical processes of brain and performance was studied by EEG spectral analysis, auditory-evoked potentials (AEP), reaction time (Roletaking) and target-deletion test (TDT). Fourteen volunteers were exposed for 15 min to an intermittent (1 s on/off) 45- Hz magnetic field at 1000 A/m (1.26 mT). Each person received one real and one sham exposure. Statistically significant increases in spectral power through alpha- and beta- bands, as well as in mean frequency of the EEG spectrum were observed after magnetic field exposure. Field-dependent changes of N100 were also revealed. No changes in the amplitudes or latencies of the earlier peaks were observed. No direct effects on Roletaking, nor on TDT performance were seen. However, practice effects on Roletaking (decrease of Roletaking in the course of the test-sessions) seemed to be interrupted by exposure to the magnetic field.

NOTES

1:

A review and methodological critique. Updates Putnam, 1984. Currently, psychophysiological differences reported in the literature include changes in cerebral electrical activity, cerebral blood flow, galvanic skin response, skin temperature, event-related potentials, neuroendocrine profiles, thyroid function, response to medication, perception, visual functioning, visual evoked potentials, and in voice, posture, and motor behavior. Reviews the new research on the psychophysiological investigation of MPD from published, unpublished, and ongoing studies, and attempts to place current findings into a conceptual framework. Authors note results from unpublished and ongoing studies and include a critical analysis of current research methodology as well as suggestions for future research.

1990

Arendt-Nielsen, Lars; Zachariae, Robert; Bjerring, Peter (1990). Quantitative evaluation of hypnotically suggested hyperaesthesia and analgesia by painful laser stimulation. Pain, 42, 243-251.

## NOTES

1:

Sensory and pain thresholds to laser stimulation were determined, and the laser-pain evoked brain potentials were measured for 8 highly hypnotizable (Harvard Scores 10-11) student volunteers in 3 conditions: (1) waking, (2) suggestion of hyperaesthesia during hypnosis, (3) suggestion of analgesia during hypnosis.

The investigators used a laser beam 3 mm in diameter, with a 200 msec stimulus duration; the same area (but different points within the area) was used for consecutive stimulations. Ss were otherwise maintained in low stimulus conditions so they would not have visual or auditory cues about laser beam onset; they wore goggles, had eyes shut, and had earphones on. Sensory threshold was defined as warmth; pain threshold was defined as a distinct sharp pin prick.

The laser intensity used for stimulation corresponded to strong pain. Interstimulus intervals averaged 15 sec (but were randomly varied between 10-20 sec). Sensory and pain thresholds as well as two evoked potential measurements were taken during waking, hypnotized hyperaesthesia, and hypnotized analgesia conditions in a single 1 1/2 hour session.

The evoked potential component of interest was the negative complex N1 with latency of 300 msec; amplitude (P1=N1-P2) and latency of this complex (N1) were measured. EEG epochs contaminated by eye movement were omitted from analysis.

The standardized induction and deepening of hypnosis required 15-20 minutes; then the suggestion was given that Ss could alter their perception of stimuli such as pain. Hyperaesthesia suggestions were to imagine the right hand was in very hot water, then taken out but still very red, hot, sensitive so that even the vaguest stimulus would be detectable and unpleasant. They were told that they would receive a series of painful but tolerable stimuli, and to raise the left index finger if they could just perceive a laser pulse (sensory threshold), and again if they felt pricking pain (pain threshold).

Suggestions for analgesia were to imagine that their right hand was placed on their chest, and that their 'former right hand' was no longer their own but was made of some heavy and completely insensitive material like wood or stone. Sensory and pain threshold measures were then taken. During the evoked potential measurement period they received continuous suggestions of analgesia. They also were told to relax and imagine they were in a pleasant place, ignoring everything except the pleasant, relaxed feelings and imagining pleasant sights, sounds, feelings and the imagined place. They were told that though they would receive stimuli, they probably would be able to ignore the stimuli completely.

Results were as follows.

1. In the hypnotic hyperaesthesia condition, sensory and pain thresholds decreased significantly by 47% and 48%, respectively. Three Ss reacted to laser intensities far below what normally can be perceived in the waking state. [The authors ran a separate small control experiment to make sure that the Subjects were not using any

other cues, but mention the possibility of light-sensitive skin reacting to the blue laser light, creating evoked potentials.]

2. In the hypnotic analgesia condition, sensory and pain thresholds increased by 316% and 190%, respectively. 7 of 8 Ss did not even respond to pain threshold when the laser intensity was increased to the noxious level of 3W, which is the level at which tissue damage can occur.

3. Pain-related evoked potentials. Amplitude of the first pain-related potential was increased significantly by 14% in the hyperaesthesia condition and reduced significantly by 31% in the analgesia condition. Changes in the evoked potentials were considered minor however compared to those observed for thresholds, which are subjective response measures. Even in Subjects who reported complete analgesia, the experimenters observed the laser pain evoked responses. There were no differences in latencies of the first pain-related potentials for the three conditions (indicating that peripheral and central afferent conduction velocities were the same).

Discussion. "There has been some dispute concerning the experimental design and the reliability of the data obtained in studies dealing with hypnotic suggested analgesia [Spanos & Chaves, 1970]. In our design 2 'opposite' conditions were induced, and the 2 inductions gave 'opposite' results.

"The experience of pain can be significantly altered by suggestions of analgesia, which is in accordance with a number of other studies (for review see [Barber & Adrian, 1982; Hilgard & Hilgard, 1975]). The finding that suggestions of hyperaesthesia can decrease the sensory and pain thresholds and increase the amplitude of the pain evoked potential is a new observation. Since synchronized auditory and visual stimuli from the laser were blocked, and the stimulus was given at random intervals, the changes might be induced by the hypnotic suggestions" (p. 247).

The authors discuss their results in terms of (1) four pain modulation systems (neural/opiate, hormonal/opiate, neural/non-opiate, and hormonal/non-opiate) and (2) focusing and defocusing attention. Because in their pilot study it was necessary to give suggestions continually in order to affect the laser evoked potentials, they conclude that endogenous substances or hormonal/non-opiates would play a minor role, if any, in hypnotic analgesia. (Price and Barber [25] had also found it important to give suggestions continuously.)

On the other hand, "event-related potentials [7, 26] and pain-related potentials have, previously, been shown to be sensitive to focused and de-focused attention. Recently, Miltner et al. [23] showed the influence of attention on the late pain-related component of potentials, evoked by painful intracutaneous electrical stimulation. The degree to which the subject paid attention to the painful stimulus had a powerful effect on the pain-related complex. When subjects ignored the pain, it was still possible to record the pain-related complex although all the subjects consistently reported less or no pain. In wakeful subjects where cutaneous pain was abolished by lignocaine infiltration, the pain-related evoked potentials were abolished [4]. In our study, we could also record evoked potentials although the subject subjectively did not feel pain. The reason might be that the S acted as if there was full analgesia to the stimuli, in order to satisfy the hypnotist. During

suggested hyperaesthesia the thresholds declined below what normally could be perceived in the wakeful state. The volunteers could, therefore, not act hypersensitive, so something did happen.

"The discrepancy in subjective and objective responses might, however, be useful when investigating levels of the neuroaxis at which hypnosis might work" (pp. 248-249).

The authors note that this laser induced pain and the tooth pulp stimulation pain of Mayer & Barber both use the A-delta fibers. Barber & Mayer found it impossible to elicit pain within the output range of the stimulator (up to 150 microA) and reached maximal intensity for all volunteers during suggested analgesia. Using cutaneous laser stimulation the authors found that the skin damage level (3W) could be reached in 7 of 8 volunteers without any reaction of pain.

During the hyperaesthesia condition the sensory threshold was sometimes lower than can be detected in the waking state. Although some researchers have suggested that red light from a helium-neon laser might activate cutaneous photosensitive receptors and thereby elicit brain potentials, the authors were unable to elicit potentials in waking Subjects using their blue and green argon laser light with below sensory threshold intensity.

The authors also note that previous attempts to use physiological correlates of pain such as heart rate, blood pressure, respiration, and galvanic skin response have yielded confusing results. The physiological indicators are present even when Subjects report analgesia, leading some investigators to conclude that the subjective reports are due to illusion [Sutcliffe, 1961], compliance [Wagstaff, 1986], or a placebo induced by the hypnosis context [Wagstaff, 1986]. "These confusing results lead to the conclusion that both the traditional methods used for induction of pain and the monitored physiological responses have been unsatisfactory. The present study has sought to eliminate some of the methodological difficulties by (1) using brief well-defined argon laser stimuli which in awake volunteers induce very stable perceptions between trials [Arendt-Nielsen & Bjerring, 1988], and (2) recording psychophysical thresholds and objective parameters quantitatively related to the intensity of the pain perceived (1, 3)" (p. 249).

1989

Spiegel, David; Bierre, Pierre; Rootenberg, John (1989). Hypnotic alteration of somatosensory perception. American Journal of Psychiatry, 146, 749-754.

The effects of hypnotic alterations of perception on amplitude of somatosensory event-related potentials were studied in 10 highly hypnotizable (HH) Subjects and 10 Subjects with low hypnotizability. The HH Subjects showed significant decreases in amplitude of the P100 and P300 waveform components during a hypnotic hallucination that blocked perception of the stimulus. When hypnosis was used to intensify attention to the stimulus, there was an increase in P100 amplitude. Findings are consistent with observations that HH individuals can reduce or eliminate pain by using purely cognitive methods such as hypnosis. Together with data from the visual system, these results suggest a neurophysiological basis for hypnotic sensory alteration.

## NOTES

1:

Four conditions were presented in random order to each Subject. Normal Attention - subjects were instructed to button-press each time they felt the target stimulus. Passive Attention - subjects were instructed to attend to the stimuli but not button-press. Hypnotic Attention - subjects received a hypnotic induction (eye closure and arm levitation, which provided behavioral confirmation; then instructed to attend carefully to the stimuli, which they were told to experience as 'pleasant and interesting,' and button-press in response to targets. Hypnotic Obstructive Hallucination - hypnotic induction exercise was followed by the hypnotic suggestion of a local anesthetic, such as novocaine, spreading from fingers to hand to forearm on the stimulated limb; then instructed to make the limb cold, tingling, and numb; then told to button-press if they felt any of the target stimuli.

Experimenter was blind to hypnotizability scores.

Results were that the Highs showed significant decreases in P100 (45%) and P300 (38%) amplitudes during a hypnotic hallucination which blocked perception of the stimulus, but an increase (35%) in P100 amplitude when hypnosis was used to intensify attention to the stimulus. The authors view this as cognitive flexibility akin to the clinical situation in which high hypnotizables reduce or completely eliminate pain. They consider this evidence (along with earlier findings on similar blocking of perception in the visual system) of a neurophysiological basis for hypnotic sensory alteration.

1988

Aravindakshan, K. K.; Jenner, F. A.; Souster, L. P. (1988). A study of the effects of hypnotic regression on the auditory evoked response. International Journal of Clinical and Experimental Hypnosis, 36, 89-95.

Hypnotic regression in 6 hypnotizable Ss experienced in regression was studied by means of the auditory evoked response (AER). AER latency and amplitude is affected by arousal, attention, stimulus strength, and age. Ss aged between 27 and 61 years were regressed to the age of 7-9 years, and AERs were compared among three states of consciousness: normal awareness, hypnotic relaxation, and hypnotic regression. There was no change in AER morphology in the direction of that seen in children. Thus, age regression is not seen as a reversion to an earlier stage of neurological development but perhaps as role playing which is spontaneous and uninhibited, with the benefit of innocent belief in its accuracy.

## NOTES

1:

Raikov (1982) regressed 2 experienced Ss, comparing his results with those of actors acting as children and low hypnotizable subjects; he claimed to be able to reproduce neonatal reflexes in the highly hypnotizable Ss but not in the actors and low hypnotizable subjects.

AER's were used "because latency of the major waves and amplitude of the response is affected by level of arousal and attention..., strength of the stimulus, and,

more importantly for this study, by age.... Surwillo (1981) noted that peak latencies of AERs were 16-21 msec longer in children aged 9-13 than in adults..." (p. 90)

**DISCUSSION** reviews the literature.

Changes in the intensity of light stimulation can cause significant shifts in the amplitude and latency of the visual evoked response, but neither the amplitude nor the latency have been changed by suggested alterations in stimulus intensity during hypnosis (Andreassi, Balinsky, Gallichio, de Simone, & Mellers, 1976; Beck & Barolin, 1965; Beck, Dustman, & Beier, 1966; Zakrzewski & Szelenberger, 1981). Similarly, significant changes were seldom found in the AER with suggested variations of sound intensity during hypnosis (Amadeo & Yanovski, 1975) and in somatosensory responses to electrical stimuli applied to the fingers with suggested anesthesia during hypnosis (Halliday & Mason, 1964). Deehan and Robertson (1980) were able to abolish the AER completely during hypnosis, but their stimuli were very different from that used in the present study.

"In all such studies, hypnosis and suggestions were aimed at changing the intensity of the stimulus to S's awareness, while the actual intensity of the stimulus was unaltered. In the present study, the authors attempted to find whether the morphology of the AER in children could be reproduced by age regression, without altering the nature or intensity of the stimulus in its delivery.... Like previous investigators, the present authors noticed that the tracings were cleaner and easier to produce during hypnosis (see Figure 1), although the changes in neurological development observed by Raikov (1982) were not evident" (pp. 93-94).

**Spiegel, David; Barabasz, Arreed F. (1988). Effects of hypnotic instructions on P300 event-related-potential amplitudes: Research and clinical applications. American Journal of Clinical Hypnosis, 31, 22-27.**

Apparently conflicting findings in two recent studies of the effects of hypnotic hallucination on the P300 component of cortical event-related potentials are examined. In one study, Barabasz and Lonsdale (1983) found an increase in P300 amplitude in response to hypnotic anosmia instructions. However, Spiegel, Cutcomb, Ren, and Pribram (1985) obtained a decrease in P300 amplitude after instructing high hypnotizables that an imaginary cardboard box blocked their view of the stimulus generator. These differences are reconciled on the basis of differences in the hypnotic instructions given. The former study employed language which emphasized negation ("You will not smell anything at all"), while the latter had subjects focus on a competing obstructive hallucination. The anosmia subjects were surprised when they smelled anything at all, leading to an enhanced P300 response, while the subjects in the visual study were so absorbed in the hallucinated obstruction that perception of the stimulus was reduced. Clinical implications of these two studies are examined.

**Meszaros, Istvan; Banyai, Eva I.; Greguss, Anna C. (1985). Evoked potential correlates of verbal versus imagery coding in hypnosis. In Waxman, David; Misra,**

Prem C.; Gibson, Michael; Basker, M. Anthony (Ed.), Modern trends in hypnosis (pp. 161-168). New York and London: Plenum Press.

In our previous works it has been demonstrated that late components of midline evoked potentials recorded in the associative cortical areas do reflect significant modifications of selective attention caused by hypnosis. More and more data can be found in the literature indicating that subdominant hemispheric functions--significant in imagery coding--are more expressed in hypnosis as compared to the waking state. The purpose of the present experiment was to study how the motor reactions and the bilaterally recorded evoked potentials reflect the hypnotic modifications in processing visually exposed vs. imagery commands. A warning tone signal was followed by a tachistoscopically exposed verbal or imagery command to push a button either by the right or the left hand, according to the content of the command. Correct and incorrect responses and their reaction time were recorded together with the registration of EEG, EMG, ECG, EOG and evoked potentials in frontal, central, and occipital right and left monopolar leads. The alterations of the motor responses and of the negative evoked potential peak appearing with 120 ms latency and of the positive peaks with 200 and 300 ms latencies showed characteristic differences as functions of verbals vs. imagery task (i.e. dominant vs. subdominant hemispheric processing) as a result of hypnosis.

Spiegel, David; Cutcomb, Steven; Ren, Chuan; Pribram, Karl (1985). Hypnotic hallucination alters evoked potentials. Journal of Abnormal Psychology, 94 (3), 249-255

Brain electrical potentials evoked by visual stimulation were analyzed to study the neurophysiological mechanism associated with hypnotic hallucination. The visual evoked responses of 6 high- and 6 low-hypnotizable subjects were compared in three hypnotic conditions: stimulus enhancement, stimulus diminution, and stimulus elimination (obstructive hallucination). High-hypnotizable individuals demonstrated significant suppression of the later components of the evoked response (N1 and P3) while experiencing obstructive hallucinations, indicating a change in information processing. This effect was significantly greater in the right, as compared to the left, occipital region.

#### NOTES

1:

In the stimulus enhancement condition, Ss were told that one of two colored stimuli would appear unusually bright and interesting. In the stimulus diminution condition, Ss were told that the alternate color stimulus would appear drab, dull, uninteresting. In the obstructive hallucination condition, Ss were told to visualize a box that blocked their view of the TV monitor, making it impossible to see anything on the TV screen. The stimuli were 8 cm x 8 cm squares (colored gratings) presented 1 meter in front of S: 50% were blue vertical gratings, 50% were pink horizontal gratings.

Ss were told to press a button in response to any stimulus they happened to see; hence all stimuli were potential targets. To control for the effect of motor potentials

when they pressed the button, a button-pressing/passive-attention control group was added. Only results significant beyond this control group were attributed to a hypnotic hallucination effect. A second control group of medium level hypnotizable Ss were required to (a) button press after each stimulus presentation and (b) attend passively to the TV monitor screen without button pressing. "Thus, we had three control conditions: (a) for attentional demands, comparing the performance of high hypnotizables in the obstructive hallucination versus the hypnotic stimulus enhancement condition, (b) for hypnotizability, in comparing the high hypnotizables in the obstructive hallucination condition versus the low hypnotizables in the same condition, and (c) for button-pressing behavior, comparing the performance of the high hypnotizables to that of control subjects in press versus no-press conditions" (p. 250).

In their discussion, the authors state, "Our results are consistent with the hypothesis that an hypnotic instruction of obstructive hallucination among high- hypnotizable subjects is accompanied by a decrease in the amplitude of the P3 component of the evoked response throughout the brain, and of the N2 and P3 components in the occipital region. This dampening of amplitude is particularly notable among high hypnotizables in the right, as compared with the left, occipital area, suggesting greater inhibition of scalp-recorded response to a visual stimulus in the right hemisphere.

"These data show that while experiencing an obstructive hallucination blocking the stimulus, high-hypnotizable subjects demonstrate a change in the information-processing components of the evoked response (Baribeau-Braun, Picton, & Gosselin, 1983), rather than primarily in channel selection, which is reflected more by P1 and N1 (Ford, Roth, Dirk, & Kopell, 1978; Hillyard & Picton, 1979). Although there were differences at P1 and N1 between high and low hypnotizables, they were not significantly greater than those observed in the press/no-press control group. These observations make it possible to address several alternative explanations for the findings, such as the possibility of differences in nonspecific arousal leading to a differential preparation (Naatanen, 1969), which should be reflected primarily in changes in the early components, as would any differences in pupil size. Drowsiness or inattention in this condition should be associated with an increase, rather than a decrease, in response amplitudes (Schacter, 1976). The possibility that high hypnotizables might have defocused their view of the monitor (Schulman-Galambos, & Galambos, 1978) is made less likely by the fact that defocusing is accompanied by increases in P1 latency (Sokol & Moskowitz, 1981), whereas there were no P1 latency differences in the obstructive hallucination condition" (p. 254).

1984

Hogan, Marjorie; MacDonald, John; Olness, Karen (1984). Voluntary control of auditory evoked responses by children with and without hypnosis. American Journal of Clinical Hypnosis, 27 (2), 91-94.

Reports ability of children to voluntarily change brainstem auditory evoked responses (BAER). Fifteen children were studied. Both control and hypnosis groups showed changes in interwave latencies after verbal suggestions when compared to a

normal control group. These findings suggest that children may be able to modify peripheral auditory input into the brainstem through simple suggestion alone. Children in the formal hypnosis group did have more specific control for the task suggested. However, it is possible that children in the control group moved into an altered state of consciousness after listening to a taped story, reading a book, or spontaneously. They may have attained the observed changes in BAER while in a hypnosis-like state. This study encourages additional research in self-regulatory skills of autonomic processes in children.

1983

Barabasz, Arreed F.; Lonsdale, Christopher (1983). Effects of hypnosis on P300 olfactory-evoked potential amplitudes. Journal of Abnormal Psychology, 92 (4), 520-523.

From a sample of 93 undergraduates, 4 high- and 5 low-hypnotic susceptibility (the Stanford Hypnotic Susceptibility Scale: Form C) Ss were exposed to a waking condition and a hypnotic induction condition that included a suggestion for anosmia. ANOVAs of the P300 showed significant amplitude increases for weak and strong odors for high-hypnotizable Ss in hypnosis, but not for high-hypnotizable Ss in the waking state. No such amplitude increases were found for the low-hypnotizable ss

Nash, John (1983). Negative visual hallucination and concomitant changes in cortical event-related potentials (Dissertation, University of California, Santa Barbara). Dissertation Abstracts International, 45 (2), 716-B. (Order No. DA 8411224)

The purpose of this investigation was to examine the effects of negative visual hallucination (NVH) on cortical event-related potentials (ERPs), and to compare these effects with those of selectively attending to and ignoring stimuli. Five highly hypnotically susceptible subjects, four female and one male, were trained to block from subjective experience, i.e., negatively hallucinate, a ring of strobe-illuminated circles surrounding a central, independently strobe-illuminated circle. This stimulus array was modeled after part of the Titchener-Ebbinghaus circle illusion, since previous research had shown that subjects could attenuate the effects of the optical illusion via NVH of the outer, illusion-producing circles. "Analysis of the ERP data revealed amplitude and latency changes in various ERP components across the three experimental conditions (Attend, Ignore, NVH) for the four female subjects, a negative result which is explained in motivational terms. "The most noteworthy finding was the selection of the P3 amplitude variable at C2 by stepwise discriminant analysis for the four females, and the fact that this amplitude systematically decreased across conditions from largest in Attend to smallest in NVH. A variety of individual patterns were observed in terms of other ERP components which allowed discrimination (successful classification) among the three conditions. The results suggest that both Ignoring and NVH of a stimulus result in a decrease in the subjective certainty of perception of the stimulus. Individual

differences in patterns of ERP changes are interpreted in terms of differing strategies for execution of the experimental instructions. The results support the view that NVH instructions produce distinctive ERP effects and that NVH generally can be viewed as an extreme level of ignoring" (p. 716).

1982

Cutcomb, Steven Donald (1982, May). Studies in the brain correlates of human cognitive function (Dissertation, Stanford University). Dissertation Abstracts International, 42 (11), 4609-4610-B.

Three studies in the electrophysical correlates of human cognitive function are described. In study one, colored gratings were presented tachistoscopically to humans in two selective attention paradigms based upon the design of Hansen and Hillyard (1980), and Hillyard, Hink, Schwent, and Picton (1973). Visual event-related potential (ERP) data from Fz, Cz, Pz, T5, T6, O1, and O2, and behavioral responses were collected, and averaged ERPs were subjected to feature extraction (P1, N1, P2, N2, and P3 amplitudes and latencies) as well as a principle components factor analysis. Both analyses revealed as a significantly larger N2 component in the visual ERP, peaking at 310 msec and maximally frontally, during attending to task-relevant (attended-channel) stimuli. The P3 component was significantly larger in response to all attended-channel stimuli. In study two, the task was repeated using a group of six high and six low susceptible subjects during hypnosis. ERPs from Fz, Cz, Pz, O1, and O2, and behavioral responses were recorded during the task, and during a hypnotic suggestion of a negative hallucination (obstructed view of the stimulus monitor) while the stimuli were presented. The averaged ERP data was subjected to feature extraction followed by analyses of variance. No inter-group differences were found in the ERPs during the selective attention tasks. "During the obstructed view suggestion, the lows showed a normal visual ERP, while the highs had a visual ERP with a significantly diminished P1, P2, N2, and P3 component amplitude at O1 and O2. These results are evidence for an altered brain response during the obstructed view suggestion in high susceptible hypnotized subjects. "In study three, EEG were recorded from twelve high and twelve low susceptible hypnotic subjects (frontal, central, occipital) during baseline and hypnotized conditions. Data were transformed to normalized theta and alpha-band power spectral averages for each group. No significant inter-group alpha differences were found. Highs had significantly more relative theta energy frontally. During hypnotic tasks, the highs showed higher relative theta power at all leads. These results are consistent with the trait conception of hypnotic susceptibility" (pp. 4609-4610).

Blum, Gerald S.; Nash, John; Jansen, Robert D.; Barbour, John S. (1981, June). Posthypnotic attenuation of a visual illusion as reflected in perceptual reports and cortical event-related potentials. Academic Psychology Bulletin, 3, 251-271.

Highly selected and trained hypnotic subjects, capable of ablating portions of visual stimuli from conscious awareness, showed varying degrees of ability to attenuate the

**Titchener-Ebbinghaus circles illusion post-hypnotically under a negative visual hallucination instruction. The presence or absence of such inhibitory skill, inferred from perceptual reports, was differentially reflected in changes in cortical event-related potentials not typically associated with shifts in selective attention. These findings point to the cognitive operation of a distinctive mechanism of selective inattention.**

## **NOTES**

**1:**

**Blum et al. postulate an inhibitory mechanism of the central nervous system with stages of amplification and attenuation. They suggest that individual differences in inhibitory skill may be improved with practice even for very skilled Subjects. They studied this type of inhibition using a visual illusion (the Titchener-Ebbinghaus circles) because the neural locus of such illusions is thought to be more central in the nervous system rather than at the level of the retina.**

**Experiment 1. Three Ss trained in using hypnosis viewed stimuli in waking and posthypnotic negative visual hallucination (NVH) conditions. All three had previously passed a negative hallucination item (not seeing a playing card of three such cards placed on a table). Training included practice sessions applying NVH to the experimental stimuli. S1 reported immediate success; S2 experienced some initial difficulty ("I have a feeling something's there") but then reported success; S3 required a couple of long practice sessions.**

**The classic Titchener-Ebbinghaus illusion stimuli were used. Stimuli were ten slides with drawings of a standard 17-mm-diameter black circle on the left and a comparison black circle on the right. The black circle on the right was either 14, 15, 16, 17, or 18 mm in diameter, skewed intentionally around 17, to compensate for the proportion of smaller and larger judgments applied to the comparison figure in relation to the standard. One black comparison figure was surrounded by seven 15-mm diameter white circles; the other by seven 10 mm diameter white circles. The key drawings were both black circles of 17 mm. The second set of five drawings, used as a control, contained the same black circles but lacked outer rings of white circles.**

**The Subject was to state whether the black circle on the right appeared larger, smaller, or the same as the standard black circle on the left. Slides were shown for 4 seconds each, with 6 seconds in between slides.**

**Alternating blocks of trials were given under baseline (B) condition and a posthypnotically programmed negative hallucination condition (NVH). In the NVH condition, "the rings of white circles surrounding the standard and comparison black inner circles were 'ablated' from consciousness. The observers were amnesic in the waking state for their prior hypnotic instructions and were cued in advance of a block of trials simply by the phrases 'This will be a mixed series' (referring to B, in which the stimuli appeared as they really were, some with outer rings of white circles present and others not), or 'This will be a black only series' (referring to NVH, in which all stimuli appeared to the observer as black circles only, whether the outer rings were physically present or not)" (pp. 254- 255). Sessions were spread out over 8-12 months for each observer, interspersed with a variety of other experiments.**

In one session the Experimenters used a selective attention instruction, with Ss given posthypnotic suggestions to regulate their cognitive arousal to a peak of mental alertness and concentration (+AA) and focus on the inner black circles but not to negatively hallucinate the outer white circles.

Although all three Ss showed the illusion effect, they varied in ability to attenuate the illusion when negative visual hallucination suggestions were given. "S1 showed a very greatly reduced frequency of reports in the illusory direction under the NVH condition, a less marked reduction under +AA concentration, and no reduction at all under a waking instruction to ignore the outer circles; S2 revealed a moderate but significant reduction under NVH but not under +AA; S3 gave no evidence of attenuation in either condition" (p. 258). The response times for the two more successful Ss (1 and 2) with the 17 mm stimuli under NVH conditions were not different when the outer circles were either present or absent.

Experiment 2. The next year S1 and S2 returned but S3 was no longer available as a Subject; S4 and S5 were added and trained in hypnosis skills. EEG evoked response potentials (ERPs) were recorded while Ss made size judgments as in Experiment 1. Averaged ERPs for each block of 100 stimulus presentations were obtained for the first 500 milliseconds following stimulus onset. Judges blind to the experimental conditions evaluated the ERP records.

All Subjects experienced the Titchener-Ebbinghaus illusion, but again there were individual differences in ability to attenuate the illusion: S1 was the most successful; S2 gave significantly fewer responses in the larger category under NVH than B conditions; and both S1 and S2 improved attenuation performance over the previous year. S4 fell between S1 and S2 in ability; S5 was unable to attenuate the illusion in the NVH condition.

Results. "All three observers whose perceptual reports indicated some attenuation of the visual illusion during the NVH condition also showed a consistent reduction of the P2-N2 amplitude during NVH" (p. 262) at the Occipital sites. Median amplitude reduction was 36%, 40%, and 36% for S1, S2, and S4; only 7% for S5. There were no similar reductions for the other electrode sites, though "enhancement of P2-N2 amplitudes occurred in the lateral prefrontal and frontal areas in the two most successful individuals, S1 and S4" (p. 263). There was also a lag in N2 peak latencies for the three best subjects. The Experimenters noted that the N2 peak occurred 50 msec later in the frontal and prefrontal areas than in the occipital area.

In their Discussion, the authors express the view that it is not likely that faking could have occurred, for several reasons: 1. The Subjects were trained to report honestly, and they often had reported failures to experience hypnotic phenomena suggested during training sessions. 2. The task elicited rapid responses, usually in less than 2 seconds, to 10 different slides in randomized blocks of 100 trials, which would make self monitoring of responses extremely difficult. 3. Subjects exhibited a consistency of responses over experimental sessions that were widely separated in time, making conscious or unconscious deception unlikely. 4. The finding of no difference in latency between 17 mm stimuli with and without outer rings of white circles supports an interpretation of reliable reporting. 5. Differences in ERP data between the B and NVH conditions were obtained only for those Ss who successfully attenuated the illusion.

The authors also state, "In terms of our conceptual model of the mind, inhibitory skill is attributable to the capacity for invoking inhibitory action earlier in the sequence as signals are processed through stages of amplification and attenuation en route to consciousness (Blum & Barbour, 1979). In the NVH condition of the present task, first- stage attenuation ... [Subject 1] ... occurs in time to negate the illusion as well as preventing conscious awareness of the outer white circles, second-stage attenuation takes place too late to disrupt the illusion but still in time to keep the outer circles from consciousness" (p. 265). Note that the unsuccessful Subject 5 had the highest score on the screening hypnotizability tests. The variation among very high hypnotizables casts doubt on the practice of grouping Ss who score between 9 and 12 on the SHSS. "It is perhaps not surprising that many previous hypnotic studies involving alterations in such subtle phenomena as visual illusions have yielded negative results." p. 266.

N.B. None of the Ss was able to eliminate the illusion under a strong waking instruction to ignore the outer circles while judging the inner black ones. "These different results for AA and NVH instructions pinpoint the contrast between selective attention (+AA) and selective inattention (NVH)" (p. 266).

The ERP changes seen in occipital and frontal areas were in opposite directions. Thus "the data suggest an effect which seems to parallel both investment of attention (increases in late components over frontal cortex) and withdrawal of attention (relative decreases in late components over occipital cortex). This parallel leads us to speculate that our occipital decreases may have been due to active inhibition of information-processing in the occipital regions, and that the late component enhancement over frontal areas may have been due to the mobilization of resources in these areas necessary to accomplish the tonic inhibition of visual input. ... Activity in the frontal cortex apparently 'programs' inhibition on the specific sensory nuclei of the thalamus, in a modality specific and topographical way, accomplishing gating of sensory information to primary sensory cortex" (p. 268).

Zakrzewski, Kajetan; Szelenberger, Waldemar (1981). Visual evoked potentials in hypnosis: A longitudinal approach. International Journal of Clinical and Experimental Hypnosis, 29 (1), 77-86.

Visual Evoked Potentials (VEP's) were recorded in 5 healthy 20-24 year-old-females during hypnosis, hypnosis after the suggestion of blindness, and in 3 waking conditions. VEP's were recorded in these conditions 10 times within each S on different days. Both within-Ss and between-Ss analyses showed a tendency of VEP N-250 latencies (and possibly also amplitudes) to increase in hypnosis when compared to the waking state. Overall, these changes tended to be rather small. No changes were found in the earlier VEP waveform components, and some tendencies noted in the later P-300 component were largely nonsignificant. Decrease in N-250 amplitudes after the hypnotic suggestion of blindness was significant for the whole group, but was difficult to interpret, since amplitude in this condition was not significantly different from the wake control condition N-250 amplitude.

The results are considered preliminary, and a few possibilities of confirming and/or explaining them using somewhat more stringent methodology are discussed. The within-Ss approach is recommended for future studies of evoked potentials in hypnosis.

1980

Bauer, Herbert; Berner, Peter; Steinringer, Hermann; Stacher, Georg (1980). Effects of hypnotic suggestions of sensory change on event-related cortical slow potential shifts. Archiv fur Psychologie, 133 (3), 161-169.

The purpose of this study was to evaluate whether cortical slow potentials related to a S1-S2 paradigm are influenced by hypnotic suggestions of sensory change. Five healthy subjects susceptible to hypnosis participated each in two identical experiments with three conditions. In condition (1) and (2) each three intensities of 800 and 4000 Hz tones were presented. Preceding condition (2) hypnosis was induced and the subjects received the suggestion to hear the 800 but not the 4000 Hz tones. In condition (3), the tones were presented as S1 and a flash as S2. The subjects received the same suggestions as in (2) and a motor response to S2 was required. EEG was recorded from Cz. In (1) 800 and 4000 Hz tones caused negativities of equal amplitude, in (2) only minute negativities developed, possibly due to hypnosis induced deactivation. In (3) the S1-S2 related negativities were significantly smaller in amplitude during 4000 Hz tones than during 800 Hz tones, while the negativities preceding S2 differed only after the most intense S1. Hypnotic suggestions attenuate S1-S2 related negative potentials, possibly by affecting cognitive functions.

NOTES

1:

SUMMARY. Contingent negative variation behavior was studied in 12 voluntary normal subjects in basal conditions and in the hypnotic trance state under different emotional suggestions. A CNV voltage decrease and the appearance of a PINV were observed in the hypnotic state. Furthermore 12 nonhypnotizable control subjects were tested under the same experimental conditions and no CNV modification was found" (p. 505).

Parwatarikar, Sadashiv D.; Brown, Marjorie S.; Stern, John A.; Ulett, George A.; Sletten, Ivan S. (1978). Acupuncture, hypnosis and experimental pain - I. Study with volunteers. Acupuncture and Electro-Therapeutic Research: International Journal, 3, 161-190.

An experiment was designed to evaluate the protective effects of different agents - acupuncture, hypnosis, Morphine, aspirin, Diazepam and placebo - upon

experimentally-induced pain in humans. Twenty normal, healthy volunteers were subjected to cold water and tourniquet- induced pain and the protective effects of 35 minutes of hypnotic suggestion, electro- stimulation of both acupuncture points and non-acupuncture points, 10 mg/kg of Morphine, 5 grains of aspirin, 10 mg of Diazepam and a mild sugar placebo were evaluated. Data was collected on subjective evaluation of pain, EKG, EEG, respiration, skin temperature, peripheral vascular activity and EMG. A special study was also done to evaluate the effects of all the above agents on the somatosensory evoked potentials and EEG. The data were further analyzed on the basis of hypnotic susceptibility of the volunteers. The results indicated: 1) Hypnosis, acupuncture at specific sites with electrical stimulation and Morphine Sulphate had about the same reduction in experimental pain. 2) Hypnosis produced different effects from those resulting from acupuncture stimulation on EEG. 3) Acupuncture stimulation in specific loci resulted in a latency increase in the early secondary response on somatosensory evoked potential. 4) Cold water pain was remarkably reduced after true acupuncture point stimulation. 5) Tourniquet (ischemic) pain was reduced by both hypnosis and true acupuncture site stimulation. 6) Skin temperature was significantly reduced on the side of acupuncture points (true) stimulation.

1975

Saletu, B.; Saletu, M.; Brown, M.; Stern, J.; Sletten, I.; Ulett, G. (1975). Hypno-analgesia and acupuncture analgesia: A neurophysiological reality?. Neuropsychobiology, 1, 218-242.

The effects of hypnosis, acupuncture and analgesic drugs on the subjective experience of pain and on objective neurophysiological parameters were investigated. Pain was produced by brief electric stimuli on the wrist. Pain challengers were: hypnosis (induced by two different video tapes), acupuncture (at specific and unspecific loci, with and without electrical stimulation of the needles), morphine and ketamine. Evaluation of clinical parameters included the subjective experience of pain intensity, blood pressure, pulse, temperature, psychosomatic symptoms and side effects. Neurophysiological parameters consisted of the quantitatively analyzed EEG and somatosensory evoked potential (SEP). Pain was significantly reduced by hypnosis, morphine and ketamine, but not during the control session. Of the four acupuncture techniques, only electro- acupuncture at specific loci significantly decreased pain. The EEG changes during hypnosis were dependent on the wording of the suggestion and were characterized by an increase of slow and a decrease of fast waves. Acupuncture induced just the opposite changes, which were most significant when needles were inserted at traditional specific sites and stimulated electrically. The evoked potential findings suggested that ketamine attenuates pain in the thalamo-cortical pathways, while hypnosis, acupuncture and morphine induce analgesia at the later CNS stage of stimulus processing. Finally some clinical-neurophysiological correlations were explored.

1960

Hernandez-Peon, R.; Dittborn, J.; Borlone, M.; Davidovich, A. (1960). Changes of spinal excitability during hypnotically induced anesthesia and hyperesthesia. American Journal of Clinical Hypnosis, 3, 64. (From 21st International Congress of Physiology, Buenos Aires, 1959, pg. 124, Abstracts)

Although hypnosis is well established, the physiological mechanisms of the hypnotic state and their related sensory phenomena are far from clear. Hernandez-Peon and Donoso have found that the magnitude of photic evoked potentials in the optic radiations of awake human subjects changed in response to previous verbal suggestions concerning the intensity of the expected photic stimulus. This striking observation led the cited authors to propose that certain hypnotic sensory phenomena might be explained, at least partially, by changes occurring as far down as second-order sensory neurons by centrifugal mechanisms controlling the sensory input to the brain. In the intact subject it is impossible to record uncontaminated electrical indexes of afferent impulses from those lower sensory neurons. However, it is possible to gain indirect evidence of tactile sensory inflow to the spinal cord by recording cutaneous reflexes. In young males, a forearm skin reflex evoked by a single square pulse of 0-.1 msec. duration was recorded with cathode-ray oscilloscope. The amplitude of the evoked potentials was often reduced during the hypnotic state, and it was further reduced by verbally suggesting to the hypnotized subject complete anesthesia of the forearm. Reciprocally, during hypnotically suggested hyperesthesia the cutaneous reflex was enhanced. It is concluded that during hypnotic anesthesia and hyperesthesia excitability changes occur at the spinal level, and it is suggested that these changes probably involve the spinal internuncial system interposed between the dorsal root ganglion cells and the motoneurons. (From Abstracts, 21st Internat. Cong. Physiol., Buenos Aires, 1959, p. 124.)

## EXPECTANCY/ATTRIBUTION

1995

Kirsch, Irving; Lynn, Steven Jay (1995). The altered state of hypnosis: Changes in the theoretical landscape. American Psychologist, 50 (10), 846-858.

Presentations of theories of hypnosis in scholarly and introductory texts portray the field as dominated by two warring camps, variously referred to as state and nonstate or as special process and social psychological. Current issues and theories in the hypnosis literature are examined. In the process, we seek to dispel the myth that hypnosis theorists can be grouped into two camps. Although there is considerable controversy about the nature of hypnosis, no issues separate all so-called special process theorists from all social psychological theorists. Instead, virtually all substantive differences between theorists cut across this apparent distinction. Furthermore, the positions taken on many of the important issues dividing the field can no longer be portrayed as simple dichotomies, such as state versus nonstate or trait versus situation. Positions on these issues can more

accurately be described as points on a continuum. We conclude by drawing attention to specific questions and issues that remain unresolved.

1994

Atkinson, Richard P. (1994). Relationships of hypnotic susceptibility to paranormal beliefs and claimed experiences: Implications for hypnotic absorption. American Journal of Clinical Hypnosis, 37, 34-40.

This study examined the relationship of hypnotic susceptibility level to belief in and claimed experience with paranormal phenomena. The Harvard ... and the Inventory of Paranormal Beliefs and Experiences [developed for this study] were administered on consecutive days to 43 undergraduate students (14 men, 29 women) ... . a significant multiple correlation was obtained ( $r = .55, p < .001$ ). A partial correlation between hypnotic susceptibility and belief in paranormal phenomena was also significant ( $r = .53, p < .001$ ), while hypnotic susceptibility was not found to be significantly related to claimed paranormal experiences. Implications of these relationships for the role of absorption in hypnosis are discussed.

#### NOTES

Discusses relationship to Absorption, and the fact that Labelle, Dixon, Laurence, & Nadon (1990) got correlation of hypnotizability with paranormal experience

Martin, D.; Tomak, J.; Lynn, S. J. (1994, October). Detecting simulation with the hypnosis simulation index. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

Orne described demand characteristics of the hypnotic situation, such that some Ss want to either deceive the hypnotist or to please the hypnotist or to help the experiment work. To separate essence of hypnosis he devised an experimental technique, which informs S to role-play, and tells them intelligent Ss will be able to do this. Sheehan & McConkey note that though the model specifies subjective experience, it lacks a way of determining if people are truthful.

We developed a scale assuming hypnotized Ss would be truthful and wouldn't say they had experiences they didn't, but that simulators would exaggerate. The scale included events plausibly reported by highs but not widely reported.

The scale has 31 items, and is titled the Hypnotic Experience Scale. It has 24 items for experiences during hypnosis, 5 for experiences after hypnosis, and 2 for how deeply hypnotized they felt and what kind of hypnotic subject they thought they were.

Ss participated in 2 sessions. They had the Harvard group scale in the first, and simulation instructions in second session. Simulation instructions were read to Low and Medium subjects. To encourage Ss to keep eyes closed, they were told it was essential to keep their eyes closed. We had scores on:

Hypnosis Simulation Index

SCL 90

## **DES**

### **Tellegen Absorption Scale**

**Highs did not receive any simulation suggestions. Then the Stanford Scale was administered. Highs and Simulators had to pass at least 9 Harvard items.**

**Of the predictors, only the Hypnosis Simulation Index discriminated. It correctly classified 94% of the Ss. To eliminate non-useful items, a stepwise discriminate analysis was performed. 15 items remained. These 15 items were used in a series of analyses. They discriminated between the 2 groups from 100% to 70% of the time.**

**This study is the first to successfully discriminate hypnotized from dissimulating subjects. Simulators' performance indicate they tend to respond in stereotypic ways that exaggerate how hypnotized Ss respond. Hypnotized Ss who passed more than 10 items only rated themselves as average on hypnotizability.**

**This has potential applications in forensic situations.**

## **1993**

**Bruehl, Stephen; Carlson, Charles R.; McCubbin, James A. (1993). Two brief interventions for acute pain. Pain, 54, 29-36.**

**This study evaluated two brief (3-5 min) interventions for controlling responses to acute pain. Eighty male subjects were randomly assigned to 1 of 2 intervention groups (Positive Emotion Induction (PEI) or Brief Relaxation (BR)) or to 1 of 2 control groups (No-instruction or Social Demand). The PEI focused on re-creating a pleasant memory, while the BR procedure involved decreasing respiration rate and positioning the body in a relaxed posture. All subjects underwent a 60-sec finger pressure pain trial. Analyses indicated that the PEI subjects reported lower ratings of pain, fear, and anxiety, and experienced greater finger temperature recovery than controls. The BR procedure resulted in greater blood pressure recovery, but did not alter ratings of pain or emotion relative to controls. Further research is needed to explore the clinical use of the PEI for acute pain management.**

**Council, James R.; Grant, Debora L. (1993, October). Context effects: They're not just for hypnosis anymore. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL**

## **NOTES**

**Context effects in Absorption research are found in correlations, not in mean differences. Original paper has been replicated and yet results are not always significant. Now we are trying to generalize the effect to other areas: an individually administered measure will influence other measures made in the same session.**

**Other tests that correlate with hypnosis are studied with 2 x 2 design, enabling order effects and same vs separate contexts to be studied. Or two tests are administered at two points in time, with "bridges" between the two sessions (e.g. same experimenter, same consent forms, etc.) As one adds more and more bridging cues, the correlation of Absorption with other Tellegen MPQ subscales increases.**

**Same context assessment increases correlation between hypnotizability and 6-8 other scales; with childhood trauma scale when trauma scale is administered first;**

with beliefs in paranormal phenomena when the measure is related to an adjustment scale. The same inflation of correlations was found in Beck Depression scale research.

These results are of concern because we may have to re-do a lot of personality research that suggested correlation between personality test variables, as the correlations may be inflated by the effects of testing in the same context.

Gearan, Paul; Kirsch, Irving (1993). Response expectancy as a mediator of hypnotizability modification: A brief communication. International Journal of Clinical and Experimental Hypnosis, 41 (2), 84-91.

The role of response expectancy in bringing about increases in hypnotic susceptibility by use of the Carleton Skill Training Program (CSTP) was assessed with 27 subjects selected for their low hypnotizability scores. Subjects were randomly assigned to one of two conditions: 13 received the CSTP to increase their hypnotic susceptibility, and 14 received no training. In addition to assessing hypnotizability, hypnotic response expectancies were assessed before and after training. With pretreatment hypnotizability controlled, subjects in the training group scored significantly higher than control subjects on all self-report measures of hypnotizability but not on a measure of observed behavioral response. Changes in response expectancy were found to be highly correlated with changes in hypnotizability. With changes in expectancy controlled, no significant differences between the trained and control groups were found.

Morgan, William P. (1993, October). Use of hypnosis in exercise and sport psychology. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

Performance of exercise is rated as equal effort with hypnosis and waking conditions; but with hypnotic suggestion they will perceive it as more or less effortful (uphill exercise vs going down the hill). When they think they are going up hill both cardiac and respiratory response increase physiologically, with catecholamine differences.

Mitchell (1981) suggests that respiration changes with exercise do not result from muscle feedback, but that central motor brain signals go to both the cardiovascular centers and to exercising muscle. Actually, it appears that both muscle and cortex give signals, and their synergy governs whether ventilation or heart rate increase.

Wang & Morgan, Psychophysiological responses to imagined exercise, Sport Psychology Lab, University of Wisconsin-Madison. Reported that both external (watching someone else) and internal (imagining oneself) visualizing give responses similar to actual exercise.

We have done research on the prediction of respiratory distress (dyspnea) - work we have done with fire fighters. The best predictor of this on treadmill with air supply is trait anxiety. Sometimes the firefighters who took off face mask even though they had air did not know why they did. It is an opportunity to use hypnotic age

regression. SCUBA divers described in Lynn & Rhue also were age regressed to obtain information that was repressed. They have demonstrated stress responses like panic in a 12 foot tank also.

For active people and athletes there is an "iceberg" profile on the POMS, below average on tension, depression, anger, fatigue, and confusion, but higher on vigor. But the divers who panic have a flat profile, around the 50th percentile on all POMS scales.

Middleman et al used Navy divers in 25 degree C. water and used hypnosis to increase and decrease their body temperature--one of the best papers on the topic. Ss who were best able to use imagery, to think of a beach, had the poorest responses; the ones who could relax did poorest, because shivering produces heat and keeps you warm. It is opposite of what is needed.

In our work, we took 5 highest and 5 lowest anxiety Ss; the latter had higher rates of respiration than the former.

All Ss are similar in oxygen use whether volunteers or not. When people volunteer for research before they know hypnosis will be used, the males are lower than females [on hypnotizability?] when they finally volunteer. [He presents a lot of different tests on which volunteers do not differ from nonvolunteers personality wise.]

Ikai & Steinhaus is a classic study of Disinhibition of Inhibitory Mechanisms. Taking Ss up to their maximum (in weight training) to a plateau, Ikai & Steinhaus said this is a pseudomaximum. They showed that strength increases if - you fire a starter pistol behind them - you ask them to shout just as they do it - they have alcohol - they have amphetamine sulfate - they have hypnosis It is disinhibition of the inhibitory mechanisms.

[He referred to the book Mind of the Marathoner.]

In Tibet an anthropologist was amazed to see a man running into their camp, and he ran straight through--a monk carrying messages. He created a non-cultic form of meditation in the laboratory (trained to visually "fix" on mountaintop, to have respiration in synchrony with locomotion, and to use a pseudo mantra "down" each time they put their foot down). Placebo condition was used also. Ss were tested by blinded lab assistants. Endurance time increased from 16 minutes to 20, while controls decreased a minute.

Now we can predict who will win a race. Elite runners do not dissociate; they use association strategy. They pay close attention to race strategy, they monitor themselves constantly (they slow down when they feel bad), and attempt informally to stay loose, not get tight, and relax. Dissociation has, however, been used for the last 300 meters of a marathon (New Zealander Dixon).

NOTES

These notes summarize only that part of the chapter concerning nonvoluntary behavior (pp 38-39; 58-61).

The concept of 'nonvolition' has been and continues to be an important issue in hypnosis research. The concept pertains to the "subjective report that the hypnotic suggestion is enacted without the subject's conscious and willful participation" (p. 38). When hypnosis was attributed to a magnetic fluid, in the days of Mesmer, the issue did not arise (because of course a person would not have control over something that happened to them physically). However, when hypnosis came to be considered a psychological phenomenon, the issue of how a behavior could be the result of motivated action and yet not perceived as being under conscious influence became important. In 1819 Faria wrote that the nonvolition paradox is due to the hypnotized subject's tendency to misattribute the source or reason for one's behaviors; he noted that successful suggestions depended upon the subject falsely attributing to the hypnotist the power to influence them. From that point forward, circular reasoning was used to state that one is hypnotized if one experiences their behavior as nonvolitional, and nonvolitional behavior signifies that a person is hypnotized.

"The observation of the seemingly complete automaticity of response in the highly hypnotizable subject led Liebeault in his 1866 book (followed later on by Bernheim and Liegeois) to describe these subjects as 'puppets' in the hands of the hypnotist. This was a quite unfortunate statement, since it would lead to one of the fiercest legal debates surrounding the use of hypnosis in the last 20 years of the 19th century (Laurence & Perry, 1988). ...

"The most prominent author (if not the only one) who attempted to tackle this difficult question was Pierre Janet, who would make the investigation of automatisms the basis of his theory of hypnosis, rather than suggestion or suggestibility. This theoretical orientation is best exemplified by his concept of desagregation psychologique seen in some psychopathologies, or the carrying out of a posthypnotic suggestion in the normal individual (Janet, 1889; see also Ellenberger, 1970; Perry & Laurence, 1984; Prevost, 1973). Nonetheless, until the end of the 19th century, and for a good part of the 20th century, these reports of nonvolition were thought to be the end result of some neurological changes happening during hypnosis--an idea that has not been substantiated by contemporary research." (pp 38-39)

Reports of nonvolition are explained as due to dissociation by Hilgard, or as the results of misattributing the origins of behaviors and experiences by Spanos and by Lynn. Neodissociationists like Hilgard regard misattribution to be a cognitive alteration, mainly an internal triggering mechanism, while social psychologists like Spanos and Lynn regard the misattribution to be the results of situational demands and therefore an external triggering mechanism.

"Regardless of one's preferred metaphor, the issue of nonvolitional reports remains at the core of an integrated view of hypnosis and hypnotizability. The question remains as follows: By which mechanisms does this occur, and how can we predict a priori who will report involuntariness and under what circumstances? Whereas dissociationists have emphasized general cognitive mechanisms and de-emphasized situational factors, social- psychological theorists have emphasized situational

variables and de-emphasized individual differences. Given the limitations of both approaches, emphasis will have to be placed not on their continued separation but on their integration, as more and more investigations demonstrate that they clearly interact with each other (see, e.g., Nadon, Laurence, & Perry, 1991)." (p. 60)

"At the height of the confrontation between the two French schools, hypnosis found its way into the legal arena. Following a series of criminal cases in which hypnosis had been allegedly involved, the two schools once again found themselves on opposite sides of the fence. For La Salpetriere, only those who had a propensity toward criminality (and hystericals were prime candidates) could be the victims of hypnosis. For the Nancy school, in highly responsive individuals suggestions could lead to criminal behavior. Unfortunately for the Nancy school, it soon became evident that the concept of suggestion was not sufficient in explaining the questions raised by the courts, and Bernheim was forced to recognize that in cases where suggestions had played a role, other dispositional and situational factors were probably more important in the genesis of the reprehensible behaviors. His espousing a too extreme position meant that the baby was thrown out with the bathwater. History may indicate that the same fate is now awaiting contemporary theoretical positions that adopt an extreme stance vis-a-vis the phenomenon of hypnosis" (p. 61).

1992

Giolas, M. H.; Saners, B. (1992). Pain and suffering as a function of dissociation level and instructional set. Dissociation, 5, 205-209.

48 female student Ss who scored above 20 on the Dissociative Experiences Scale and 48 subjects scoring below 20 on the DES were compared for response to ischemic pain. Experimental conditions included (1) a group imagining their arm becoming numb and insensitive, (2) a distraction group focusing on their breathing, and (3) a control group with no instructions. Subjects rated pain at one-minute intervals for the sensory experience of pain and for suffering (the emotional experience). The procedure was ended at subject's request or after 20 minutes. Across all conditions, the high dissociative group tolerated pain significantly longer than low dissociatives. Analysis revealed lower suffering ratings for high dissociators in the condition where, like in hypnosis, they imagined their arm numb. This is consistent with beliefs that during abuse in childhood the child learns to use imagination to reduce suffering.

Kvaal, Steven; Lynn, Steven Jay; Myers, Brian (1992, October). The Gulf war: Effects on hypnotizability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

We did a study that follows the line that volunteers may differ from nonvolunteers for hypnosis experiments (Authors cite 3 studies, including one with Hilgard as later author; Brodsky; Zamansky). Also, Ss who volunteer early in the quarter at the

university are motivated for hypnosis; later volunteers want course credit. The former want to experience hypnosis.

Previously we did a study on authoritative vs permissive suggestions with Ss who volunteered early or late in the quarter; Ss were tested twice. For Ss who volunteered in first 2 weeks of the quarter, scores decreased across testing; for Ss volunteering late, scores remained stable across testing. This implies that if an experiment were conducted late in a quarter we would conclude that repeated testing has no effect; if done earlier, we would have concluded repeated testing decreases scores.

This result has been replicated. It is therefore important to run Ss across an entire quarter or year.

The present study differs from the foregoing study. It addresses the question: Do life events affect scores on the Harvard Scale? Do tension, uncertainty, etc. affect scores? Would they depress scores? Are scores reactive to environmental events?

On January 14 the U.S. issued an ultimatum to Iraq; that very day we administered a tape recorded version of the Harvard Scale of Hypnotic Susceptibility, preceded by the Tellegen Absorption Scale. The hypnotizability tests were self-scored for involvement and involuntariness. Tension throughout the day escalated, culminating with bombing 2 hours before the hypnosis screening. The graduate student announced war had started and told Ss they could leave if they wanted. All 52 Ss stayed!

Control group was 58 Ss tested at same time of the quarter, one year before (10 days into the quarter).

Analysis was by a 3 x 2 ANOVA. There was no main effect for time of testing, sex, or interaction for any measures on hypnotizability, or subjective involvement.

The Tellegen Absorption scale showed a significant timing x sex interaction: males on outbreak of war scored lower than all other groups (15 vs 21 or more for all other groups). Tensions had no effect on subjective or objective scores of hypnotizability. Thus the males were affected on the Absorption Scale by outbreak of war.

The fact the Tellegen Scale was more reactive suggests hypnotizability may be more stable than Absorption. Absorption might have been depressed because males were more upset by images of military services.

Little research has been conducted to examine the possible positive effects on hypnotizability of positive events in real life.

Lynn, Steven Jay; Sivec, Harry (1992). The hypnotizable subject as creative problem-solving agent. In Fromm, Erika; Nash, Michael R. (Ed.), Contemporary hypnosis research (pp. 292-333). Guilford Press.

## NOTES

These notes are taken only from the section of this chapter that deals with Hypnotic Responding, Imaginative Activity, and Expectancies, and they treat of the concept of nonvoluntary responding (pp 315-316). Other topics covered in the chapter include: Imagination, Fantasy, and Hypnosis Theories; The Hypnotizable Subject as Creative Problem-Solving Agent; Hypnosis and Subjects' Capability for

**Imaginative Activity; Goal-Directed Fantasy: Patterns of Imaginative Activity during Hypnosis; Hypnosis and Creativity; and a Conclusion.**

Several studies manipulated expectancies re the relationship between imagination and involuntariness. When Ss were told that "good" hypnotic subjects could (or could not) resist suggestions, "this information affected their ability to resist the hypnotist and tended to affect subjects' report of suggestion-related involuntariness ... [Lynn, Nash, Rhue, Frauman, & Sweeney, 1984]. Furthermore, subjects who successfully resisted suggestions and subjects who failed to do so reported comparable levels of hypnotic depth and imaginative involvement in suggestions.

"Spanos, Cobb, and Gorassini (1985) conducted a similar experiment in which they found that hypnotizable subjects who were instructed that they could become deeply involved in suggestions and yet resist them successfully resisted 95% of the suggestions and rated themselves as maintaining voluntary control over their behavior. Thus, subjects are able to resist nearly all of the suggestions when resistance is facilitated by situational demands. It is worth noting that subjects in this research who resisted hypnotic suggestions rated themselves as just as deeply involved in the suggestions as Ss who failed to resist suggestions after being informed that deeply hypnotized subjects were incapable of resisting suggestions" (pp. 315-316).

Lynn, Snodgrass, et al. (1987). showed that hypnotizable Ss who were just "imagining" along with suggestions but instructed to resist responding to motoric suggestions acted the way hypnotized Ss did in their earlier countersuggestion research: imagining subjects tended to move in response to suggestion (that "good" Ss responded in certain ways), despite being instructed to resist. In this study, with instructions designed to increase the use of goal directed fantasies (GDFs), low and high hypnotizable subjects reported equivalent GDF absorption and frequency of GDFs. However, highs responded more and reported greater involuntariness than lows, even when their GDFs were equivalent.

"A number of other studies have examined the effects of expectancies on imaginings and hypnotic behavior. Spanos, Weekes, and de Groh (1984) informed subjects that deeply hypnotized individuals could imagine an arm movement in one direction while their unconscious caused the arm to move in the opposite direction. Even though subjects so informed moved in the opposite direction, they imagined suggested effects and described their countersuggestion behavior as involuntary" (p. 317).

Lyons, Larry C. (1992, October). Absorption and hypnotizability: Meta-analysis of studies to determine if contextual effects are important. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

Correlations between hypnotizability and Absorption range from .20 to .40; Council et al. suggest the correlation between these variables is a context effect (expectancy). In our review there was no statistically significant difference between correlations

that were found in and out of context (.26 and .23, weighted means) in more than 40 studies with more than one correlation per study.

When Absorption was measured before hypnosis experience the  $r = .25$ ; after the hypnosis experience,  $r = .32$  (significantly different), which also was different from what context hypothesis would predict. Any context difference may be a function of length of time between the Absorption and hypnosis sessions.

Data does not support the context hypothesis. Measuring Absorption after hypnosis resulted in higher mean correlations with susceptibility. However, the magnitude of this relationship was small. Variation due to test reliability and small sample size are likely explanations of the differences in the magnitude of the correlations across studies. We also must consider scale reliability and sample error (samples less than 1000 have departures from the population correlation that are fairly large).

## CONCLUSION

We should construct confidence intervals around observed correlations and look at the overlap; don't look only at the significance of the difference between correlations.

Author is in the process of conducting a mail survey to obtain unpublished results on context effect.

Morse, Donald R.; Martin, John; Moshonov, Joshua (1992). Stress induced sudden cardiac death: Can it be prevented?. Stress Medicine, 8, 35-46.

Previously, psychosomatically induced death relative to stress, hypnosis, mind control, and voodoo was discussed. In this article, emphasis is on one aspect of that - stress induced sudden cardiac death (SCD). A brief review is presented of the sympathetic aspects of the acute stress response and stress induced SCD. Findings from previous studies are presented to highlight sympathetic aspects of the acute stress response. This is followed by a presentation of various strategies to prevent or decrease the possibilities for stress induced SCD. These include long-term measures (e.g. diet control, smoking control, hypertension control, stress management strategies) and immediate measures (e.g. calm, controlled approach, elicitation of the relaxation response, selected use of drugs, and heart rate variability monitoring). Relative to prevention strategies, findings are presented both from previous studies and new investigations.

Murrey, Gregory J.; Cross, Herb J.; Whipple, Jim (1992). Hypnotically created pseudomemories: Further investigation into the 'memory distortion or response bias' question. Journal of Abnormal Psychology, 101 (1), 75-77.

In order to study whether pseudomemories represent actual memory distortions or are a result of response bias, 60 highly hypnotizable subjects and subjects from the general population were divided into 4 experimental groups and were tested for pseudomemory manifestation after receiving a false suggestion. Of the 4 groups of subjects, 3 were offered a monetary reward as a motivation to distinguish false suggestion from the actual occurrence. Pseudomemory manifestation was found to

be significantly higher among subjects not offered a reward than among subjects who were offered such a reward. The implications of these findings are discussed.

**NOTES**

The article contains a review of the literature through 1989. The study tested the hypothesis that when it is important to distinguish fantasy from reality in a hypnosis experiment, subjects can do so--a position presented by Spanos and McLean (1986). They used a verifiable event to test for pseudomemory production, as in research published by McCann and Sheehan (1988). Subjects were 30 high hypnotizable and 30 unselected students.

Subjects were shown a videotape of a mock robbery scene. The next week, Groups A, B, and C heard audiotapes "to enhance memory," but in addition to motivating statements about "trying to remember" certain details, the tapes included misleading information (e.g. "Remember the color of the hat the robber was wearing" when in fact there was no hat on the robber). Subjects in these groups were 'influenced.'

"Both highly hypnotizable subject groups (Groups A and B) listened to the audiotape after being administered a 10-min hypnotic induction procedure (modified from that of Barber, 1969). Subject Group C listened to the audiotape without hypnosis. The control group, Group D, did not listen to the audiotape and was, therefore, classified as 'uninfluenced.'"

A week later subjects responded to multiple-choice and yes-no or true-false questions about the robbery scene. The yes-no question about whether the robber was wearing a hat served as the dependent variable, a measure of pseudomemory. "To motivate subjects to report the truth rather than to follow any perceived expectations of the experimental of social context, we offered subjects in Groups B, C, and D a monetary reward if they achieved the most correct answers on the quiz (according to the videotape). The reward was offered just before administration of the quiz to ensure that no collusion between the subjects could occur. Group A was not offered any such reward" (p. 76).

"The number of subjects in Group A (hypnotized, influenced, no reward) who reported the false information at posttest (12) was significantly greater than that of Group B (hypnotized, influenced, offered reward.... However, the difference in incidence of pseudomemory between Group B and the control group, Group D (not hypnotized, uninfluenced, offered reward), was nonsignificant" (p. 76).

Table 1 Incidence of Pseudomemory Per Group -----  
----- False suggestion Group A Group B Group C  
Group D  
result (n=15) (n=15) (n=15) (n=15) -----  
-----

Accepted 12 6 7 3

Rejected 3 9 8 12 -----

----- Note. Group A = hypnotized, influenced, not offered reward.

Group B = hypnotized, influenced, offered reward.

Group C = not hypnotized, influenced, offered reward.

Group D = not hypnotized, not influenced, offered reward.

In the Discussion, the authors wrote, "Because the only variable among these groups was the reward, a reasonable conclusion from the findings is that pseudomemories manifested by the subjects were (for the most part) not actual memory distortions. Presumably, the reward provided the subjects in Group B an incentive to 'report the truth' and a disincentive to give biased reports on the basis of the perceived expectations of the social or experimental context. Thus these data suggest that pseudomemory effects or the occurrence of the pseudomemory phenomenon among highly hypnotizable subjects can be minimized by providing a motivation to subjects to give unbiased reports.

"A major implication of these findings is that researchers should control for response bias resulting from perceived social demands or from leading test designs when they conduct pseudomemory research. Of further concern is the fact that a number of researchers contend that hypnotic interrogation of eye-witnesses can greatly facilitate the creation of pseudomemories (Levitt, 1990; Loftus, 1979; Orne, 1979; Putnam, 1979), and therefore hypnosis either should not be allowed in the courtroom or should be strictly controlled. Yet in light of our findings, response bias may be a confound in pseudomemory research, and thus researchers need to be cautious when making inferences to specific situations from data obtained in an experimental setting.

"Despite the existence of a confound of (unmeasured) differences in hypnotizability between the two groups, there was no significant difference between Group B and the control group (Group D). This suggests that if response bias is controlled for, there may not be significant differences in manifestation of pseudomemories between highly hypnotizable subjects and subjects representative of the general population. However, further research is needed in order to address this question" (pp. 76-77).

Oakman, Jonathan M.; Woody, Erik Z. (1992, October). Automaticity, the Stroop effect, and hypnotic ability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

## NOTES

Builds on the first Dixon study of Stroop effect and hypnotizability, which presented stimuli too fast and also the probabilities of congruent/noncongruent stimuli were varied. Highs had more interference in all conditions, seeming to process with language more. It cast doubt on the use of strategies by highs. Measurement of hypnotizability outside the situation cast doubt on expectancy (social psychology influence) theories.

Automaticity refers to responses that seem effortless, fast, and require little attention. They propose that this characterizes hypnosis. Highly automatic behavior cannot be suppressed. Reading is automatic; color naming is not. The greater the automaticity factor, the more the Stroop effect. Automaticity relates to automatic movement in hypnosis.

Previous research on Stroop used visual tasks, while hypnosis is largely auditory. So we used identification of volume of a word presented over a speaker, plus the regular (visual) Stroop task.

The words "loud" or "soft" were presented as loud or soft in volume. Lows = 4 or lower; highs = 8 or more on Canadian test of hypnotizability, the Waterloo Group Form C.

[In the Visual Stroop?] Reaction Time was greater for incongruent than congruent stimuli for highs (almost statistically significant) but not lows. It is an 8 ms difference for highs.

The Auditory Stroop is very different for both groups; however highs did not show more difference in reaction time than lows.

Auditory and Visual Stroop tasks did not correlate. Waterloo hypnotizability correlated: .28 with Visual Stroop, .11 with Auditory Stroop.

Logan's theory about automaticity seems appropriate: automatization is a shift from using a strategy to relying on memory; inhibition of the automatic response is based on using a strategy instead of relying on memory. Lows may be very able to inhibit automatic processing when necessary; they are the interesting exceptions to the rule, because the Stroop has been a reliable finding in psychological research for years.

Page, Roger A.; Handley, George W. (1992). Effects of 'deepening' techniques on hypnotic depth and responding. International Journal of Clinical and Experimental Hypnosis, 40, 157-168.

The present study attempted to assess the effectiveness of commonly used deepening techniques and of surreptitiously provided stimulation on hypnotizability scores, in-hypnosis depth reports, retrospective realness ratings, and the Field Inventory of Hypnotic Depth (Field, 1965). High, medium, and low hypnotizables were assigned in equal numbers to 1 of 3 groups, each containing 54 Subjects. Controls were compared to Subjects receiving 2 deepening techniques or 2 suggestions for positive and negative hallucinations that were surreptitiously enhanced. Of the 4 dependent measures employed, the only significant different between groups related to a change in depth reports for the manipulation items themselves, leading to the conclusion that the effect of the techniques was at best minimal and transient. Some methodological and conceptual issues are also discussed.

Perry, Campbell (1992). Theorizing about hypnosis in either/or terms. International Journal of Clinical and Experimental Hypnosis, 40, 238-252.

The present paper addresses 3 issues raised by Coe (1992). First, it maintains that the "altered state" issue of the 1960s remains buried in current dichotomous classifications of hypnosis theories as involving either "special processes" or the social- psychological position. Given the current diversity of the field, it appears imprudent to classify theorizing in either/or terms; additionally, despite a history of using the term "altered state" in a circular way, it is not an inherently circular formulation. It can be used descriptively simply to point to the observation that some individuals in hypnosis report subjective alterations. A second issue broached concerns the metaphorical status of the term "hypnosis"; it is accepted as a

**misleading metaphor inherited from 19th century investigators such as Braid, Faria, Puysegur, and Liebeault. Provided that it is recognized that this metaphor refers to a "domain" (E. G. Hilgard, 1973) of characteristically elicited behaviors, no problem ensues in retaining this metaphor derived from nocturnal sleep. A subsequent discussion of current conceptualizations of hypnosis indicates considerable agreement among investigators; there is much consensus that hypnosis is an individual differences phenomenon, in which imagination may, in some individuals, become so intense and so vivid, as to take on "reality value," to the extent that a hypnotized person may have difficulty in distinguishing fantasy from reality. The S abilities of imagery/imagination, absorption, dissociation, and automaticity (which may be proved to be an index of dissociation) are proposed as being the main ingredients of the hypnotic experience. Finally, a synergistic approach is proposed as a means of progressing beyond the current impasse of either/or theorizing.**

**30 low hypnotizability Ss were administered the Carleton Skills Training (CST) program, while 8 were assigned to a practice group. Prior to treatment, an attempt was made to facilitate training by altering the ecological conditions of the laboratory. All Ss were tested immediately after treatment, and trained Ss were retested after 5-7 months. Immediate training gains were large and were comparable in magnitude to those routinely found at Carleton University. In addition, (a) trained Ss responded comparably whether screened once or twice, (b) practice alone did not enhance hypnotic performance, and (c) natural high hypnotizability Ss obtained significant larger Field Inventory of Hypnotic Depth (Field, 1965) scores than created high hypnotizables. Follow-up scores fell between scores posted at screening and immediately after training. Current findings are interpreted in the context of existing evidence concerning the CST program.**

#### **NOTES**

**(based on the Discussion) "Results from these two investigations (include Bates et al., 1988) challenge the claim that lasting changes have occurred in the ability of most trained Ss to experience hypnosis. With regard to the present findings, it is reasonable to wonder whether scores would have been even lower had follow-up data been gathered a few months later. In the only other published study to address the problem of maintenance, Spanos, W. P. Cross, Menary, and Smith (1988) found that after at least 9 months, trained Ss outscored low hypnotizability Ss who had never received training. Unfortunately, these investigators do not report comparisons between trained Ss' follow-up scores and either original screening or immediate posttest scores. The authors do report, however, that 20% of trained Ss obtained high scores at follow-up. Given that at least 50%, and as high as 80%, of Ss routinely score in the high range immediately after receiving the CST program at Carleton University, a follow-up figure of 20% implies that with time, the hypnotic performance of most trained Ss began to return to baseline levels.**

**"With regard to the subjective experience of trained Ss.... These results confirm previous findings by Bates & Brigham (1990) which indicated that the hypnotic experiences of CST graduates - even those who are the most responsive to the**

modification program - may not be comparable in all respects to those of untrained, high hypnotizable individuals" (pp. 237-238).

"The present study altered the context in which training occurred by increasing the salience of the laboratory; adding, repainting, carpeting, and redecorating experimental rooms; requiring Es to dress professionally; and temporarily attributing the CST program to Washington State University. When demand characteristics were arranged in this manner, training gains were of the same magnitude as those found at Carleton University and were much larger than those found in all prior replication studies. The apparent importance of contextual factors is underscored by findings reported by Bates et al. (1988), who manipulated demand characteristics in a systematic fashion and observed that Ss' responses to the CST program are moderated by the context in which training occurs. Given the important role that ecological variables have generally played in hypnosis research, it should come as no surprise that factors like these would affect attempts to modify hypnotic performance" (p. 238).

1991

Daglish, Mark R. C.; Wright, Peter (1991). Opinions about hypnosis among medical and psychology students. Contemporary Hypnosis, 8, 51-55.

A survey was undertaken of opinions about hypnosis among first year medical and psychology students at the University of Edinburgh. Data are presented on the effects of self-estimated hypnotizability and sex, on opinions about hypnosis. The results are compared with those from similar studies conducted in Australia and the USA. Overall, the surveyed population showed a similar level of knowledge about hypnosis to that found among the general public.

Grabowski, Karen L.; Roese, Neal J.; Thomas, Michael R. (1991). The role of expectancy in hypnotic hypermnesia: A brief communication. International Journal of Clinical and Experimental Hypnosis, 39, 193-197.

Previous research has yielded equivocal evidence of hypnotic memory enhancement. This study assessed effects of expectancy and hypnotizability on recall for videotaped material under waking and hypnotic conditions. Ss (n = 138) were informed of hypnotic induction either before (expectancy condition) or after (no expectancy condition) watching a videotaped enactment of a crime and completing an initial waking recall test (R1). Both groups then underwent hypnotic induction, and completed the test again (R2). Ss' raw recall scores were significantly greater under hypnotic than waking conditions, but this hypermnesia was not evident when scores were corrected for mere increase in rate of responding. Ss expecting later hypnosis scored significantly higher than Ss with no such expectations, but again, this difference was not evident in corrected scores. Hypnotizability of Ss was, however, related to corrected recall, with high hypnotizability Ss displaying the greatest increase in rate of responding from R1 to R2. No evidence for the hypothesized "suppression effect" underlying hypnotic hypermnesia was found.

Thus Ss tended to answer more questions on R2 but most of this increase was error. Moreover, high hypnotizability Ss displayed this pattern to a far greater extent than other Ss, indicating that they were more likely than others to increase the no. of responses made between tests.

The finding of an interaction effect between hypnotizability and corrected recall suggests that hypnosis does play some role in the hypnotic hypermnnesia described in the literature, possibly refuting the findings of several recent studies (e.g., Nogrady, McConkey, & Perry, 1986; Register & Kihlstrom, 1987). High hypnotizability Ss increased the number of responses made from R1 to R2 to a greater extent than other Ss. The lack of an interaction between hypnotizability and expectancy, however, fails to support the suggestion by Salzberg and DePiano (1980) that people of differing hypnotizabilities differ also in their susceptibility to demand biases.

As both Klazky and Erdelyi (1985) and Whitehouse et al. (1988) have noted, however, the use of hypnosis with witnesses of crimes may be useful if it can stimulate individuals to share uncertain recollections, perhaps providing otherwise unconsidered clues. The present data suggest that such guessing may also be increased by mere expectation of hypnosis. The value of forensic hypnosis may, therefore, be in part one similar to placebo: the simple notion of hypnosis placed in witnesses' minds may be sufficient to inspire useful leads.

Lynn, Steven Jay; Weekes, J. R.; Neufeld, U.; Ziuney, O.; Brentar, J.; Weiss, F. (1991). Interpersonal climate and hypnotizability level: Effects of hypnotic performance, rapport, and archaic involvement. Journal of Personality and Social Psychology, 60, 737-743.

Designed to extend research by McConkey and Sheehan, they tested 24 hypnotizable and 21 un hypnotizable Ss in high interpersonal/high rapport (including education about misconceptions about hypnosis, eye contact, and friendly self-disclosure) and low interpersonal/low rapport testing contexts. Overall, hypnotizable Ss were more responsive to hypnosis, rated the hypnotist more positively, and experienced greater involuntariness and archaic involvement than un hypnotizable subjects. However, results provide support for the hypothesis that low hypnotizable Ss are particularly sensitive to variations of the hypnotist's interpersonal behavior. Only low hypnotizable Ss' objective and subjective hypnotic performance on the SHSS, Form C, was enhanced by hypnotist behavior designed to optimize rapport. Hypnotizable Ss' behavior was stable across testing contexts.

Oettingen, Gabriele; Wadden, Thomas A. (1991). Expectation, fantasy, and weight loss: Is the impact of positive thinking always positive?. Cognitive Therapy and Research, 15 (2), 167-175.

Investigated the impact of expectation and fantasy on the weight losses of 25 obese women participating in a behavioral weight reduction program. Both expectations of reaching one's goal weight and spontaneous weight-related fantasies were measured at pretreatment before Ss began 1 year of weekly group treatment. Consistent with the hypothesis that expectation and fantasy are different in quality,

these variables predicted weight change in opposite directions. Optimistic expectations but negative fantasies favored weight loss. Ss who displayed pessimistic expectations combined with positive fantasies had the poorest treatment outcome. Expectation but not fantasy predicted program attendance. The effects of fantasy are discussed with regard to their potential impact on weight reduction therapy.

Persinger, M. A.; Makarec, Katherine (1991-92). Interactions between temporal lobe signs, imaginings, beliefs and gender: Their effect upon logical inference. Imagination, Cognition and Personality, 11, 149-166.

Rotton's Paralogic Test, Wilson-Barber's Inventory of Childhood memories and Imaginings (ICMI) and the PPI (Personal Philosophy Inventory) were administered to 100 male and 100 female university students. Both sexes displayed moderately strong (0.50) correlations between content-selected and factor analyzed clusters of possible temporal lobe signs, exotic beliefs and the numbers of childhood imaginings. Although there were no sex differences between the accuracy of logical statements that contained paranormal or neutral content, males who displayed more temporal lobe signs were more accurate for logical items that contained paranormal content. Females who displayed more imaginings were more accurate for valid than for invalid items. Accuracy for items with paranormal content increased with exotic beliefs but not with conservative religious beliefs for both sexes. The relationship between exotic beliefs and accuracy for items with paranormal content was especially strong for females. These results suggest: 1) gender differences in the neurocognitive processes that contribute to logical problem solving and 2) accuracy may depend upon the degree to which the subject matter is commensurate with the person's history of enhanced temporal lobe signs, capacity for fantasy and imaginings and beliefs in exotic concepts.

#### NOTES

Review of related literature indicates that Personal Philosophy Inventory (PPI) temporal lobe signs are correlated with temporal lobe EEG alpha but not occipital lobe alpha (Makarec & Persinger, 1990), with increased suggestibility (Persinger & DeSano, 1986; Ross & Persinger, 1987), with creativity and proneness towards fantasy (Persinger & DeSano, 1986; Ross & Persinger, 1987; Makarec & Persinger, 1987), and with reports of psi experiences and beliefs in such things as reincarnation and aliens in UFOs ('exotic themes') (Persinger & Makarec, 1987; Persinger & Makarec, 1990).

This experiment was designed to answer four questions: " 1) Do imagery and temporal lobe signs emerge from the same source of variance?; 2) Do males and females differ significantly in their incidence of imaginings and temporal lobe signs?; 3) Do males and females differ in their ability to solve logical problems?; and 4) Is the accuracy of problem solving affected by the subject matter of the problem and the problem solver's temporal lobe signs and capacity for imagery?" (p. 151).

The PPI consists of 140 true-false items that were selected with a goal of discerning temporal lobe signs within a normal population. One 30-item subscale has items that are similar to experiences reported by patients with verified electrical foci in the

temporal lobes, albeit milder (the TLS or temporal lobe sign scale). Of these 30 items, 16 refer to ictal-like experiences (the CPES, or complex partial epileptic signs), and 14 refer to interictal-like behaviors (ILB). CPES items are items like "Sometimes an event will occur that has special significance for me only," and "While sitting quietly, I have had uplifting sensations as if I were driving over a rolling road." ILB items are items like "People tell me I blank out sometimes when people are talking," and "When I lose an argument I spend a lot of time thinking about what I should have said."

Wilson and Barber's Inventory of Childhood Memories and Imaginings (ICMI) has 52 true-false items that include reports of paranormal experiences (5 items), moderate imaginings (18 items) such as 'When I was a child I enjoyed fairytales,' and extreme imaginings (15 items) such as 'When I was a child or teenager, at times I was afraid my imagining would become so real to me that I would be unable to stop it.'

Rotton's Paralogic Test [unpublished, at Florida International University, Miami] has 16 syllogisms, each with major premise, minor premise, and conclusion. "The person must decide if the argument is valid (n = 8) or invalid (n = 8). Half of each of the valid and invalid arguments refer to mundane material while the other half of the arguments refer to paranormal-related material. An example of the former is 'If a president is a crook, he would be impeached; Congress did not impeach Nixon. Therefore Nixon is not a crook' and 'If flying saucers really existed, somebody would have photographed one. Nobody has ever photographed a flying saucer. Therefore, flying saucers do not exist'" (p. 153).

Correlations were computed separately for males and females. Both groups increased in accuracy for paranormal items as their belief in things like reincarnation and UFOs ('exotic concepts') increased. Males with a higher number of temporal lobe signs demonstrated more accuracy for logic test items with paranormal (psi) content than logic test items with mundane content.

"The single most important correlation was between exotic beliefs and the interaction term for the Rotton scale; the coefficient was unusually strong (0.54) and highly statistically significant ( $p < 0.001$ ) for females only. Because of the manner in which the interaction term was calculated, this correlation meant that females who reported more exotic beliefs were also more accurate for valid items that contained paranormal content only" (p. 159).

In their Discussion, the authors write, "The significant positive correlations between exotic beliefs and the clusters of CPES items and extreme Wilson-Barber imagining items are expected associations according to Bear's concept of sensory-limbic hyperconnectionism [Temporal Lobe Epilepsy: A Syndrome of Sensory-Limbic Hyperconnectionism, *Cortex*, 15, pp. 357-384. It would predict that concepts (or word trains) that are unusual, strange or infrequent would be charged with emotional significance and personal value. Ideas that generate substantial imagery, such as time- travel, reincarnation and alien intelligence, would be particularly prone to this affective infusion from limbic sources.

Induction of such unique or intensified affective states, especially during childhood, would facilitate the development of more frequent or more extreme periods of dissociation in the adult. We have collected (unpublished) clinical evidence to

suggest that the emergence of this pattern is found in the propensity for creative thinkers, including writers, poets, musicians, artists and scientists, to have had developmental histories that could have promoted temporal lobe lability without overt seizure activity; clusters of such "promoters" include mild physical abuse, febrile episodes, minor head injuries and likely hypoxic periods during extreme physical exertion (competitive athletics)" (pp. 161-162).

Another conclusion of the study is that males and females do not differ in their accuracy in solving syllogisms, but "the neurocognitive processes, as inferred from inventories of temporal lobe signs or childhood imaginings, by which the two sexes arrive at solutions may be quite different" (p. 162).

Peterson, Patricia; Coe, William C. (1991, April). Negative sequelae to hypnosis: A function of expectations?. [Paper] Presented at the annual meeting of the Western Psychological Association.

#### NOTES

Researchers have theorized that the ways in which hypnotic subjects respond may result from their expectancies of the experience. If so, it seems likely that warning subjects of possible negative aftereffects before they are hypnotized could elicit subsequent reports of such effects.

Three groups of subjects were given varied expectancies prior to a hypnotic induction and scale: (A) a specific warning of a 50% chance of negative aftereffects, (B) a vague warning of negative aftereffects, and (C) no mention of aftereffects. Subjects later reported positive, negative, sleep related, and bodily change sequelae. The findings were in the expected direction in that Group A reported more negative sequelae than Groups B or C. However, Group C (the controls) also reported more negative sequelae and bodily changes than Group B. The inadvertent addition of a positive expectancy administered in the Group B scenario may have acted as a confound and caused that group's lower level of negative sequelae.

Reiss, Steven (1991). Expectancy model of fear, anxiety, and panic. Clinical Psychology Review, 11, 141-153.

The purposes of this article are to summarize the author's expectancy model of fear, review the recent studies evaluating this model, and suggest directions for future research. Reiss' expectancy model holds that there are three fundamental fears (called sensitivities): the fear of injury, the fear of anxiety, and the fear of negative evaluation. Thus far, research on this model has focused on the fear of anxiety (anxiety sensitivity). The major research findings are as follows: simple phobias sometimes are motivated by expectations of panic attacks; the Anxiety Sensitivity Index (ASI) is a valid and unique measure of individual differences in the fear of anxiety sensations; the ASI is superior to measures of trait anxiety in the assessment of panic disorder; anxiety sensitivity is associated with agoraphobia, simple phobia, panic disorder, and substance abuse; and anxiety sensitivity is strongly associated with fearfulness. There is some preliminary support for the hypothesis that anxiety sensitivity is a risk factor for panic disorder. It is suggested that future researchers

evaluate the hypotheses that anxiety and fear are distinct phenomena; that panic attacks are intense states of fear (not intense states of anxiety); and that anxiety sensitivity is a risk factor for both fearfulness and panic disorder.

Kihlstrom, John F.; McConkey, K. M. (1990). William James and hypnosis: A centennial reflection. Psychological Science, *1*, 174-178.

For William James, hypnosis was both an experimental technique for creating divisions of consciousness, and a laboratory model of naturally occurring disorders of awareness. James' treatment of consciousness in hypnosis presages contemporary interests in dissociation and implicit cognition, and underscores the role of the self in conscious mental life. At the same time, James recognized the complexity of hypnosis as an interpersonal process. In the end, James' views suggest how a rapprochement between the cognitive and social approaches to hypnosis might be achieved.

Kirsch, Irving (1990). Changing expectations: A key to effective psychotherapy. Pacific Grove, CA: Brooks/Cole. (Reviewed in American Journal of Clinical Hypnosis, *34*, 138)

#### NOTES

This is a clinical hypnosis textbook written from the perspective of a cognitive therapist, and based on response-expectancy theory. The author discusses how expectancy theory can account for results obtained with hypnosis, cognitive behavioral, and psychodynamic psychotherapy, as well as with psychopharmacology. The book draws heavily upon psychological research in psychotherapy as well as hypnosis, and discusses how therapists can mobilize patient positive expectations for change. Hypnotic responses are viewed as 'genuine' responses that subjectively are not perceived to be under voluntary control (similar to other classes of response behavior).

Lynn, Steven Jay (1990). Is hypnotic influence coercive? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, *32* (4), 239-241.

#### NOTES

Unlike Levitt, Baker, & Fish (1990), Lynn, Rhue, & Weekes (Psychological Review, 1990 in press) concluded that nonvoluntary behaviors in hypnosis are similar to other spontaneous social behaviors (like conversational response to social stimuli). "Hypnotized subjects, like nonhypnotized subjects, act in terms of their aims, according to their point of view, and in relation to their interpretation of appropriate behavior and feelings" (p. 239).

"Research shows that hypnotizable subjects resist and even oppose suggestions as a function of their expectancies and perceptions about appropriate hypnotic behavior (Lynn, Nash, Rhue, Frauman, & Sweeney, 1984; Lynn, Snodgrass, Rhue, & Hardaway, 1987; Lynn, Weekes, Snodgrass, Abrams, Weiss, & Rhue, 1986; Spanos, Cobb, & Gorassini, 1985). In one study (Spanos et al., 1985), when subjects were

informed that deeply hypnotized subjects were capable of becoming involved in suggestions and simultaneously resisting them, subjects resisted 95% of the suggestions. When subjects were told that deeply hypnotized subjects were incapable of resisting suggestions, they passed the majority of suggestions. Thus, knowledge about what constitutes appropriate hypnotic role behavior is a reliable determinant of resistance, apparently more reliable than the monetary lures used by Levitt et al." (P. 240).

These studies by Levitt et al. only used behavioral measures of resistance and hypnotizability, and Ss' perceptions of the resistance instructor and hypnotist. "The ratings of global perceptions are, however, no substitute for measures of subjects' perception of the \_relationship\_. ... The failure to measure important variables relevant to the central dimensions of concern--coercion, compliance, involuntariness, and relational factors--precludes meaningful interpretation of the nonresisters' motivation and behavior" (p. 240).

As Orne (1959) has suggested, we should not attribute behavior in the hypnosis context to something unique to hypnosis (such as coercive influence), because other kinds of social context also constrain behavior, e.g. psychotherapy and psychology experiments, with coercive features. Therefore, it seems important in the future to compare the responses of hypnotized subjects with those of subjects in waking-imagination and hypnosis-simulating conditions. In addition to looking at their behavior, it is important to examine their own perceptions of their actions, given the complexity of the social situation entailed in hypnosis.

"Finally, there are statistical grounds to be wary of the authors' conclusions. They assert that 'relational factors in the hypnotic dyad influence hypnotic responsiveness,' yet in three of the studies (I, II, and IV), subjects' ratings of the hypnotist failed to discriminate whether they resisted or responded to the suggestion" (p. 241). Even where Study III was compared with Study II, the difference in the percentage of Ss who resisted failed to reach statistical significance. "In fact, across all studies, differences in overall resistance rates were not documented by statistical tests--despite procedural variations and differing monetary incentives. So contrary to authors' assertion, relational factors \_in the hypnotic dyad\_ generally had little bearing on resistance behavior. If anything, ratings of the resistance instructor had greater weight" (p. 241).

McCue, Peter A. (1990). Unsuggested effects in the hypnosis setting: Evidence of a special state?. British Journal of Experimental and Clinical Hypnosis, 7, 69-79.

Controversy still surrounds the traditional view that a special state ('hypnotic trance', 'hypnotic state' or simply 'hypnosis') arises in responsive subjects when they are exposed to hypnotic induction procedures. The existence of reliable unsuggested (spontaneous) effects would lend support to a special state interpretation of hypnosis, provided that such effects only tended to occur in hypnosis or self-hypnosis settings and provided that the possibility that they arose from inadvertent suggestion, cues in the situation or from subjects' knowledge of, or expectations about, hypnosis could be excluded. Several supposedly unsuggested effects are considered (e.g. increased 'primary process thinking', 'trance logic', and

literalness), but it is concluded that the evidence bearing on them does not provide strong support for a special state interpretation of hypnosis.

## NOTES

Increased suggestibility following a hypnotic induction procedure could arise from subjects' expectations: if subjects believe that they will respond better to suggestions if they are 'hypnotized', they may be less likely to respond if no induction procedure is administered. Further, hypnotic induction procedures themselves contain suggestions, and successful response to them may facilitate responsiveness to subsequent suggestions - not through the development of a special state of consciousness ('trance'), but through simple changes in subjects' beliefs and expectations. For example, take the case of a subject exposed to a hand levitation induction procedure: the hypnotist asks the subject to focus his or her attention on a spot on the back of one of the subjects hands. The hypnotist then suggests that the hand will feel light and will lift by itself towards the subject's face, whereupon the subject will enter a hypnotic trance. The subject might not realize that hand levitation can be experienced fairly easily by many people, and when his or her hand starts to lift, without any feeling that it is being deliberately lifted, he or she may infer that it is due to entering a trance. Believing that he or she is entering an altered state, the subject may interpret certain sensations, which actually result from sitting still and relaxing, as additional evidence that he or she has been 'hypnotized'. When given further suggestions, the subject may be less inclined to harbour negative, doubting thoughts and may be more likely to respond positively" (pp. 69-70).

"Hypnotic state theorists might argue that some people can readily 'slip into hypnosis' without the necessity of an induction procedure, but such reasoning threatens the 'special' quality of the presumed 'hypnotic state', i.e. if people can drift into and out of a 'state of hypnosis' in the course of everyday life, it has to be asked whether the presumed hypnotic trance state is anything other than an ordinary state of consciousness. If it is not, then the term 'hypnotic trance' or 'hypnotic state' is essentially redundant" (p. 70).

"It is conceivable that simply labeling a condition as 'hypnotic' may, in itself, facilitate 'primary process' material, i.e. if subjects believe that hypnosis entails dream-like experiences, their being exposed to a hypnotic induction procedure may constitute a tacit suggestion for such experiences" (p. 72).

McNally, Richard J. (1990). Psychological approaches to panic disorder: A review. Psychological Bulletin, 108 (3), 403-419.

Panic disorder has been the subject of considerable research and controversy. Though biological conceptualizations have been predominant, psychological theorists have recently advanced conditioning, personality, and cognitive hypotheses to explain the etiology of panic disorder. The purpose of this article is to provide an empirical and conceptual analysis of these psychological hypotheses. This review covers variants of the "fear-of-fear" construal of panic disorder (i.e., Pavlovian interoceptive conditioning, catastrophic misinterpretation of bodily sensations, anxiety sensitivity), research on predictability (i.e., expectancies) and controllability,

and research on information-processing biases believed to underlie the phenomenology of panic. Suggestions for future research are made.

Nilsson, Kayla Mae (1990). The effect of subject expectations of 'hypnosis' upon vividness of visual imagery. International Journal of Clinical and Experimental Hypnosis, 38, 17-24.

This study explored how the expectation of hypnosis and the expectation of relaxation affected the vividness of visual imagery. 63 Ss who volunteered for a visual imagination study were randomly assigned to 4 groups. Ss were administered the vividness subscale (VS) of the Vividness and Control of Imagery Scale twice. In the 3 experimental groups, expectations were varied during the 2 VS administrations. All 3 groups were presented with a relaxation exercise between VS administrations. In 2 groups, it was labeled "hypnosis," and in the third group it was correctly labeled "relaxation." A control group listened to a neutral tape between their VSs. All groups were administered the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. C. Orne, 1962) after the 2 imagery tests. The results indicated that the vividness of visual imagery was significantly enhanced (equally) in the experimental groups but not in the control group.

Perry, Campbell (1990). Coercion by hypnosis? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 242-243.

#### NOTES

1:

NOTES: "A postexperimental inquiry (following Orne, 1959) might have informed the reader of the degree to which operationalization of the coercion in terms of disobedience was successful. Without this additional step, it is difficult to determine whether what was found in the laboratory by these investigators applies to what has been reported in clinical and field settings for almost 200 years" (p. 242).

"In particular, elsewhere, the authors equate coercion with involuntariness and appear to view involition as a euphemism for coercion. While I agree that perceiving involition of one's own behavior may contribute to the commission of unconsenting acts in hypnosis, the two are easily distinguished at the conceptual level. Laboratory subjects ordinarily report much behavior in hypnosis that is experienced involuntarily, without the issue of it being coerced ever being broached" (p. 242).

Author describes cases in which patients claimed they participated in sex with hypnotist against their wills because they were hypnotized. "What may be happening in both of these reports is that the hypnotized subjects found themselves responding involuntarily; from this, they appear to have adduced that they could not resist the hypnotist's suggestion. That is, they were coerced not by hypnosis but by their belief, which was a direct function of the experience of involuntariness, that they could not resist" (p. 243). "In short, if a hypnotized person equates involuntary behavior with powerlessness, "coercion" may occur in this limited sense.

Conceptually, this appears to be a far cry from equating involition with coercion" (p. 243).

1990

Rokke, Paul D.; Carter, Alice S.; Rehm, Lynn P. (1990). Comparative credibility of current treatments for depression. Psychotherapy, 27, 235-242.

Current treatments of depression were evaluated for credibility. Interpersonal, communication, self-control, cognitive, social skills, and relaxation placebo therapies were rated significantly more credible and efficacious than psychodynamic and activity-change therapies, which were rated significantly more credible than biological (drug) therapy. Implications were addressed.

#### NOTES

The authors presented the basic theoretical rationale and procedures associated with the nine therapies. They used the Beck Depression Inventory and the Eysenck Personality Inventory to investigate individual differences.

Subjects were 252 psychology students, 128 male and 124 female; 22% had previously sought counseling and 34% had previously been clinically depressed.

Jupp, J. J.; Collins, J. K.; Walker, W. L. (1989). Relationships between behavioural responsiveness to hypnotic suggestions and estimates of hypnotic depth following 11 sequential instances of hypnosis. Australian Journal of Clinical and Experimental Hypnosis, 17, 93-98.

Behavioral responsiveness to suggestions was assessed in an initial hypnosis session, and hypnotic depth was assessed in this session, followed by 10 weekly standardized hypnotic experiences. Correlations were calculated between behavioral responsiveness, initial and subsequent depth estimates, and between successive trance depth estimates. Levels of trance depth estimates were found to increase through weeks 1 to 11. Significant positive correlations were found between behavioral responsiveness scores and trance depth estimates to the fourth week but not beyond. Significant positive relations were found between successive estimates of trance depth except for the correlation between estimates for the fourth and fifth weeks. These results are discussed in terms of the estimates of trance depth being attributions from self-observations of behavioral responsiveness to hypnotic suggestions.

Ronnestad, Michael Helge (1989). Hypnosis and autonomy: A moderator analysis. International Journal of Clinical and Experimental Hypnosis, 37, 154-168.

The study focused on autonomy as a moderator variable in the prediction of subjectively reported hypnotic depth. Ss in the experimental part of the study were 56 undergraduate psychology and education majors classified as either high or low in autonomy. Ss who were equated on capacity for absorption were individually administered 1 of 3 hypnotic inductions: an authoritarian induction, a permissive hetero- induction, or a self-hypnosis induction. The study had a double-blind design.

The data suggest that situational manipulation has greater impact on low than on high autonomy Ss. Individual-difference variables such as absorption, have greater impact on hypnotic depth for high than for low autonomy Ss. The data indicate that the hypnotic behavior of high autonomy Ss is more likely to be self-congruent and less likely to be demand-congruent. A factor-analytic inquiry of absorption confirmed the importance of affective/regressive capacity for hypnotic functioning for high autonomy Ss. The study supported the alternate-path perspective of hypnosis.

#### NOTES

There is very little research on autonomy and hypnosis. The authors cite studies showing only a modest relationship between hypnotizability and locus of control.

In this study, 176 students were assigned to the high autonomy group if they were in the upper 1/3 of two of 3 autonomy scales (Rotter's Locus of Control Scale, the Inner-Directedness Subscale of the Shostrom Personal Orientation Inventory, and the Autonomy subscale of Jackson's Personality Research Form) and not in the lower 1/3 of the third scale. Ss were designated as low autonomy if the obverse obtained. This procedure yielded 27 high and 29 low autonomy Ss.

Ss were hypnotized with one of three inductions: authoritarian with many motor items (Barber Suggestibility Scale), permissive with mostly imagery (Barber & Wilson's Creative Imagination Scale), or guided self-hypnosis with mostly imagery (taken from Fromm et al, 1981). After hypnosis, Ss rated their own hypnotic depth on a 1-10 scale, and their perception of E or the procedure as authoritarian and directive. Ss' attitude, expectations, motivation, and experienced effortlessness were measured. E rated Ss for pre-hypnosis rapport and post-hypnosis rapport.

The results indicated that there was no difference in hypnotizability level between high and low autonomy Ss. The correlation between effortlessness of experience and hypnotic depth was high for low autonomy Ss (.51) but not significant for high autonomy Ss (.12). In general the two groups were very similar in terms of mean scores on most variables. The differences appeared in the correlations between self-reported hypnotic depth and the other variables. For low autonomy Ss correlations were not significant between depth and pre-hypnotic variables (rapport-pre, absorption, expectation) but for highs the same correlations were significant (rapport-pre .47, absorption .54, expectation .48).

But for post-hypnosis variables, low autonomy Ss had significant correlations between depth and the two variables measured from post-hypnosis interviews (perceived authoritarian/directiveness .40, effortlessness .51) and the highs did not have significant correlations. The multiple correlation between these variables and depth was  $R = .28$  for low autonomy Ss (with no contribution from rapport-pre) and  $R = .72$  for high autonomy Ss, with absorption contributing most. The more they perceived the induction as authoritarian or directive, the greater depth reported by low autonomy Ss. Although low and high absorption Ss did not differ on the Absorption Scale, absorption predicted hypnotic depth better for the highs.

The author divided the Absorption Scale into four rational factors: Affective/Regressive, Perceptual/Cognitive, Dissociative, and Mystical. Low and high autonomy Ss scored at approximately the same level on these categories, but

correlations between these categories and depth for low and high autonomy Ss were somewhat different. (See Table.)

#### **Correlations between Categories of Absorption and Hypnotic Depth for Low and High Autonomy Ss**

**Absorption Low Autonomy High Autonomy All Ss Category r r r**

**Affective/Regressive .14 .56\*\* .33\*\* Perceptual/Cognitive .25 .33\* .29\* Dissociative .32\* .57\*\* .47\*\* "Mystical" .07 .16 .11**

In their discussion, the authors note that one might assume that high autonomy Ss would be less affected by variations in hypnosis procedures than low autonomy Ss. The differences found in depth scores for these two groups were supportive of this expectation. "Fluctuations in subjectively reported depth scores for low autonomy Ss only, clearly suggest autonomy to be a moderator variable" (p. 163).

Moreover, the results indicate "that high autonomy Ss in comparison to low autonomy Ss are more likely to express their inner dispositions, such as absorption and expectation, in the hypnotic setting. High autonomy Ss may be more reflective of and attuned to individual predisposing characteristics and less influenced by situational demands. ... the hypnotic behavior of high autonomy Ss is more likely to be self- congruent and less likely to be demand-congruent. Low autonomy Ss, however, are more likely to be demand congruent and less likely to be self-congruent. The latter finding was suggested both by the significant F ratio for low autonomy Ss across treatments, and also by the stronger relationship found for this group between depth and how authoritarian/directive they perceived the procedure to be" (p. 163).

[Paradoxically, among low autonomy Ss an authoritarian approach yields less depth but greater suggestibility (higher hypnotizability scores).] "The tendency for low autonomy Ss to have a higher behavioral score on the authoritarian procedure is consistent with Tellegen's (1979) assumption that there are two pervasive dimensions in current hypnotizability measures--a compliance dimension and a true hypnotic responsiveness dimension. According to Tellegen, motor items may be more saturated with compliance, while cognitive items may be more saturated with true hypnotic responsiveness. The BSS has a motor emphasis, and the higher behavioral scores for the low autonomy group of Ss may be interpreted as an expression of compliance.

"In addition to the inner-directedness and self-congruence hypothesis of why autonomy may be a moderator variable, another possible explanation is related to accuracy of self-perception. The intercorrelational and multiple regression data showed repeatedly that a stronger relationship existed between prehypnotic variables and hypnotic depth for high autonomy than for low autonomy Ss. The relational capacity, as tapped by the rapport-pre variable, absorption, which may be conceptualized as a personality trait; and expectation, a cognitive variable, were all related to depth for high autonomy Ss. For low autonomy Ss, none of these variables were individually related to depth. Differences in Ss' accuracy of self-reporting may explain this. According to ego-psychology theory, highly individuated Ss, with clear self-other differentiation and congruence in self-perception, are better able to make accurate statements about themselves. The self-assessments of Ss with low differentiation capability may be less accurate and possibly more affected by

demand characteristics and response set. In other words, their self-assessments have more error. The generally lower correlations for the low autonomy Ss may reflect this" (p. 164).

"A report of subjectively reported hypnotic depth following CIS and the self-hypnosis scales may reflect clarity of imagery, while a report of depth following BSS may reflect experiences of kinesthetic/bodily changes" (p. 165).

1989

de Groh, Margaret (1989). Correlates of hypnotic susceptibility. In Spanos, Nicholas P.; Chaves, John F. (Ed.), Hypnosis: The cognitive-behavioral perspective (pp. 32-63). Buffalo, NY: Prometheus Books.

#### NOTES

The author describes a non-linear relationship between imagery and hypnotizability and between absorption and hypnotizability. People good at imagery may be high or low on hypnotizability scales; the same is true for people high on absorption trait. However, people low on those traits generally are low on measured hypnotizability.

1988

Elton, D.; Boggi-Cavallo, P.; Stanley, G. V. (1988). Group hypnosis and instructions of personal control in the reduction of ischaemic pain. Australian Journal of Clinical and Experimental Hypnosis, 16, 31-37.

Three groups of students were tested on ischemic pain threshold and pain tolerance. The control group of 95 subjects received a single pain test. The hypnosis group of 42 subjects received a single session of hypnotic induction prior to the pain test. The hypnosis and personal control group of 32 subjects received hypnotic induction and suggestions of personal control prior to the pain test. The hypnotic procedure included the use of a pendulum, coupled with suggestions of arm elevation and lip analgesia. It was found that hypnotic induction resulted in lower [sic] pain threshold and pain tolerance. Suggestions of personal control and hypnosis further lowered [sic] the pain measures.

#### NOTES

The ABSTRACT appears to have mis-statements, for the word should be "higher" or "raised." In the article the results are stated as, "The hypnosis conditions with suggestion of personal control produced the higher pain threshold (mm/Hg) and longer tolerance (seconds) than the hypnosis only group and both hypnotic inductions produced higher threshold and longer tolerance than the control condition" (p. 35)

"The results suggest that a single brief group session of hypnosis can produce a significant change in response to ischaemic pain. The added instruction of increased personal control produced a greater effect and reinforces the importance of the self concept in the reaction to pain" (p. 36).

Gorassini, Donald R.; Hooper, Cynthia L.; Kitching, Kathleen J. (1988). The active participation of highly susceptible hypnotic subjects in generating their hypnotic experiences. Imagination, Cognition and Personality, 7 (3), 215-226.

Hypnotized individuals have traditionally been considered to be detached from the control of their own suggested behavior. We tested this and the alternative notion that hypnotized subjects attempt to self-generate the experiences (i.e., mainly of involuntariness) as well as produce the behaviors thought to be prototypical of high hypnotic ability. In an experimental investigation, highly susceptible hypnotic subjects were found to engage in the kind of imaginative activity that would be expected of individuals who were attempting deliberately to generate their experiences of involuntariness; they engaged as actively in imagery-generation as did subjects who were specifically instructed to imagine during suggested responding, and they experienced as much involuntariness as subjects in whom suggested movements were produced by an external physical force. The implications of these findings for the neodissociation and social psychological theories of hypnotic responding are discussed.

Katsanis, Joanna; Barnard, Joanna; Spanos, Nicholas P. (1988). Self-predictions, interpretational set and imagery vividness as determinants of hypnotic responding. Imagination, Cognition and Personality, 8 (1), 63-77.

Two studies assessed the effects of self-predictions and interpretations of suggested demands on hypnotizability. Subjects overestimated their responsiveness to suggestions. Those who believed that they would fail all or almost all suggestions invariably attained low hypnotizability scores. However, those who believed that they would be highly responsive exhibited wide variability in their actual hypnotizability. Among subjects who self-predicted high responsiveness, those who adopted a passive "wait and see" interpretation toward suggestions scored significantly lower in hypnotizability than those who believed that they should actively bring about suggested effects. Study 2 also found that the relationship between adopting an active interpretation and hypnotizability was moderated by subjects' level of imagery vividness. Theoretical implications are discussed.

Pavia, M.; Stanley, R. O. (1988). Effect of defining induction as hypnosis or relaxation. Australian Journal of Clinical and Experimental Hypnosis, 16, 11-21.

Previous studies have shown that the perceived definition of an induction may sometimes affect the subject's responses to the induction. These variations in the effect of induction definition may be due to interactions between a subject's motivations and expectations of the induction technique and the way the induction is defined. These authors explored this interaction with groups of clinical and student subjects. Differing definitions of induction as 'hypnosis' or 'relaxation' did not result in significant differences in response among either group, though subjects in neither group were found to have high expectations of motivation (sic).

Perry, Campbell (1988, November). An interactionist position on hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

#### NOTES

Context makes differential contributions across items on scales, e.g. amnesia depends mostly on individual differences. Yet in the 19th Century it occurred almost inevitably, spontaneously, because of expectancy of therapist and patient.

Success in pain reduction is much greater in clinic (Crasilneck; Melzack et al; Cedercrentz - skull injury) than in lab (Hilgard's studies of highs and lows).

Central to the disagreement about special state/socio-behavioral theories is the question, "What are the origins of beliefs about hypnosis?" The beliefs can be modified by experience, which is mediated by individual differences.

Author suggests trying to predict which individual will respond to which hypnosis item. Since there are at least 3 factors in hypnotizability scales, one needs a number of variables to do this type of research. Nadon et al (Journal of Personality and Social Psychology 1987) predicted hypnotizability with PICS (an imagery control test) and Absorption scale plus Evans' Sleep Questionnaire subscale plus Belief in [paranormal events] subscale: predictions were 63% correct. PICS (as compared with other imagery tests) reflects imagery as a preferred mode of thinking. Now, can we predict who will make highly confident errors when asked to remember details of a crime? Who is more vulnerable when told a pseudomemory is veridical? In a test of this question, mimicking a field setting, the authors weren't able to predict the people who would make errors, who functioned at the same level following neutral instructions ("We don't know what we'll find") and Reiser-type instructions ("You can use a zoom lens to see the scene up close") in hypnosis. Also, the effect of an increase in confident errors was greater for highs than for lows. People with high hypnotizability and low PICS made the most errors. N.B. Since lows also increased in errors, one should be cautious in any case.

Creation of pseudomemory research: Using SHSS:C and PICS one can predict 81% of those who accepted and reported the implanted

Bandura, A.; O'Leary, A.; Taylor, C. B.; Gauthier, J.; Gossard, D. (1987). Perceived self-efficacy and pain control: Opioid and non-opioid mechanisms. Journal of Personality and Social Psychology, 53, 563-571.

#### NOTES

Subjects who were trained to use psychological coping strategies (e.g. imagery, distraction, dissociation, sensation transformation) had both better pain tolerance on a cold pressor test and higher self efficacy ratings. Those subjects who were given naloxone (which blocks pain reduction effects of beta endorphins) showed more pain tolerance than subjects not given the cognitive training experiences. They attributed much of the pain tolerance increase associated with cognitive interventions to opiate release, suggesting that cognitive interventions may have physiological mediating effects on pain perception.

Evans, Frederick J.; McGlashan, Thomas H. (1987). Specific and non-specific factors in hypnotic analgesia: A reply to Wagstaff. British Journal of Experimental and Clinical Hypnosis, 4, 141-147. (Comment in response to Wagstaff, G. (1987). Is hypnotherapy a placebo? Hypnosis, 4, 135-140.)

#### NOTES

This article is a reply to Wagstaff's (1984) critique of the McGlashan, Evans & Orne (1969) article which was entitled "The nature of hypnotic analgesia and the placebo response to experimental pain," published in Psychosomatic Medicine, 31, 227-246. The paper to which the authors are replying is Wagstaff, G. F. (1984). Is hypnotherapy a placebo? Paper given at the First Annual Conference of the British Society of Experimental and Clinical Hypnosis, University College, London. An abridged version appeared in the British Journal of Experimental and Clinical Hypnosis, 1987, 4, 135-140.

The closing comments of this Evans & McGlashan 1987 paper read as follows: "The strategy in this study [i.e. McGlashan, Evans & Orne, 1969] was quite different from the usual experimental design. Our goal was to maximize all of those non-specific factors that we could build into the experimental procedure. Only by attempting to maximize non-specific effects is it possible to see whether hypnosis in appropriately responsive subjects can exceed that degree of pain control which occurs due to the maximal operation of these non-specific effects. These non-specific components of the hypnotic situation may account for a great deal of clinical change. ... The critical finding was that hypnosis did add a level of pain control that occurred after maximizing clinically related non-specific factors contributing to change in pain tolerance, and that this increased tolerance occurred only in subjects markedly responsive to hypnosis, in contrast to the significant non-specific effects which were uncorrelated with measured hypnotizability" (pp. 143-144).

The principal findings of the McGlashan, Evans & Orne (1969) study were: "(a) The improved ability to tolerate pain following the ingestion of placebo was roughly the same for high hypnotizable and low hypnotizable subjects. (b) The response to the non-specific aspects of taking a 'drug' among low hypnotizable subjects was identical to, and highly correlated (.76) with, their response to the legitimized expectation that change would occur under hypnosis for low hypnotizable subjects. The placebo component of a believe-in 'drug' ingestion was the same as the placebo component of a believed-in hypnotic experience for these low hypnotizable subjects. (c) The performance of the highly hypnotizable subjects was significantly greater under hypnotic analgesia conditions than it was under placebo conditions.

"This last finding is important conceptually, though of less clinical relevance. It should be noted that not all high hypnotizable subjects showed this result. Even among highly hypnotizable subjects, not all of them had the experience that profound analgesia had occurred! Thus, based on their subjective experience of the relatively small degree of analgesia, 6 of the 12 highly hypnotizable subjects behaved exactly as the low hypnotizable subjects had -- their placebo and hypnotic responses were small, significant, but equal. Only 6 out of 12 carefully screened hypnotizable subjects who subjectively experienced marked analgesia showed dramatic objective changes in pain endurance. Dr. Wagstaff might consider the physiological

implications of the observation that we became somewhat frightened about the possibility of tissue damage with two of these six subjects. We had to stop their performance at a point where physiologists had assured us that tissue damage could be expected. They had also assured us, wrongly for these subjects, that we did not have to worry about such a critical point because nobody could endure such a degree of occlusion with this procedure. In fact, for these two subjects, anoxia and muscle cramping were not even apparent!" ( p. 144).

**Hilgard, Ernest R. (1987). Research advances in hypnosis: Issues and methods. International Journal of Clinical and Experimental Hypnosis, 35, 248-264.**

There are substantial areas of agreement upon the classical phenomena of hypnosis, illustrated by what we now have learned about hypnotic talent, amnesia, hallucinations, analgesia, and dissociative processes. While genuine advances in knowledge about hypnosis have been made in recent decades, differing orienting attitudes have kept some controversy alive, particularly in the interpretation of empirical findings. Differences of interpretation of the phenomenal and behavioral facts are to be expected in the present stage of developmental, cognitive, and social psychology.

#### **NOTES**

The author writes of the "domain of hypnosis" as within the larger domain of social psychology (because it is usually interpersonal); cognitive psychology (because of alterations in perception, imagination, memory, and thought); developmental and personality psychology (because of individual differences); and physiological psychology (because of neurophysiological aspects).

In terms of what we know about hypnotic talent, he notes that high hypnotizability is not generally associated with psychopathology; that it may however be associated with a personality measure called absorption; and that there may be some inherited ability (Morgan, 1973). In the author's view, hypnosis is no longer considered simply a response to suggestion, since imagination and/or fantasy are very important.

In reviewing evidence of posthypnotic amnesia the author writes, "Subtleties in language require making careful distinctions among concepts such as compliance, suggestion, compulsivity, belief, self-deception, automaticity, the voluntary, the involuntary, and a happening. If these distinctions are glossed over, the choice of words (e.g., substituting compliance for response to suggestion) may give the impression that a finding departs more widely from conventional views than it does. We, too, have found that Ss used varied strategies or skills during amnesia, but this need not deny augmentation by suggestion.

"It takes genuinely high Ss to illustrate truly high posthypnotic amnesia... Many of the truly high hypnotizable individuals cannot break amnesia, no matter how hard they try" (p. 253).

Regarding the evidence for hypnotic hallucinations and trance logic, the author suggests that trance logic is not a clear concept because the Subject is capable of good logic while tolerating some inconsistencies. "It is ordinary logic to assume that if your hallucination is your own construction, it is you who can influence it by your

own wishes. In the rare cases of transparent or diaphanous hallucinations there is still an 'out there' quality. People who report that they see wispy ghosts also see them as 'out there,' so that they qualify as hallucinations. The distinction appears to be one of perception and perception-like experiences within hypnosis rather than of logic" (p. 256).

In reviewing the evidence for hypnotic analgesia, the author acknowledges that pain relief is available with other kinds of interventions, or by using other kinds of psychological processes, but that does not diminish the contribution of hypnosis (which has a long and impressive clinical history). Following laboratory studies, it is noted that "the amount of alleviation of pain through hypnosis is positively correlated with the hypnotizability of the candidate for pain reduction. This result is not universally accepted, because some clinicians are convinced that those unsuccessful in hypnotic pain reduction are resisting hypnosis" (p. 256-257). In the present paper he acknowledges but does not review physiological literature on hypnoanalgesia.

Regarding the concept of dissociation, the author indicates that he considers it a more useful concept than the concept of trance or hypnotic state "when a person is only slightly or moderately involved in hypnosis ... . The advantage is that dissociations, as compared with altered states, can be described according to limited or more pervasive changes in the cognitive or motor systems that are being activated or distorted through suggestion in the context of hypnosis. Perhaps when all-inclusive enough, such changes can justify the use of the term trance or altered state, but I believe that these terms should be used, if at all, only for those for whom the immersion in the hypnotic experience is demonstrably pervasive" (pp. 258-259). The author goes on to describe his initial discovery of the 'hidden observer' in an experimental context, and to relate the 'hidden observer' to others' earlier observations of a secondary report of an experience previously concealed from S's consciousness (Binet, 1889-1890/1896; Estabrooks, 1957; James, 1899; Kaplan, 1960). "The issues are still being worked on, but as in the case of trance logic the heart of the problem is not whether to speak of a hidden observer, but to recognize that there may be cognitive distortions in hypnosis even while some more realistic information is being processed in parallel, so that everything is not reportable by S" (p. 260).

1986

Council, James R.; Kirsch, Irving; Hafner, L. P. (1986). Expectancy versus absorption in the prediction of hypnotic responding. Journal of Personality and Social Psychology, 50, 182-189.

The Absorption Scale was administered to subjects in the context of a hypnosis experiment and in a context unrelated to hypnosis. Expectancies of responding to hypnotic suggestions were assessed both before and after trance induction, but before administration of suggestions. Hypnotic depth was assessed by different methods before suggestions were given, and after hypnosis. Absorption was correlated with hypnotic responsivity and expectancy, but only when assessed in a hypnotic context. Completing the Absorption Scale in a hypnotic context appeared

to affect responsiveness by altering expectancies. Only postinduction expectancies were predictive of response to suggestions. Results of path analysis suggest that trance inductions alter expectancies for responding to hypnotic suggestions and that these altered expectancies determine subsequent hypnotic behavior.

Echterling, Lennis G.; Emmerling, David A. (1986, August). Contrasting response expectancies of stage and clinical hypnosis. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, DC.

Although both are labeled hypnosis, the experience, behaviors, and effects of hypnosis in stage and clinical settings differ dramatically. We explore these differences between stage and clinical hypnosis and conceptualize them within the framework of nonvolitional response expectancy. Two methods were used to gather information for this study. First, we observed the contrasting styles, strategies and situations in both stage and clinical hypnosis. Second, we identified and interviewed individuals who had experienced trance in both clinical and stage settings. We found significant differences in hypnotist style, subject attribution of causality, trance depth, trance behavior, and outcome. Our discussion contrasts the differing response expectancies of stage and clinical hypnosis in terms of situation, subject's role, and subject's perception of hypnotizability.

Hendler, Cobie S.; Redd, William H. (1986). Fear of hypnosis: The role of labeling in patients' acceptance of behavioral interventions. Behavior Therapy, 17, 2-13.

One hundred and five outpatient cancer chemotherapy patients were interviewed to assess their attitudes toward hypnosis and relaxation as well as to determine their beliefs in and willingness to try a behavioral procedure. Patients were randomly assigned to groups receiving identical descriptions labeled "hypnosis," "relaxation," or "passive relaxation with guided imagery." The description stressed the behavioral components of hypnosis and relaxation rather than the nonbehavioral techniques often associated with hypnosis such as age regression and posthypnotic suggestion. Patients believed hypnosis to be a powerful process that involved loss of control and altered states of consciousness. When compared with a group of college students, patients held significantly more fearful, conservative views about hypnosis. Patients who received a description of an intervention labeled "hypnosis" were significantly less likely to believe the procedure would effectively control their nausea and vomiting and were significantly less likely to state they would try the procedure than patients in the other two label conditions. This reaction to the label occurred independently of patients' degree of nausea, vomiting, and pain due to their chemotherapy treatments.

Laurence, Jean-Roch; Nadon, Robert (1986). Reports of hypnotic depth: Are they more than mere words?. International Journal of Clinical and Experimental Hypnosis, 34, 215-233.

The empirical work relating hypnotizability, the hypnotic situation, and the reports of hypnotic depth is reviewed and evaluated. Asking Ss to assess their hypnotic depth is a complex task involving the interaction of experiential, cognitive, and contextual variables. Accordingly, future experimental work should take into account this multidimensionality; phenomenological, situational, cognitive, and motivational factors implicated in verbal reports should be explored in terms of their respective relationships with both hypnotizability and self-ratings of hypnotic depth. More sophistication in the experimental inquiries of hypnotic depth is required in order to further our understanding of the cognitive and affective structures underlying the hypnotic experience.

#### NOTES

In past years, hypnotic susceptibility and hypnotic depth were regarded as the same thing, and depth was inferred from responses to test suggestions on hypnotizability scales (e.g. Davis & Husband, 1931; LeCron, 1953).

There has been little investigation of the relationship between Subjects' subjective experiences and reported "depth." Research suggests that "hypnotic depth reports are usually significantly higher for Ss who have undergone a hypnotic treatment than for those who have received task-motivation (Ham & Spanos, 1974; Spanos & Barber, 1968; Spanos, Stam, D'Eon, Pawlak, & Radtke-Bodorik, 1980); imagination-control; or relaxation-control instructions (Connors & Sheehan, 1978; Gilbert & Barber, 1972; Spanos & Barber, 1968; Spanos, Radtke-Bodorik, & Stam, 1980, Experiment 2)" (pp. 217-218). Others have found that changes in inward experiencing (e.g. feelings of unreality, a sense of disappearance of body parts) could not be attributed simply to sitting quietly with the eyes closed (Barber & Calverley, 1979). [A footnote on p. 218 indicates some studies didn't find this difference between a hypnosis group and a task-motivation control group.]

When Ss are asked to estimate subjective depth after having experienced hypnotizability test items, they are likely to infer depth from whether or not they passed the items (and indeed, early scales promoted that assumption). Reports of subjective depth taken before rather than after the test items still correlate with overall hypnotizability score, though not to as high a degree (E. R. Hilgard & Tart, 1966; Tart, 1970). Although usually depth estimates correlate with hypnotizability in the .50 to .75 range (Perry & Laurence, 1980), the correlations were obtained in the hypnotic context, and Ss may use their own behaviors as one determinant of their estimated depth.

From another line of study it is observed that Ss' subjective depth may be at variance with behavioral performance on hypnosis scales (Bowers, 1981). High hypnotizables judge their own depth from their performance on cognitive items (e.g. amnesia, hallucinations) while mediums and lows judge their own performance based on their responses to motor items and challenge items (Kihlstrom, 1981). In one experiment on amnesia, it appeared that Ss did not judge their own depth by how well they did on the amnesia task (Spanos, Stam, D'Eon, Pawlak, and Radtke-Bodorik, 1980). "M. T. Orne (1966, 1980) has emphasized that although it is necessary to operationalize S's responses to hypnotic suggestions, behavioral

concomitants are only valid if they accurately reflect subjective alterations in an individual's experience" (p. 221).

"The social-psychological approach (see Barber, 1969; Radtke & Spanos, 1981, 1982; Spanos, 1982; Wagstaff, 1981) rejects the notion of hypnotic depth as an indicator of a unique state. These authors argue that the reports of having been hypnotized reflect attributions made by Ss when confronted with a hypnotic context. ... Bem (1972) and Kelley (1972) have emphasized the idea that the more ambiguous an experience is, the more a person is likely to base his or her judgment primarily on available external information" (p. 222). In this case, defining the situation as involving "hypnosis" is one of the most potent predictors of Ss' reports of subjective experience (Spanos, Radtke- Bodorik, and Stam, 1980). Other variables that influence subjective depth estimates are the wording of the hypnotizability scale, expectancy, and information provided directly or indirectly. On the other hand, McCord (1961) found that his patients had widely disparate expectations for how they thought they would feel when hypnotized, so expectancy as a predictor would not necessarily determine specific experience.

Direct experimental work on predicting response to hypnosis test items from expectancies (Council, Kirsch, Vickery, & Carlson, 1983; Kirsch, Council, & Vickery, 1984) suggests that expectations may predict test response when people are given a cognitive skill type of induction, but not when given a 'typical trance' type of induction. Also, another study from that laboratory (Council & Kirsch, 1983) established that only when expectancies are assessed after an induction (but before the test items) do they effectively predict hypnotic behaviors. The present authors express the view that these results are difficult to account for on the basis of social psychology theories that weight heavily the role of expectancy in generating hypnotic response.

When Ss are permitted to use several different descriptors for their experience (being hypnotized, experiencing the effects, being absorbed, and responding to the suggestions), most Ss rated their own experiences as nonhypnotic (Radtke & Spanos, 1982). This was particularly true for medium hypnotizable Ss. Thus, unidimensional scales purporting to measure "depth" actually force Ss to interpret their multi-aspect experience in terms of the investigator's frame of reference, in this case "hypnotic depth." Nevertheless, the highly hypnotizable Ss were the least likely to be swayed from their self description of being "deep" when offered alternative ways of describing their experience. This is concordant with results reported earlier by Barber et al. (1968).

"The attribution literature may provide clues as to why most highly hypnotizability Ss retain their high ratings of experienced depth when confronted with situational manipulations. Self-perception theory strictly applies when Ss' experiences are ambiguous, forcing them to fall back on contextual factors to make self-appraisals. The relationship between expectancies, absorption, effect of scale wording, and hypnotizability scores suggest, however, that high hypnotizable Ss do not rely heavily on contextual factors when assessing their levels of hypnotic depth. Most of these Ss maintain their reports of altered experiences, even when situational determinants are changed (Harackiewicz, 1979; Kihlstrom, 1984; Lepper, Greene, & Nisbett, 1973). Thus, the hypnotizability by depth scale interaction found by

Radtke and Spanos (1981) may suggest that experiences reported by high hypnotizable S are not inherently ambiguous. Accordingly, self-perception theory may not apply to them" (pp.226-227).

In their Discussion, the authors state, "Several studies have attempted to relate personal, real-life events to the experience of hypnosis. A number of studies (e.g., As, 1963; Field, 1965; Shor et al., 1962; Wilson & Barber, 1982) have shown that absorption, tolerance of unusual experiences, automaticity, compulsion, and trust are related to the capacity to be hypnotized. Other studies (Bowers & Brenneman, 1981; Tellegen & Atkinson, 1974; Van Nuys, 1973) have shown that certain variants of attention are also related to hypnotizability. Extensive work by J. R. Hilgard (1970, 1979) has shown that patterns of personal development relate to hypnotizability in adult life. It appears then that hypnotizable individuals bring a host of experiences and abilities with them to the hypnotic context. It makes intuitive sense which is supported by the available empirical data, that a complex interaction among these experiences and abilities, the hypnotic context, and hypnotic responsiveness is implicated in Ss' assessments of their hypnotic depth. Studies are needed in which all of these potential determinants of hypnotic depth reports are taken into account. Only then will a clearer picture of their respective importance emerge" (p. 228).

1985

Kirsch, Irving (1985, November). Response expectancy as a determinant of experience and behavior. American Psychologist, 40 (11), 1189-1202.

Response expectancies, defined as expectancies of the occurrence of nonvolitional responses, have generally been ignored in theories of learning. Research on placebos, hypnosis, and fear reduction indicates that response expectancies generate corresponding subjective experiences. In many cases, the genuineness of these self-reported effects has been substantiated by corresponding changes in behavior and physiological function. The means by which response expectancies affect experience, physiology, and behavior are hypothesized to vary as a function of response mode. The generation of changes in subjective experience by corresponding response expectancies is hypothesized to be a basic psychological mechanism. Physiological effects are accounted for by the mindbody identity assumption that is common to all nondualist philosophies of psychology. The effects of response expectancies on volitional behavior are due to the reinforcing properties of many nonvolitional responses. Classical conditioning appears to be one method by which response expectancies are acquired, but response expectancy effects that are inconsistent with a conditioning hypothesis are also documented.

Patterson, C. H. (1985). What is the placebo in psychotherapy?. Psychotherapy, 22 (2), 163-169.

Although there is an extensive literature on the placebo effect in psychotherapy, the distinction between the placebo and other elements of the therapeutic process has not been clear. This paper analyzes the therapeutic relationship in terms of separating the placebo elements and the specific factors. The so-called nonspecific

elements, often equated with the placebo, are proposed as the specific factors. It is contended that those variables focused upon by those studying the social psychological factors are actually part of the placebo.

A class of 145 college students was given Barber's Creative Imagination Scale (CIS) and Spiegel's Eye Roll Sign, and later given several opportunities to volunteer for research projects, some of which specified hypnosis was involved. Those S's who volunteered for the hypnosis experiments took the Harvard Group Scale of Hypnotizability (HGSHS). Hypnosis volunteers differed from the non-hypnosis volunteers by significantly higher grades and more total experimental volunteerism, but were no significantly different on the CIS or Eye Roll Sign. In general, nonwhites scored higher on the CIS. Among hypnosis volunteers, there was a low negative correlation between the Harvard Consciousness scale and volunteering for experiments other than hypnosis.

1984

Critelli, Joseph W.; Neumann, Karl F. (1984). The placebo: Conceptual analysis of a construct in transition. American Psychologist, 39, 32-39.

The placebo in psychotherapy has unfortunately retained the negative connotation of an inert "nuisance variable," a label that it originally incurred in the field of medicine. In addition, the transition toward more cognitive models of psychotherapy, particularly Bandura's theory of self-efficacy, has led to problems in defining the placebo within psychology. This transition has resulted in an awkward interface between certain preferred cognitive metaphors and the negative connotations of a presumably cognitive placebo construct. As a result, suggestions have recently been made to dismiss the placebo construct from psychology and to do away with the use of true placebo controls in outcome research. The present analysis maintains that (a) the placebo can be adequately defined within psychology, (b) the negative connotation of the placebo label is largely undeserved, (c) the placebo retains a continuing conceptual and empirical utility for evaluating psychotherapy, and (d) the therapeutic efficacy of current therapies is well established even though they have not generally been shown to be more effective than nonspecific treatment.

Handelsman, Mitchell M. (1984). Self-hypnosis as a facilitator of self-efficacy: A case example. Psychotherapy, 21 (4), 550-553.

This article presents the four-session treatment of Elaine, using self-hypnosis to facilitate the mourning process. It is argued that self-hypnosis-- rather than enhancing imagery-- increases self-efficacy, a person's feeling that he/she can perform behaviors that lead to desired outcomes. Elaine's sense of self-efficacy was increased by allowing her to choose scenes from her life to be explored in the context of the use of imagery. Elaine imagined events surrounding her father's death, and "rewrote history" in an attempt to permit herself the direct expression of emotions.

Kirsch, Irving; Council, James R.; Vickery, Anne R. (1984). The role of expectancy in eliciting hypnotic responses as a function of type of induction. Journal of Consulting and Clinical Psychology, 52 (4), 708-709.

## NOTES

Combined data from a study by J. R. Council et al (see PA, vol 7:4975) and from a study by the present 3rd author (1983) on cognitive skill hypnotic induction to test the hypothesis that the relationship between expectancy and suggestibility varies as a function of type of induction. Analysis of data on 100 Ss shows significant Expectancy x Type of Induction interactions on the Stanford Hypnotic Susceptibility Scale, the Creative Imagination Scale, and an inventory of hypnotic depth. Within-cells correlations revealed a significant relationship between expectancy and responses to skill induction. Correlations between expectancy and responses to a traditional trance induction were nonsignificant.

Lynn, Steven Jay; Nash, Michael R.; Rhue, Judith W., Frauman, David C.; Sweeney, Carol A. (1984). Nonvolition, expectancies, and hypnotic rapport. Journal of Abnormal Psychology, 93 (3), 295-303.

Prior to hypnosis, subjects were informed either that hypnotizable subjects can resist motoric suggestions or that such control does not characterize good hypnotic subjects. During hypnosis, susceptible and simulating subjects received countering suggestions involving inhibiting suggestion-related movements. Susceptible subjects' responses were found to be sensitive to prehypnotic normative information. There was a corresponding tendency for reports of involuntariness to be sensitive to the expectancy manipulation. Furthermore, subjects were able to feel deeply hypnotized and to rate themselves as good subjects yet concomitantly experience themselves as in control over their actions when normative information supported this attribution. Reports of suggestion-related sensations but not imaginative involvement were associated with movements in response to countersuggestion. Simulators were unable to fake susceptibles' reports of sensations and involuntariness. However, for all subjects, movements paralleled expectancies about appropriate response, supporting the hypothesis that involuntary experiences are sensitive to the broad expectational context and are mediated by active cognitive processes. Also, rapport with the hypnotist was found to be a factor. Susceptible subjects with highly positive rapport resolved hypnotic conflict, in part, by achieving a compromise between meeting normative expectations and complying with the hypnotist's counterdemand.

## 1983

Council, James R.; Kirsch, Irving; Vickery, Anne R.; Carlson, Dawn (1983). 'Trance' versus 'skill' hypnotic inductions: The effects of credibility, expectancy, and experimenter modeling. Journal of Consulting and Clinical Psychology, 31 (3), 432-440.

A hypnotic induction procedure based on social learning principles (skill induction) was compared with a traditional eye-fixation/relaxation trance induction, a highly credible placebo induction, and a no-induction base-rate control. The trance induction surpassed the skill induction only on the Field Inventory, a measure of hypnotic depth that contains items corresponding to suggestions contained in the

trance induction. Experimenter modeling was not found to enhance the effectiveness of the skill induction. Skill and trance inductions elicited slightly higher behavioral scores on the Stanford Hypnotic Susceptibility Scale: Form C than did the placebo induction. However, this difference was not obtained on other measures of hypnotic responsibility and depth. Significant correlations were found between expectancy, absorption, and responsiveness on all dependent measures. Multiple regression analyses indicated that the relationship between absorption and responsivity was mediated by expectancy. The results are interpreted as supporting the hypotheses that hypnotic responses are elicited by the expectancy for their occurrence and that induction procedures are a means of increasing subjects' expectancies for hypnotic responses.

## NOTES

Trance induction resulted in a higher score on subjective experiences (cognitive & perceptual distortions) but not higher suggestibility scores than cognitive-behavioral skill induction. 2) Trance and cognitive-behavioral inductions got slightly higher scores in suggestibility than placebo biofeedback induction. 3) All inductions did better than a "no induction" control group on subjective and behavioral indices of hypnosis.

One of the goals of this research was to examine the contribution of experimenter modeling to the behavioral skill induction that "trains the subject in hypnosis skills and requires the subject's conscious cooperation in learning cognitive strategies that will enhance hypnotic responsivity" (p. 432). Another goal was to assess the contribution of "a subject's expectancies for the occurrence of behaviors perceived as being involuntary" (p. 433). A third goal was to determine whether congruence between a subject's beliefs about hypnosis and the rationale for a particular induction would increase expectancy. Two different skill inductions were employed (one with, one without a model). Subjects were asked to predict their performance, based on a description of the induction that they would receive. The contributions of credibility and expectancy were assessed using a highly credible placebo (pseudo biofeedback of EEG theta rhythm).

The investigation used only subjects who had never experienced hypnosis.

Independent variables included Rotter's (1966) Internal-External Locus of Control Scale, Rotter's (1967) Interpersonal Trust Scale, and Tellegen's Absorption Scale (Tellegen & Atkinson, 1974). Mediating variables included a measure of induction credibility based on Borkovec and Nau (1972), and a 20-item inventory measuring expectancies for hypnotic performance. Dependent variables included 20 standard hypnotic suggestions taken from the Stanford Hypnotic Susceptibility Scale, Form C; the Creative Imagination Scale; ratings of the 'realness' or experienced intensity of each suggestion; and the Field Inventory of Hypnotic Depth (Field, 1965).

The authors conclusion reads as follows: "The results of this study may be summarized as follows: (a) Traditional trance hypnotic inductions and cognitive-behavioral skill inductions were shown to be equally effective in eliciting experiential and behavioral responses to hypnotic suggestions, although trance subjects reported a somewhat greater alteration in conscious experience. (b) Experimenter modeling was not found to be an effective component of the skill

induction package. (c) Subjects' expectancies for hypnotic responses, reported prior to hypnotic induction, bore a very strong relationship to hypnotic responsivity. (d) A highly credible placebo induction resulted in levels of expectancy and hypnotic responsivity generally comparable to those produced by trance and skill hypnotic inductions. (e) Absorption was significantly correlated with expectancy, but was not found to be significantly related to responsiveness once variance due to expectancy was taken into account. Thus the relationship between absorption and hypnotic responsiveness appears to be mediated by expectancies.

"In sum, these results suggest that various hypnotic inductions elicit expectancies for responding to hypnotic suggestions and that these expectancies are sufficient to elicit hypnotic responses. Further studies are needed to determine the nature of the relationship between absorption and hypnotic response expectancies" (p. 439).

McConkey, Kevin M. (1983). Behaviour, experience, and effort in hypnosis. Australian Journal of Clinical and Experimental Hypnosis, 11, 73-81.

Subjects were administered the Harvard Group Scale of Hypnotic Susceptibility, Form A, and were afterwards asked to rate the degree to which they experienced the items; subjects also scored their behavioural performance on the items. Data were analyzed to explore the relationships among behaviour, experience, and effort. Findings indicated a significant positive relationship between behaviour and experience on all of the HGSHS:A items, a significant negative relationship between behaviour and effort on the ideomotor items, and a significant positive relationship between behaviour and effort on the cognitive items. A similar pattern was observed between experience and effort. Also, subjects of varying HGSHS:A responsivity differed in terms of overall experience of the scale but not in terms of the overall amount of effort that they expended. Implications of the data are discussed in terms of the factors influencing subjects' experiential response and behavioural performance as well as the attributions that they make concerning effort during hypnosis.

Myles, (1983, April). Cognition, hypnotic susceptibility, and laboratory induced pain (Dissertation, University of Waterloo). Dissertation Abstracts International, 43 (10), 3360-B.

Individuals' experiences of pain, and responses to pain treatments vary greatly. This study attempted to relate two areas of research concerned with this variation: (a) cognitions and pain (thoughts, images, etc.), in particular, catastrophizing versus coping; and (b) hypnotic susceptibility and analgesia. "Subjects were preselected for high or low hypnotic susceptibility. Susceptibility assessment was divorced from the laboratory study to minimize the potential bias of expectancies concerning hypnosis. High hypnotic susceptibility was expected to potentiate therapeutic effects of hypnotic-like treatment that did not involve a hypnotic induction. "Ten high and ten low-susceptible subjects were assigned to each of three groups: (a) a cognitive treatment, encouraging subjects to reduce spontaneous catastrophizing and increase self-generated coping cognitions; (b) a dissociative imagery treatment, encouraging

subjects to engage in self-generated engrossing images; (c) an attention- placebo manipulation. "Pre and post-treatment assessments involved tolerance and pain-report measures during the cold-pressor task, and interview and questionnaire information concerning cognitions. "No treatment effects were evident on measures of pain. Cognitive data indicated less catastrophizing and more coping during the post-treatment stressor across all groups. Subjects in the dissociative imagery group did report more imagery during the post- treatment assessment than subjects in the other groups, but this increased use of imagery was not associated with a decrease in pain. "Interview and questionnaire data supported prior reports that catastrophizing is related to increased pain. Low catastrophizing was associated with a high sense of control, high use of a variety of coping strategies, and lower pain reports. These relationships were altered following treatment, however, leading to a caution in generalizing about such variables. "High susceptibility did not potentiate therapeutic effects for either experimental treatment. Nor was susceptibility related in any other consistent way to pain, although high susceptibility was associated with more extensive use of post-treatment imagery. "Methodological inconsistencies and problems in laboratory pain research were discussed, and suggestions made for future work in the area" (p. 3360).

Nogrady, Heather; McConkey, Kevin M.; Laurence, Jean-Roch; Perry, Campbell (1983). Dissociation, duality, and demand characteristics in hypnosis. Journal of Abnormal Psychology.

Examined hypnotic dissociation (as indexed by the "hidden-observer" method), duality in age regression, and the potential impact of situational cues on these phenomena. 12 high- and 9 low-susceptible undergraduates (as determined by the Stanford Hypnotic Susceptibility Scale) were tested in an application of the real-simulating paradigm of hypnosis; 10 high- to medium-susceptible Ss were also employed. Inquiry into Ss' experiences was conducted through the experiential analysis technique, which involves Ss viewing and commenting on a videotape playback of their hypnotic session. Results demonstrate that neither the hidden-observer effect nor duality could be explained solely in terms of the demand characteristics of the test situation. The hidden-observer effect was observed in high-susceptible Ss only; all Ss who displayed the hidden-observer effect also displayed duality in age regression. High-susceptible Ss were distinctive in their reports of multiple levels of awareness during hypnosis. Findings are discussed in terms of the cognitive skills that Ss bring to hypnosis and the degree to which the hypnotic setting encourages the use of dissociative cognitive processes. (43 ref).

O'Connell, Sean (1983). The placebo effect and psychotherapy. Psychotherapy: Theory, Research and Practice, 20 (3), 337-345.

The power of psychotherapy to cure can be comprehended through an investigation into the efficacy of placebo in medical history. The evolution of "placebo" leads to a conceptualization of psychotherapy as a form of placebo. Explanations for the presence of the placebo effect, as well as guidelines for its elicitation, are outlined.

"Faith in the gods or in the saints cures one, faith in little pills another, faith in a plain common doctor a third, hypnotic suggestion a fourth. ... Faith in us, faith in our drugs and methods, is the great stock in trade of the profession (paracelsus, 1570)" (p. 337).

Ross, Sherman; Buckalew, L. W. (1983). The placebo as an agent in behavioral manipulation: A review of problems, issues, and affected measures. Clinical Psychology Review, 3, 457-471.

Need for greater recognition and appreciation of placebo effects was stated, and problems hindering their clear conceptualization are noted. Previous reviews of the history and use of placebos are acknowledged. This review provides a summary of research primarily within the last 20 years, and in particular considers studies reflecting on placebos as agents of psychomotor, physiological, cognitive, affective, and clinical manipulations. General conclusions of manipulative efficacy are provided, and issues and problems related to clarification of placebo phenomena are identified. Psychological and medical evidence reflects increasing attention to the placebo and of effects on a wide range of behavioral functions. While important ethical and methodological questions remain, recent evidence of a physiologic basis for placebo action suggests exciting new insights into placebo phenomena.

Farthing, G. William; Brown, Scott W.; Venturino, Michael (1982). Effects of hypnotizability and mental imagery on signal detection sensitivity and response bias. International Journal of Clinical and Experimental Hypnosis, 30, 289-305.

It was hypothesized that the ability to selectively concentrate attention on mental images would be greater among high hypnotizable Ss than among low hypnotizable Ss, as indicated by a greater interference with visual signal detection by concurrent visual mental imagery in response to specified nouns. This hypothesis was not supported in the overall results, though the finding of a significant interference effect among the high hypnotizable female Ss, but not among other subgroups, indicates that further research with a more refined procedure might be worthwhile. On the control trials without images, the high hypnotizable Ss made more false alarms than lows, and had a significantly different bias index indicating that high hypnotizable Ss were more likely than lows to respond "yes" when uncertain about whether the signal was present; false alarms can be interpreted as a nonhypnotic measure of suggestibility. The high and low hypnotizable Ss did not differ in their times to generate images in response to the specified nouns.

1981

Fling, Sheila; Thomas, Anne; Gallaher, Michael (1981). Participant characteristics and the effects of two types of meditation vs. quiet sitting. Journal of Clinical Psychology, 37 (4), 784-790.

Randomly assigned 61 undergraduate volunteers to Clinically Standardized Meditation (CSM), quiet sitting (SIT), or wait list1 and 19 others to Open Focus

(OF) or wait list2. Ss were tested before training and again 8 weeks later. All groups but wait list2 decreased significantly on Spielberger's trait anxiety. All groups became nonsignificantly more internal on Rotter's locus of control. On the Myers-Briggs Type Indicator, meditation volunteers were more introverted than extraverted, intuitive than sensing, feeling than thinking, and perceiving than judging. All groups became more intuitive, approaching significance for CSM only. OF became significantly more extraverted than both CSM and SIT, and CSM significantly more so than wait list1. Practice time correlated with anxiety reduction for the combined treatment groups. More evidence was found for correlations of practice time and outcome with growth motivation than with either new experience motivation or expectancy of benefit.

Franck, Jerome (1981, August). Therapeutic components shared by all psychotherapies. [Paper] Presented at the annual meeting of the American Psychological Association.

#### NOTES

The author summarizes as follows. 1. Patients who receive any form of psychotherapy do better than controls. 2. Followup studies show most patients who show improvement maintain it; the closing of gap between patients who improve and those who don't is due to those who do less well catching up. Perhaps the main effect is to accelerate improvement which would eventually happen anyway. 3. Determinants of successful treatment are personal qualities of Patient and Therapist. 4. There are a few conditions which have more specific treatment indications. --Behavior therapy - for phobias, obsessive compulsive disorders, sexuality problems --Cognitive therapy - for depression Further advantages of specific treatments for specific conditions may be found.

All patients seek treatment not just for symptoms but because of demoralization. The common elements are: Subjective incompetence, loss of self esteem, alienation, hopelessness, helplessness, a feeling others could help but won't, feeling of loss of control. Demoralization plus distress leads to seeking treatment.

A small percentage without demoralization seek treatment for specific symptoms (e.g., patients with a simple phobia of height). Anxiety and depression (or loss of self esteem) are most frequent symptoms in Outpatient Departments.

Success in treatment often is due to restoration of morale (which removing symptoms can do very well). 1. Citing Doehrenwald research. 2. People seek treatment only 1-2 years after symptoms appear, after trying other ways of dealing with them. 3. Many patients improve rapidly in treatment (Garfield found the Mean = 5 or 6 sessions.) Mean symptom relief is same after 4 sessions and drop-out than after 6 months; also those on waiting list in phone contact improve as much.

Shared components in the various therapies combat demoralization: 1. Emotionally charged and vital relationship with the helping person (or group). 2. Healing setting (which increases Therapist's prestige and promotes healing). (a) Therapeutic rituals (which lead to an external reason for abandoning the symptom; the more spectacular the reason, the greater the motivation). (b) Therapeutic bond.

Expectation of help is the best predictor of outcome. (Cites his own placebo study.) One problem found was that responsiveness to placebo didn't correlate with response to psychotherapy. (Cites Lieberman's study). Patients receiving psychotherapy role-induction interview improved more. 3. Provision of learning experiences - movement of values toward those of the therapist 4. Emotional arousal. Supplies motivation for change. Cites his experiments on emotional arousal and attitude change, manipulating arousal using ether drip or adrenalin (leads to temporary attitude change). Something else besides arousal may be needed to sustain change. 5. Enhances sense of mastery, control of one's self and internal states. (a) provides conceptual scheme (b) gives experience of success 6. Provision of opportunities (and incentives) to practice

Properties of Patient which assure success: 1. Distress 2. Earlier relationship with parent which leads to capacity to relate. (Molly Harrower's predictors) 3. To profit from specific procedures: capacity for insight for psychoanalysis.

Properties of Therapist which contribute to success:

We haven't gotten farther than Rogers' empathy, warmth, and positive regard; Whitehorn & Betz's Type A and B; and [missed reference name] activity level. He thinks success may be related to Therapist's parapsychological ability, healing power.

Physiology of hope: Placebos for dental pain lead to pain relief for some. Endorphin antagonist made pain re-occur for them.

1979

Beers, Thomas M.; Karoly, Paul (1979). Cognitive strategies, expectancy, and coping style in the control of pain. Journal of Consulting and Clinical Psychology, 47, 179-180.

Measures of tolerance, self-reported pain threshold, and overall discomfort of cold-pressor pain were obtained from 114 male subjects in a pretest-training-posttest experiment. Training consisted of brief practice in one of four cognitive strategies: rational thinking, compatible imagery, incompatible imagery, and task-irrelevant cognition. Analyses of covariance indicated (a) that cognitive-imaginal strategies facilitated endurance of pain and raised self-reported threshold, (b) that rational thinking and compatible imagery were generally the most effective treatments, (c) that expectancy alone was not a significant pain-attenuating factor, (d) that treatments did not affect discomfort ratings, and (e) that individual differences in imaginal ability and coping style did not correlation with changes in any of the dependent measures.

Carr-Kaffashan, Lucille; Woolfolk, Robert L. (1979). Active and placebo effects in treatment of moderate and severe insomnia. Journal of Consulting and Clinical Psychology, 47 (6), 1072-1080.

This study examines the efficacy of relaxation training and a highly credible placebo in the treatment of both severe and moderate sleep onset insomnia. The placebo treatment was designed to elicit an expectation for improvement comparable with

that of relaxation training. Expectancy of improvement was further controlled by informing subjects to expect improvement only after the third week of therapy, thus allowing comparisons of the treatments to be made during the counterdemand period (first 3 weeks) and the positive demand period (fourth week and beyond). Responses of severe and moderate insomniacs were similar across treatment conditions, over weeks, and in response to the counterdemand/positive demand manipulation. Only subjects trained in relaxation techniques improved significantly during the counterdemand period. The active treatment was significantly more effective than the placebo in reducing sleep onset latency during the counterdemand period. After the introduction of positive expectancy of therapy outcome, relaxation was no longer superior to placebo. Findings are discussed in terms of the methodological difficulties inherent in controlling for subject expectancy of therapeutic effects in treatment studies of insomnia.

Johnson, Lynn S. (1979). Self-hypnosis: Behavioral and phenomenological comparisons with heterohypnosis. International Journal of Clinical and Experimental Hypnosis, 27, 240-264.

In a study of behavioral and phenomenological differences between auto- and heterohypnosis, standard autohypnotic and hetero-hypnotic experiences were administered to 48 college students (25 males, 23 females). Total scores of behavioral and phenomenological responses were compared for each experience. The phenomenological scores were also factor analyzed for each type of hypnosis. Behavioral total scores were comparable. Inexperienced Ss were as able to hypnotize themselves as to be hypnotized by another. Scores on "challenge" items were also comparable, whereas items suggesting positive actions showed greater variability. Factor analyses showed that the subjective experiences were generally similar. Heterohypnosis evoked more feelings of unawareness, passivity, and loss of control. Self-hypnosis elicited more feelings of time distortion, disorientation, active direction, and trance variability. The relationship between hypnotic mode and order effects was discussed in terms of Ruch's (1975) facilitatory/inhibitory effects. Conclusions are drawn that self-hypnosis and heterohypnosis are sufficiently similar to be conceptualized under the same label. Data is offered on expectations of self-hypnosis and their effect on later responsiveness.

1978

Hearn, Greg (1978, November). Susceptibility and the process of social interaction in the hypnotic context. [Unpublished manuscript] (Submitted as a partial requirement for the B. S. degree with honours in psychology at the Univ of Queensland)

The hypothesis was tested that the process of social interaction between hypnotist and subject is dependent upon the susceptibility level of subjects. Using Interaction Process Analysis (Bales, 1950), the interaction patterns of 16 high susceptibles and 16 low susceptibles were analyzed. Susceptibility level had been pretested with the HGSHS:A. The hypnotist was then instructed on how to control for differences in

the process of interaction which were isolated and the initial hypnotic session was repeated on a new sample. This time the performance and interaction patterns of six high susceptibles and six low susceptibles were compared. Results suggested that trait differences give rise spontaneously to differences in the process of interaction and some combination of these effect the subjects final hypnotic performance. Hence it is argued that an interactionist framework would aid the understanding hypnotic responsivity.

Karlin, Robert; Mann, David; Carracher, John (1978, September). Placebo considerations in clinical hypnosis. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada. (Reprinted in part in American Psychological Association Division of Psychological Hypnosis Newsletter, April, 1979)

While the last 20 years have seen great progress in understanding factors underlying hypnotic phenomena in the laboratory, underlying process in clinical settings is much less clear. It is suggested that hypnosis, like most other psychotherapeutic techniques, derives most of its efficacy from its value as a placebo. Its assumed efficacy legitimizes high levels of therapist demand for change and increases the patient's efficacy expectations and perceived control. Conceptual distinctions are made between syndromes that should respond well to hypnotic treatment and those that should not. A rationale for the differing views of clinical and experimental workers in hypnosis is suggested. Finally, the central importance of the patient-therapist relationship is noted.

1977

MacMillan, M. B. (1977). The cathartic method and the expectancies of Breuer and Anna O.. International Journal of Clinical and Experimental Hypnosis, 25, 106-118.

Expectancies about the consequences of the suppression of behavior and about the effects of expressing emotions are proposed as sources of the "talking cure" which developed during Breuer's treatment of Anna O. and which later became known as the cathartic method. Although the argument is similar to one proposed by Ellenberger (1970, 1972) it sets out a more rational alternative to his explanation that the method was partly a creation of the mytho-poetic unconscious. The analysis of the interaction between Breuer and Anna O. makes explicit the expectancies underlying each of the steps through which the cathartic method developed and traces these expectancies to the general beliefs and the specific theoretical interests shared by them.

1976

Coe, William C. (1976). Effects of hypnotist susceptibility and sex on the administration of standard hypnotic susceptibility scales. International Journal of Clinical and Experimental Hypnosis, 24, 281-286.

Hypnotists' susceptibility and sex were examined for their effects on the administration of the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & Hilgard, 1962). Neither resulted in different hypnotic responsiveness from Ss. Comparatively inexperienced hypnotists obtained data similar to the normative sample for the Stanford scale. The results suggest that inexperienced hypnotists are capable of administering standardized scales validly, and that characteristics of the hypnotist are relatively ineffective in distorting Ss' responses to these scales.

Connors, J.; Sheehan, P. W. (1976). Analysis of the cue characteristics of task motivational instructions. International Journal of Clinical and Experimental Hypnosis, 24, 287-299.

This study investigated the assumption of Barber's model of hypnosis that its set of task motivational instructions is thoroughly "nonhypnotic" in character. If this assumption is correct, then the cues associated naturally with task motivational instructions should be more compatible with a suggestibility test situation explicitly defined as nonhypnotic than with one defined as hypnotic, and this affinity should be reflected in both Ss' objective and subjective suggestibility test scores. Barber's (1965) Suggestibility Scale data collected from 90 Ss did not confirm the main prediction under test, but results failed to provide unequivocal support for the model; subjective evidence, in particular, supported least well the assumptions of the paradigm.

Gatchel, Robert J.; Proctor, Janet D. (1976). Effectiveness of voluntary heart rate control in reducing speech anxiety. Journal of Consulting and Clinical Psychology, 381-389.

The effects of learned control of heart rate deceleration and therapeutic expectancy set in reducing speech anxiety were investigated in a factorial design employing 36 speech-anxious subjects. Heart rate control training and no heart rate control training were each paired with high-therapeutic-expectancy and neutral-expectancy instructions, in order to assess the individual and combined effects of the two factors. Results demonstrated that learning to control heart rate deceleration led to a significant reduction in self-report, physiological (heart rate and skin conductance level), and overt signs of anxiety, relative to the no-heart-rate control condition. High-therapeutic-expectancy instructions also contributed to a reduction in self-reported anxiety. These results demonstrate that learned heart rate control is an effective therapeutic technique for reducing anxiety.

Hemme, Robert; Boor, Myron (1976). Role of expectancy set in the systematic desensitization of speech anxiety: An extension of prior research. Journal of Clinical Psychology, 32 (2), 398-404.

## SUMMARY

The influence of expectancy set with regard to therapy outcome on the effectiveness of systematic desensitization (SD) for reducing public speaking anxiety was investigated. The 7 Ss given a high expectancy set for favorable therapy outcome were informed about psychological research that indicates that SD is effective to reduce public speaking fears. SD was administered with the standard instructions to the 11 Ss given a neutral expectancy set. This expectancy manipulation did not require deception and perhaps could be used with actual SD therapy clients. As in previous research by Woy and Efran, the expectancy set manipulation significantly modified Ss' self-report of subjective perceptions of anxiety from pretreatment to posttreatment speeches, but did not affect overt behavioral or physiological indices of anxiety. Since subjective perceptions of anxiety responses are psychologically significant behaviors, these data suggest the importance of conveying a high expectation of improvement to SD and perhaps also to other types of therapy clients. SD sessions administered to small groups of clients on consecutive days, as in this study, appeared to be as effective to reduce speech anxiety as SD sessions administered to each client individually at 1-week intervals, as in the Woy and Efran study" (pp. 403-404).

1975

Aletky, Patricia J.; Carlin, Albert S. (1975). Sex differences and placebo effects: Motivation as an intervening variable. Journal of Consulting and Clinical Psychology, 43 (2), 278.

NOTES

1:

" ... the present findings would suggest that future studies of placebo effects should take into account the nature of the dependent variable and the pertinent differential sex-role expectations" (p. 278). The performance measure was a dynamometer pull task. The placebo was a jelly applied to the forearm "and alleged to relieve muscular fatigue" (p. 278). The motivational instructions were telling Subjects that "individuals in good health and with normal muscle tonus would be expected to show improved performance on the posttreatment trial" (p. 278).

Barber, Theodore Xenophon (1975). Responding to 'hypnotic' suggestions: An introspective report. American Journal of Clinical Hypnosis, 18 (1), 6-22.

The author first presents an introspective report which describes some of his attitudes, motivations, and expectancies and ongoing thought processes while he is responding to 'hypnotic' suggestions. The introspective report indicates that (a) suggested effects are experienced when a person thinks with and imaginatively focuses on those things that are suggested and (b) a person imaginatively focuses on the suggestions when he sees the test situation as useful and worthwhile and when he wants to and expects to experience those things that are suggested. It is then argued that the responsive subject in a hypnotic situation differs in every important respect from the sleepwalker and closely resembles the person who is involved in reading an interesting novel or in observing an interesting motion picture. Finally, the author outlines a course, now being developed, that aims to teach individuals how to respond to suggestions.

Lick, John R. (1975). Expectancy, false galvanic skin response feedback, and systematic desensitization in the modification of phobic behavior. Journal of Consulting and Clinical Psychology, 43 (4), 557-567.

This study compared systematic desensitization and two pseudotherapy manipulations with and without false galvanic skin response feedback after every session suggesting improvement in the modification of intense snake and spider fear. The results indicated no consistent differences between the three treatment groups, although all treatments were significantly more effective than no treatment in modifying physiological, behavioral, and self-report measures of fear. A 4-month follow-up showed stability in fear reduction on self-report measures for the three treatment groups. Overall, the results of this experiment were interpreted as contradicting a traditional conditioning explanation of systematic desensitization. An alternate explanation for the operation of systematic desensitization emphasizing the motivational as opposed to conditioning aspects of the procedure is discussed.

1974

Chaves, John F.; Barber, Theodore Xenophon (1974). Cognitive strategies, experimenter modeling, and expectation in attenuation of pain. Journal of Abnormal Psychology, 83 (4), 356-363.

Verbal reports of pain were obtained from 120 subjects during a base-level pretest and also during a posttest conducted under one of several experimental treatments. The pain stimulus was a heavy weight applied to a finger for two minutes. During the posttest, subjects who had been asked to utilize cognitive strategies for reducing pain (to imagine pleasant events or to imagine the finger as insensitive) showed a reduction in pain as compared to uninstructed control subjects. Subjects led to expect a reduction in pain, but not provided with cognitive strategies, also showed reduced pain during the posttest as compared to control subjects, but the reduction was smaller than for subjects using cognitive strategies. An experimenter modeling procedure, used with one half of the subjects under each experimental treatment, was effective in reducing verbal reports of pain only for subjects with high pretest levels who were asked to imagine pleasant events.

Brown, H. Alan (1973). Role of expectancy manipulation in systematic desensitization. Journal of Consulting and Clinical Psychology, 41 (3), 405-411.

Expectancy, relaxation, and hierarchy content were manipulated in a 2X2 factorial design with two additional control groups. It was hypothesized that a major portion of therapeutic change following desensitization could be accounted for by the subjects' responses to positive feedback inherent in the paradigm. Spider-phobic subjects saw either photographs of spiders or blank slides that they believed to be tachistoscopically presented pictures of spiders. In the factorial part of the design, half of the subjects believed their progress through the hierarchy to be contingent on autonomic responses; the others believed rate of progress to be random. Findings

did not support the hypothesis that expectancy was the only factor in desensitization, but they did serve to clarify the role of expectancy vis-a-vis the counterconditioning elements typically discussed in the literature.

Brown, H. Alan (1973). Role of expectancy manipulation in systematic desensitization. Journal of Consulting and Clinical Psychology, 41 (3), 405-411.

Expectancy, relaxation, and hierarchy content were manipulated in a 2X2 factorial design with two additional control groups. It was hypothesized that a major portion of therapeutic change following desensitization could be accounted for by the subjects' responses to positive feedback inherent in the paradigm. Findings did not support the hypothesis that expectancy was the only factor in desensitization, but they did serve to clarify the role of expectancy vis-a-vis the counterconditioning elements typically discussed in the literature.

McReynolds, William T.; Barnes, Allan R.; Brooks, Samuel; Rehagen, Nicholas (1973). The role of attention-placebo influences in the efficacy of systematic desensitization. Journal of Consulting and Clinical Psychology, 41 (1), 86-92.

Systematic desensitization was compared with two attention- placebo control treatments - one taken from Paul and one currently devised as an elaborate, highly impressive "therapeutic" experience - and no treatment. It was hypothesized that (a) fear reductions following desensitization would be no greater than those associated with an equally compelling placebo treatment and (b) fear and control measure changes following the previously used attention-placebo treatment would be less than those following desensitization and the present placebo control manipulations. Both hypotheses were supported, although support for the first was more consistent than for the second.

1972

Barber, Theodore Xenophon; de Moor, Wilfried (1972). A theory of hypnotic induction procedures. American Journal of Clinical Hypnosis, 15 (2), 112-135.

The first part of the paper delineates nine variables in hypnotic induction procedures that give rise to heightened responsiveness to test-suggestions: (a) defining the situation as hypnosis; (b) removing fears and misconceptions; (c) securing cooperation; (d) asking the subject to keep his eyes closed; (e) suggesting relaxation, sleep, and hypnosis; (f) maximizing the phrasing and vocal characteristics of suggestions; (g) coupling suggestions with naturally-occurring events; (h) stimulating goal-directed imagining; and (i) preventing or reinterpreting the failure of suggestions. Data are presented to support the theory that the nine variables augment responsiveness to test-suggestions by giving rise to positive

attitudes, motivations, and expectancies which, in turn, tend to produce a willingness to think with and vividly imagine those things that are suggested. The second part of the paper specifies situational variables and variables involved in induction procedures that produce a trance-like appearance, changes in body feelings, and reports of having been hypnotized.

**1970**

Goldstein, M. S.; Sippelle, Carl N. (1970). Hypnotically induced amnesia versus ablation of memory. International Journal of Clinical and Experimental Hypnosis, 19 (3), 211-216. (Abstracted in Current Contents, 2, 35, 21)

Divided 33 hypnotizable undergraduates, all capable of achieving the criterion of amnesia for a 7-digit number, into 3 groups: 2 hypnotized and 1 pretend. The distributions of errors for an amnesic performance of these groups were compared with the theoretical chance distribution of errors expected in an amnesic performance. Both hypnotized groups differed significantly from the pretend group and from the theoretical distribution, while the performance of the pretend group did not differ significantly from the chance distribution. The performance of the pretend group conformed to the expectancy for amnesia significantly better than did the performance of either of the hypnosis groups. (Spanish & German summaries) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

A formulation is presented which does not invoke a special state of consciousness ("hypnosis" or "trance") to account for the behaviors that have been historically associated with the word hypnotism. Instead, so-called hypnotic behaviors - e.g., "analgesia," "hallucination," "age-regression," and "amnesia" - are conceived to be functionally related to denotable antecedent variables which are similar to those that control performance in a variety of interpersonal test-situations. The antecedent variables which determine behavior in a "hypnotic" situation include Ss' attitudes, expectancies, and motivations with respect to the situation, and the wording and tone of instructions- suggestions and of questions used to elicit subjective reports. The formulation is exemplified by several dozen experimental studies, and prospects for further research are delineated.

**1969**

Barber, Theodore Xenophon; Calverley, David S.; Forgione, Albert; McPeake, John D.; Chaves, John F.; Bowen, Barbara (1969). Five attempts to replicate the experimenter bias effect. Journal of Consulting and Clinical Psychology, 33, 1-6.

**NOTES**

Failed to cross-validate the Rosenthal & Fode, 1963, work on experimenter bias effect in five separate investigations. Concludes that the effect is more difficult to demonstrate than was implied in several recent reviews and that it is not known what preconditions are necessary to obtain it.

**1968**

Barber, Theodore Xenophon; Calverley, David S. (1968). Toward a theory of 'hypnotic' behavior: Replication and extension of experiments by Barber and co-workers (1962-65) and Hilgard and Tart (1966). International Journal of Clinical and Experimental Hypnosis, 16, 179-195.

RESPONSES TO TEST SUGGESTIONS (E.G., HALLUCINATION AND AMNESIA) WERE ASSESSED UNDER THE FOLLOWING TREATMENTS: MOTIVATIONAL INSTRUCTIONS ALONE, HYPNOTIC PROCEDURE WITH MOTIVATIONAL INSTRUCTIONS, AND IMAGINATION-CONTROL. COMPARISONS WERE MADE ACROSS INDEPENDENT GROUPS, EACH TESTED UNDER 1 TREATMENT, AND ALSO WITHIN THE SAME SS TESTED TWICE UNDER VARIOUS COMBINATIONS OF THE TREATMENTS. ALTHOUGH SS WERE SUGGESTIBLE UNDER THE IMAGINATION-CONTROL TREATMENT, BOTH THE MOTIVATIONAL INSTRUCTIONS ALONE AND THE HYPNOTIC PROCEDURE GIVEN TOGETHER WITH THE MOTIVATIONAL INSTRUCTIONS RAISED SUGGESTIBILITY ABOVE THE CONTROL LEVEL. THE HYPNOTIC-MOTIVATIONAL TREATMENT TENDED TO PRODUCE AN INCREMENT IN SUGGESTIBILITY WHICH WENT SLIGHTLY BEYOND THAT ATTRIBUTABLE TO THE MOTIVATIONAL INSTRUCTIONS. THE LATTER INCREMENT IS INTERPRETED AS DUE TO THE SLIGHTLY GREATER EFFECTIVENESS OF THE HYPNOTIC PROCEDURE IN DEFINING THE SITUATION AS ONE IN WHICH UNUSUAL MANIFESTATIONS, SUCH AS HALLUCINATION AND AMNESIA, ARE WITHIN SS" CAPABILITIES AND DEFINITELY EXPECTED BY E. Orne, Martin T.; Wender, Paul H. (1968). Anticipatory socialization for psychotherapy: Method and rationale. Official Journal of the American Psychiatric Association, 124 (9), 1202-1209.

There is a strong positive relationship between a patient's perception of psychotherapy and its ultimate success. Some patients who appear to lack motivation for treatment may be capable of profiting from psychotherapy if they are taught what to expect--if they understand the "rules of the game." A clinical procedure for introducing such patients to psychotherapy is outlined by the authors, who also present excerpts from a hypothetical socialization interview.

1966

Orne, Martin T.; Evans, Frederick J. (1966). Inadvertent termination of hypnosis with hypnotized and simulating subjects. International Journal of Clinical and Experimental Hypnosis, 14, 61-78.

6 highly hypnotizable Ss and 6 unhypnotizable Ss, instructed to simulate hypnosis, were given hypnotic instructions by means of a tape-recording. Continuous measures of subjective hypnotic depth and GSP were recorded to allow E to take the role of technician. After Ss had been hypnotized by the tape-recorder, a light went

out, the tape-recorder stopped, and E rushed from the room--apparently in search of a fuse box. The Ss were observed for 30 min. through the 1-way screen. During this time the hypnotic suggestions appeared to lose their effectiveness and the hypnotized Ss gradually awoke. However, 5 of 6 simulating Ss behaved as though they were in hypnosis throughout. 5 of 6 deeply hypnotized Ss assumed that the fuse really had blown, whereas 5 of 6 simulating Ss perceived the "accident" to be part of the experiment. It was concluded that it is necessary to construct a situation in which both groups perceive the power failure to be genuine. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

**1965**

Levitt, Eugene E.; Overley, T. M. (1965). Experience of the hypnotist as a factor in hypnotic behavior. International Journal of Clinical and Experimental Hypnosis, 12 (1), 34-38.

A group of student nurse volunteers were found to obtain scores on the Stanford Hypnotic Susceptibility Scale which did not differ when they were hypnotized by experienced or by inexperienced hypnotists. Neither did scores vary from 1st to 2nd occasion regardless of the experience of the hypnotist. The results are interpreted to mean that the factor of hypnotist experience is likely to be irrelevant to subject performance in the standardized, research situation. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

**1964**

Anderson, Milton L.; Sarbin, T. R. (1964). Base rate expectations and motoric alterations in hypnosis. International Journal of Clinical and Experimental Hypnosis, 12 (3), 147-158.

Degree of responsiveness to "suggestion" in an experiment which did not utilize hypnotic induction (the Berkeley Sample) was comparable to that obtained in an experiment which did utilize hypnotic induction (the Stanford Sample). Procedural differences between the 2 experiments--self-scoring vs. objective-scoring, and group vs. individual testing--were regarded as not crucial in making a comparison of the 2 experiments. The distribution of responses in the Berkeley Sample may be taken as the base rate. The slightly higher degree of responsiveness over the base rate in the Stanford Sample (on some tests) may be attributed to the "degree of volunteering" that characterized the sample. The importance for experiments in the future to create equal levels of motivation and expectation to perform well under both the hypnotic and the nonhypnotic conditions is stressed, and brief mention is made of a new metaphor to be used in the conceptualization of the problems of hypnosis. (25 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Brady, J. P.; Levitt, E. E. (1964). Hypnotically-induced 'anosmia' to ammonia. International Journal of Clinical and Experimental Hypnosis, 12, 18-20.

The procedure to demonstrate anosmia by the inhalation of ammonia is discussed. Deeply hypnotized Ss who are not knowledgeable of the relevant facts of physiology may fail to respond to ammonia fumes when it is suggested that they have no sense

of smell (anosmia). However, persons who, in fact, are anosmic do respond to ammonia fumes because they are a powerful stimulus to the pain fibers in the nasal mucosa. This procedure illustrates that the crucial factor in the response of the hypnotized S is not the actual facts of anatomy and physiology, but the S's concept of them. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Levitt, Eugene E.; Brady, J. P. (1964). Expectation and performance in hypnotic phenomena. Journal of Abnormal and Social Psychology, 69, 572-574.

Expectations concerning the occurrence of 7 phenomena through hypnotic suggestion were solicited from 12 female Ss, all of whom scored high on the Stanford Hypnotic Susceptibility Scale. Attempts were then made to induce these phenomena in the Ss. The results indicate that performance and expectation were discordant about as often as they were in accord. There appeared to be an interaction between task and expectation-performance accord. (PsycINFO Database Record (c) 2002 APA, all rights reserved) NOTES 1: NOTES: When Ss were not manipulated into their expectations, the relationship between expectancy and hypnotic behavior was minimal.

Melei, Janet P.; Hilgard, Ernest R. (1964). Attitudes toward hypnosis, self-predictions, and hypnotic susceptibility. International Journal of Clinical and Experimental Hypnosis, 12, 99-108.

Correlation of questionnaire results from a sample of 1326 students with hypnotic susceptibility scores of 340 of these later hypnotized showed (a) that those volunteering for hypnosis were more favorable in attitude than those who did not volunteer; (b) attitudes toward hypnosis were predictive of susceptibility for females, not for males; and (c) self-predictions yielded significant low positive correlations with actual susceptibility for both sexes. Other findings concern differences between those having prior experience with hypnosis and those without such experience. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

O'Connell, D. N. (1964). An experimental comparison of hypnotic depth measured by self-ratings and by an objective scale. International Journal of Clinical and Experimental Hypnosis, 12, 34-46.

The behavioral items of an individually-administered test of hypnotic susceptibility were scored by the Ss themselves (N = 88) and by E. Susceptibility scores derived from these self-ratings and observer-ratings were in excellent agreement ( $r = .90$ ) and did not differ significantly in distribution. Marked item scoring biases were found as a function of hypnotizability: poor hypnotic Ss tending to underevaluate their performance and good ones to overevaluate it. Moderate correlations were found between magnitude estimates made by Ss of their subjective hypnotic depth and both observer-rating ( $r = .55$ ) and self-rating ( $r = .54$ ) susceptibility scores. The interrelation and potential usefulness of these types of scoring procedures are discussed. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Hoskovec, J.; Svorad, D.; Lanc, O (1963). The comparative effectiveness of spoken and tape-recorded suggestions of body sway. International Journal of Clinical and Experimental Hypnosis, 11, 163-166.

The relative effectiveness of tape-recorded vs. spoken suggestions of body sway was measured. Both types of suggestion produced increased body sway. Spoken suggestions following recorded suggestions were the most effective. The expectation by Ss of a greater effectiveness of live presentation may have produced this result. 1961

Glass, Louis B.; Barber, Theodore X. (1961). A note on hypnotic behavior, the definition of the situation and the placebo effect. Journal of Nervous and Mental Disease, 132, 539-541.

Subjects were tested for responses to hypnotizability tests under three conditions: after 20 minute induction, after being told they would not be hypnotized but would take tests of imagination (with motivating instructions to do well), after taking a placebo pill that "would make them deeply hypnotized." Of 12 Ss who dropped in score between Session 1 and Session 2, 11 attained higher scores following placebo than during the control session; mean scores under placebo and control (5.8 and 3.7) differed significantly,  $p < .01$ . Scores were as high in the third as the first session (5.8 and 6.3 respectively).

Kroger, William S.; Schneider, Sidney A. (1959). An electronic aid for hypnotic induction: A preliminary report. International Journal of Clinical and Experimental Hypnosis, 7, 93-98.

#### NOTES

The BWS or brain wave synchronizer is "an instrument specifically designed to induce various levels of hypnosis by subliminal and photic stimulation of the brain waves" (p. 93). It was developed after noticing that radar operators on ships sometimes fell into deep hypnotic states while watching signals on a radar screen. It has been used with 2500 subjects, 200 of whom were receiving pre-natal training for childbirth under hypnosis.

"For the first five minutes there is a gradual increase in the number of subjects who enter deep hypnosis. At this level, a figure of 50% reach the deep state" (p. 95).

The instructions given were, "Concentrate on the center of the instrument. When your eyes become tired and heavy, as they will, just let them close and feel yourself going deeper and deeper into a relaxed state." It is acknowledged that this procedure worked when Ss expected to experience hypnosis; the rate of deep hypnosis increased as the expectancy of hypnosis increased. "Deep hypnosis in individual inductions reached 80% under the following conditions:

A. Synchronizer on 5 minutes

B. Expectation Level of 50 [on a scale in which 100 represented having seen demonstrations of conventional hypnosis and an explanation of what the instrument would do]" (p. 97).

1958

Barber, Theodore Xenophon (1958). Hypnosis as perceptual-cognitive restructuring: II. "Post"-hypnotic behavior. Journal of Clinical and Experimental Hypnosis, 6 (1), 10-20.

#### NOTES

The author presents "experimental evidence indicating that there is no essential difference between 'hypnotic' behavior and 'post-hypnotic' behavior" (p. 11).

##### "Summary and Conclusions

"When 'somnambulistic' subjects were told to 'wake up' after they were given a 'post-hypnotic suggestion' and 'amnesia for the suggestion' they behaved as follows:

1. They opened their eyes and became relatively more aware of their surroundings.
2. They were aware that the signal for the 'post-hypnotic- behavior had special significance for them.

3. They were 'set' to 'obey the hypnotist's suggestions' from the moment they were told to 'wake up,' until they were convinced that their interpersonal relationship with the operator was no longer that of subject and hypnotist.

4. When the 'post-hypnotic suggestion' was uncomplicated and fitted into the normal pattern of behavior, the subjects carried it out without 'going deeper into trance,' i.e., without becoming relatively more 'detached' from their surroundings. However, when the 'post-hypnotic suggestion' was of such a nature that it was necessary for the subjects to 'go deeper into trance' to properly carry it out, the subjects did 'go deeper into trance.'

"Whether the subjects did or did not have amnesia for the 'post-hypnotic suggestion' was not important. 'Amnesic' and 'non-amnesic' subjects carried out the 'post-hypnotic' behavior in essentially the same way.

"These experiments indicate that:

1. If the operator properly manipulates the situation, the 'good' hypnotic subject is 'set' to carry out the operator's commands in the 'post-hypnotic' period in the same way as during 'hypnosis.'

2. If, in order to properly carry out the 'post-hypnotic suggestions,' it is necessary for the subject to 'go deeper into trance' -- i.e., to become relatively inattentive to stimuli not emanating from the operator -- the good subject will do so.

3. There is no essential- difference between the subject's behavior in the 'hypnotic' period and in the 'post-hypnotic' period.

4. If we are to continue speaking of 'suggestions' to be carried out in the post-hypnotic period we should term them 'post'-hypnotic 'suggestions'" (pp. 19-20).

Dittborn, Julio M. (1958). Expectation as a factor of sleep suggestibility. Journal of Clinical and Experimental Hypnosis, 6 (4), 164-170. (Abstracted in Psychological Abstracts 61: 2390)

## NOTES

Authors studied expectation ("the attitude of waiting attentively for something usually to a certain extent defined, however vaguely," as defined by Drever) as a factor of sleep suggestibility. They tested young soldiers in the Chilean army using the postural sway test of suggestibility, repeated twice, to yield 12 Subjects. After a third postural sway test the Subjects were required to respond to a series of visual, then later oral, stimuli. [Experimental instruments are not clearly described in this article.]

The Subjects returned a week later and were asked to respond to the stimuli by using the word "sueno" (dream) for two Ss and "dormir" (sleep) for another two. The word "sleep" was used in the third experiment, following suggestions like "As you read more and more or as you hear yourself repeating the word 'sleep or dream' over and over again you will become more and more sleepy" (p. 166).

Apparently the outcome measure was the number of stimuli to which the Subject responded before lack of response indicated a trance. [Description is unclear.]

Barber, Theodore Xenophon (1957). Hypnosis as perceptual-cognitive restructuring: I. Analysis of concepts. Journal of Clinical and Experimental Hypnosis, 5 (4), 147-166.

### Summary

1. 'Trance' involves a selective and relative inattention to internal and external stimulation.
2. Hypnosis involves one type of 'trance' behavior but hypnosis differs from other types of 'trance' in that it is an interpersonal relationship in which one person, the operator, restructures the 'perceptions' and conceptions of the other person, the subject.
3. The operator can restructure the thoughts and 'perceptions' of the 'good' hypnotic subject because (a) the subject is relatively detached and inattentive to his self and his surroundings and (b) the subject is 'set' -- he is ready and willing -- to accept the operator's words as true statements and to 'literally think as the operator wants him to think.'
4. 'Perceptual-cognitive restructuring' and not 'suggestion' is the essential element in hypnosis.
5. We can begin to understand hypnosis and the phenomena of hypnosis by one general principle: the hypnotic subject behaves differently because he 'perceives' and conceives differently. The behavior of the hypnotic subject is in strict accordance with his altered conceptions of his self and his surroundings" (p. 162).

## EXPERIMENTAL HYPNOSIS

1992

Coe, William C. (1992). Hypnosis: Wherefore art thou?. International Journal of Clinical and Experimental Hypnosis, 40 (4), 219-237.

The present paper focuses on the influences of social-political needs of various groups with interests in hypnosis (i.e., stage hypnotists, lay hypnotists, licensed practitioners, and researchers). While hypnosis is a specific topic of interest to groups with varying needs, it also serves as an example for other topics in psychology that may overlap the needs of other groups -- especially practitioners and researchers. The identity given to hypnosis varies depending upon which particular group of persons is offering the identity, and the nature of the identity reflects each group's biases and needs. These various identities, however, are not always acceptable, in part or in whole, by the other groups, as the needs of one or more may be in conflict with those of others.

**1969**

Blatt, Sidney J.; Goodman, John T.; Wallington, Sue Ann (1969). Is the hypnotist also being hypnotized?. International Journal of Clinical and Experimental Hypnosis, 17, 160-166.

Noted that 2 hypnotists had cognitive and affective experiences similar to those expected in the S as a function of the hypnotic manipulation when they were conducting hypnotic inductions. Though the hypnotists may have been responding to the mood tone of the Ss or responding on the basis of their expectations about the effect of the hypnotic manipulation, it seemed equally possible that the hypnotists may have experienced mild forms of the trance state they had induced in their Ss. These observations seemed consistent with prior notes of such a phenomenon. This phenomenon has important implications for the clinical and experimental use of hypnosis and for concepts such as transference and countertransference, empathy, demand characteristics, and E bias. Suggestions are made for the systematic evaluation and study of this phenomenon. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

**1964**

Evans, Frederick J.; Schmeidler, D. (1964). Reliability of two observers scoring the Stanford Hypnotic Susceptibility Scale, Form C. International Journal of Clinical and Experimental Hypnosis, 12 (4), 239-251.

2 Os scored the responses of 60 Ss on a 12-item objective test, Stanford Scale of Hypnotic Susceptibility, Form C (Weitzenhoffer & Hilgard, 1962). Mean total scores reported by the 2 Es did not differ significantly. The correlation between the total scores of the 2 Es was .947. Nevertheless, differences in total scores assigned occurred with 40% of Ss, which is a significant departure from perfect agreement. The 2 Es disagreed about correct scoring of 54 items (7.5% of all items scored). The extent of disagreement was significantly greater than 0. Disagreement was not related to the level of susceptibility of Ss, nor to the relative experience of Es with hypnosis. More than 1/2 of the disagreements involved systematic differences in the interpretation and application of the scoring criteria for 2 items; item 6: Dream, and item 9: Anosmia to Ammonia. These systematic differences affecting scoring reliability happened to counterbalance to produce similar total scores in this study.

Several sources of potential scoring unreliability of SHSS:C are discussed. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

## EYE MOVEMENT

2001

**Bjick, Suzanne (2001). Accessing the power in the patient with hypnosis and EMDR. American Journal of Clinical Hypnosis, 43 (3/4), 203-216.**

Notes that both E. Rossi's ideodynamic accessing model of hypnosis and EMDR are intended to access information stored in the mind-body system. Some possibilities for effectively using hypnosis and EMDR in combination are discussed. The similarities and the uniqueness of each method, both theoretically and in terms of the different protocols, are compared to provide a rationale for combining them. Verbatim examples from a clinical case (a woman with posttraumatic stress disorder (PTSD) are presented to demonstrate exactly how these models can be usefully combined in clinical practice. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1998

**Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..**

## NOTES

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm,

accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

1992

Herbert, James D.; Mueser, Kim T. (1992). Eye movement desensitization: A critique of the evidence. Journal of Behavior Therapy and Experimental Psychiatry.

The scientific evidence supporting the efficacy of eye movement desensitization (EMD), a novel intervention for traumatic memories and related conditions, is reviewed. The sparse research conducted in this area has serious methodological flaws, precluding definite conclusions regarding the effectiveness of the procedure. Clinicians are cautioned against uncritically accepting the clinical efficacy of EMD.

Lohr, Jeffrey M.; Kleinknecht, Ronald A.; Conley, Althea T.; Dal Cerro, Steven; Schmidt, Joel; Sonntag, Michael E. (1992). A methodological critique of the current status of eye movement desensitization (EMD). Journal of Behavior Therapy and Experimental Psychiatry.

Eye Movement Desensitization (EMD) has been recently advocated as a rapid treatment for the elimination of traumatic memories responsible for the maintenance of a number of anxiety disorders and their clinical correlates. Despite a limited conceptual framework, EMD has attracted considerable interest among clinicians and researchers. The popularity and interest generated by EMD will likely result in wide usage. We present a methodological critique of it with reference to assessment, treatment outcome, and treatment process. We also provide guidelines for judging the methodological adequacy of research on EMD and suggest intensive research to assess effectiveness, treatment components, and comparisons with other procedures.

#### NOTES

A controversial issue is heating up, and therapists are beginning to feel the heat. The issue involves the common practice of helping clients recover apparently repressed memories of early childhood sexual trauma. In the second edition of my hypnosis textbook, \_Trancework\_ (1990, Brunner/Mazel), I included a special section on the possibility of hypnotically implanting false memories---vivid memories of things that never actually happened that the client comes to believe as true recollections. I pointed out the risks of suggestive procedures and urged caution in suggesting memories of any sort, whether a formal hypnotic induction took place or not.

"Early this year a non-profit foundation was formed in Philadelphia called the False Memory Syndrome Foundation which serves as a clearing house for relevant information, and even publishes a newsletter. It also provides support to families broken apart by these problems. If you are interested in the complex issues regarding suggestion and memory, you can contact the FMS Foundation at 3508 Market Street, Suite 128, Philadelphia, PA 19104, telephone (215) 387-1865. David Calof's group also publishes Treating Abuse Today. They, too, are cognizant of the relevant issues. Their address is 2722 Eastlake Avenue East, Seattle, WA 98012, telephone (206) 329- 9101" (p. 2).

**1991**

**Wolpe, Joseph; Abrams, Janet (1991). Post-traumatic stress disorder overcome by eye-movement desensitization: A case report. Journal of Behavior Therapy and Experimental Psychiatry, 39-43.**

Post-traumatic stress disorder is an exceptionally stressful syndrome that has been extremely difficult to treat. The prognosis was recently dramatically improved by the introduction of eye-movement desensitization. This paper reports, in substantial detail, a case that was precipitated by a rape 10 years earlier, describing its manifestations and various unsuccessful attempts to treat it: followed by a detailed exposition of the eventual, completely successful treatment by eye-movement desensitization.

**1990**

**Gravitz, Melvin A. (1990). Adverse behavior associated with the eye-roll test of hypnotizability: Clinical and theoretical considerations. Psychotherapy: Theory, Research and Practice, 27, 267-270.**

For 15 years, subjects' response to the eye-roll test has been used to measure susceptibility without adverse effects. A case is described of a hospitalized young man who displayed dissociative behavior when asked to do the eye-roll as part of a diagnostic evaluation. Etiological and theoretical considerations, and implications for therapeutic strategy are discussed.

**1988**

**Gabel, Stewart (1988). The right hemisphere in imagery, hypnosis, rapid eye movement sleep, and dreaming: Empirical studies and tentative conclusions. Journal of Nervous and Mental Disease, 176, 323-331.**

Reviews studies that have addressed the issue of whether there is an increased activation or efficiency of right-hemispheric processes during imagery, hypnosis, REM sleep, and dreaming. Evidence strongly supports the notion of increased right-hemispheric activation in simple imaginal or visual states during usual consciousness. There are also studies supporting this view of REM sleep, dreaming, and hypnotic phenomena. It is concluded, however, that the lack of adequate studies, contradictory or negative findings, and moderating variables (e.g., task

difficulty, cognitive style) make it difficult to draw definitive conclusions concerning right-hemispheric processes.

1987

Kluft, Richard (1987). The withheld eye-roll sign. American Journal of Clinical Hypnosis, 30, 9-19.

Within the context and the assumptions of the Hypnotic Induction Profile (HIP), the eye-roll sign is understood to indicate a stable biologically based measure of potential hypnotic capacity. Serendipitous observations seemed to suggest that the eye-roll sign underwent significant changes in 14 particular patients. On exploration of these patients' subjective experiences, it was discovered that certain patients associated the eye-roll with incipient dyscontrol and consciously withhold a full and accurate response. In others, such withholding occurred as a conversion symptom. Furthermore, some patients were aware of the implications of the eye-roll and made efforts to represent themselves as un hypnotizable by withholding a full eye-roll. No genuine changes in eye-roll signs were noted. Clinical illustrations are offered and discussed.

1984

Magnavito, F.; Gaupp, L. (1984, October). Absorption, hypnotic susceptibility, and automatization of visual attention. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

#### NOTES

Absorption (Tellegen Scale) correlated .62 with SHCS and -.45 with a measure of visual automatization. They conclude that highly absorption-prone individuals attend more to sensory information, processing their environment in a childlike, less automatized manner. The measure of visual automatization, H, was obtained by camera recorded eye movements and fixations as Ss viewed slides in any way they desired.

1982

Spiegel, David; Tryon, Warren W.; Frischholz, Edward J.; Spiegel, Herbert (1982). Hilgard's illusion. Archives of General Psychiatry, 39 (8), 972-4.

Examines E. R. Hilgard's (see PA, Vol 68:11932) critique of the hypothesis that eye roll (ER) is related to hypnotizability, clarifying the nature of the data relevant to the ER hypothesis. The authors contend that there are a number of factual errors in Hilgard's article: his (1) explanation of the procedure used in determining the Hypnotic Induction Profile (HIP) grades, (2) characterization of the HIP as a single-item test, and (3) his contention that the levitation score is the sole determinant of manifest hypnotic response. (9 ref.)

1980

Spanos, Nicholas P.; Pawlak, Anne E.; Mah, Christopher D.; D'Eon, Joyce L. (1980). Lateral eye movements, hypnotic susceptibility and imaginal ability in right-handers. Perceptual and Motor Skills, 50, 287-294.

A total of 46 male and 36 female right-handers were assessed on three measures of left-moving, as well as on hypnotic susceptibility, and several measures of imaginal ability. The three left-moving indices intercorrelated significantly. However, none of these indices correlated significantly with hypnotic susceptibility or imaginal ability variables in either sex.

1979

Sheehan, D. V.; Latta, W. D.; Regina, E. G.; Smith, G. M. (1979). Empirical assessment of Spiegel's hypnotic induction profile and eye-roll hypothesis. International Journal of Clinical and Experimental Hypnosis, 27 (2), 103-110.

39 healthy male volunteers were hypnotized twice using Spiegel's (1974) Hypnotic Induction Profile (HIP). Their responses were scored independently by 2 raters who alternated roles as hypnotist and observer. Results indicated: (a) high inter-rater reliability for HIP components and for the Hypnotic Induction Score (HIS); (b) satisfactory test-retest correlations for the eye-roll, up gaze, squint, posthypnotic arm levitation, and control differential; (c) component scores and HIS increased from Session 1 to Session 2; (d) the role of the rater was not influential; (e) inter-item correlations on HIP were similar to those reported by Spiegel; and (f) the analysis does not support the hypothesis that the eye-roll is dependably predictive of hypnotic signs measured by HIP subsequent to measurement of the eye-roll.

1978

Spanos, Nicholas P.; Rivers, Stephen M.; Gottlieb, Jack (1978). Hypnotic responsivity, meditation, and laterality of eye movements. Journal of Abnormal Psychology, 87 (5), 566-569.

Right-handed male subjects were pretested on a number of person variables; they then meditated for eight sessions. Measures of hypnotic responsivity, meditating skill, imaginal abilities, and attitudes toward hypnosis loaded on a common factor that was labeled sustained nonanalytic attending. However, laterality of eye movement (left moving) failed to load on this factor. The implications of these findings for current theorizing concerning hypnosis and meditation are discussed.

Weerts, Theodore C.; Lang, Peter J. (1978). Psychophysiology of fear imagery: Differences between focal phobia and social performance anxiety. Journal of Consulting and Clinical Psychology, 46 (5), 1157-1159.

Spider phobics and speech anxious subjects imaged fear scenes with spider and public-speaking content and a series of standard scenes that were constructed to vary in degree of emotional arousal and movement. Heart rate, skin conductance, and ocular activity were recorded. Spider phobics rated all imagery contents as

more vivid and reported more scene movement than speech anxious subjects. Both groups responded to their own fear scenes with higher ratings of emotion and a greater physiological response than to the other group's fear scenes. The arousal response of spider phobics to relevant fear scenes was greater than that of speech anxious subjects. The data suggest that the outcome of imagery-based therapies may be partly determined by type of fear.

1976

Spiegel, Herbert; Aronson, Marc; Fleiss, Joseph L.; Haber, Jerome (1976). Psychometric analysis of the Hypnotic Induction Profile. International Journal of Clinical and Experimental Hypnosis, 24, 300-315.

Psychometric analyses of the Hypnotic Induction Profile (HIP) of Spiegel (1974a), a sixteen point test designed to measure hypnotic capacity, are presented herein. Briefly summarized are the sequential phases of trance experience as monitored by the HIP. On the basis of a factor analysis of individual items entering into the HIP's of 1674 patients, two distinct factors emerged. One is defined largely by up-gaze and eye-roll, the other by some of the subsequent items. Two methods for scoring the HIP, a configurational method involving both factors (profile scoring) and an actuarial method using only items from the second factor (induction scoring), are defined. As expected from the factor analysis, eye-roll is little related to the HIP graded by either scoring method. The correlation of induction scoring with the eye-roll is .22 in a sample of 1023 patients. Such a correlation is significant, although it accounts for only 5% of the variance that eye-roll and induction scoring have in common. That the low correlation may be a function of the relationship of hypnotizability to psychopathology is shown by a highly significant correlation ( $r = .52$ ) between eye-roll and induction scores in a population selected as non-psychotic. The usefulness of the HIP in relation to psychodiagnosis has been demonstrated elsewhere and is not the subject of this paper. Evidence is presented bearing on the reliability of the profile and induction scores, both yielding satisfactory reliabilities. Some validity information is given through satisfactory correlations with existing standardized scales. The HIP and Stanford Hypnotic Susceptibility Scale (Weitzenhoffer & Hilgard, 1959) correlate .55.

Spiegel, Herbert; Aronson, M.; Fleiss, J. L.; Haber, J. (1976). Psychometric analysis of the hypnotic induction profile. International Journal of Clinical and Experimental Hypnosis, 24, 300-315.

Psychometric analyses of the Hypnotic Induction Profile (HIP) of Spiegel (1974a), a sixteen point test designed to measure hypnotic capacity, are presented herein. Briefly summarized are the sequential phases of trance experience as monitored by the HIP. On the basis of a factor analysis of individual items entering into the HIP's of 1674 patients, two distinct factors emerged. One is defined largely by up-gaze and eye-roll, the other by some of the subsequent items. Two methods for scoring the HIP, a configurational method involving both factors (profile scoring) and an

actuarial method using only items from the second factor (induction scoring), are defined. As expected from the factor analysis, eye-roll is little related to the HIP graded by either scoring method. The correlation of induction scoring with the eye-roll is .22 in a sample of 1023 patients. Such a correlation is significant, although it accounts for only 5% of the variance that eye-roll and induction scoring have in common. That the low correlation may be a function of the relationship of hypnotizability to psychopathology is shown by a highly significant correlation ( $r = .52$ ) between eye-roll and induction scores in a population selected as non-psychotic. The usefulness of the HIP in relation to psychodiagnosis has been demonstrated elsewhere and is not the subject of this paper. Evidence is presented bearing on the reliability of the profile and induction scores, both yielding satisfactory correlations with existing standardized scales. The HIP and Stanford Hypnotic Susceptibility Scale (Weitzenhoffer & Hilgard, 1959) correlate .55.

1975

Albert, Ira B.; Boone, Donald (1975). Dream deprivation and facilitation with hypnosis. Journal of Abnormal Psychology, 84 (3), 267-271.

We attempted to modify sleep and dreaming through the administration of various posthypnotic suggestions. Subjects were 17 male undergraduates who were selected for high susceptibility to hypnosis. After two adaptation nights, 5 subjects were given a dream-deprivation suggestion, 8 were given a suggestion of dream-facilitation, and the remaining 4 subjects were administered a neutral posthypnotic suggestion. Subjective dream reports were dramatically affected in the predicted directions. Electrophysiological changes were also noted in certain subjects, although these results were not nearly as consistent as the subjective data. The dream-deprivation group had significantly more Stage 1 sleep than the other two groups; and certain of these subjects had much less REM sleep.

1971

Weitzenhoffer, Andre M. (1971). A case of pursuit-like eye movements directly reflecting dream content during hypnotic dreaming. Perceptual and Motor Skills, 32, 701-702. (Abstracted in Current Contents, 3, 34, 16)

Describes a sample of eye movements from a hypnotized S spontaneously dreaming of watching a watch swing on a chain. These were repeated on another dream occasion and in imagination. The study (a) supports the notion that the content of some imagined and dreamed visual experiences is reflected in specific ways in eye movements; and (b) suggests a close relationship between nondream and dream visual and/or motor imagery. 1964

Brady, J. P.; Levitt, E. E. (1964). Nystagmus as a criterion of hypnotically induced visual hallucinations. Science, 146, 85-86.

Hypnotized Ss who report hallucinating a visual situation which would ordinarily elicit optokinetic nystagmus demonstrate nystagmus under these conditions. They and control Ss are unable to feign nystagmus in the waking state, either by imagining the situation or by direct efforts to simulate the eye movements. Thus an objective criterion is provided for the presence of visual hallucinations. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

## EYE/OPHTHAMOLOGY

1993

Lindsay, Suzanne; Kurtz, Richard M.; Stern, John A. (1993). Hypnotic susceptibility and the endogenous eyeblink: A brief communication. International Journal of Clinical and Experimental Hypnosis, 41, 92-96.

This study investigated the relationship between hypnotic susceptibility, hypnotic state, and the endogenous eyeblink with 36 undergraduates, who were assigned to four independent groups (waking-low, hypnotized-low, waking-high, and hypnotized- high susceptibles) on the basis of combined cutoff scores on both the Creative Imagination Scale and the Stanford Hypnotic Clinical Scale for Adults. The auditory vigilance task required subjects to discriminate between 200 ms and 300 ms tones over a 35-minute period. Hypnotic depth was controlled across trials using the Long Stanford Scale of Hypnotic Depth. As predicted, high-susceptible subjects had a significantly lower blink rate than low-susceptible subjects. The predicted interaction between susceptibility and hypnotic state was also confirmed. High-susceptible subjects showed a significant decrease in blinking for the hypnotized condition, whereas low-susceptible subjects did not. The need for replication with more adequate measures of susceptibility is discussed.

## NOTES

1:

In a preliminary study, Weitzenhoffer (1979) found significant differences between high- and low-susceptible subjects following a hypnotic induction. The highs showed a 66% decrease in blink rate from a baseline reading. More recently, Tada, Yamada, and Hariu (1990) reported a series of studies suggesting that blink rate was dramatically reduced during the hypnotic state, as well as finding a relationship between high susceptibility and decreased blink rate. Although these studies tend to support Weitzenhoffer's (1979) research, they are poorly controlled and report no quantitative data" (p. 93).

In the present study, "to assure that subjects kept their eyes open, they were required to maintain their gaze on a dimly lighted box (12" x 12") placed one meter in front of them. Subjects in both conditions were asked to rate their hypnotic depth by using the Long Stanford Scale of Hypnotic Depth (Tart, 1970) before being given a practice trial of 20 tones. Following the practice trial, participants were again asked to rate their hypnotic depth, and the trial period began. Subjects gave subsequent depth ratings every 10 minutes for the remainder of the 35-minute trial. The hypnotic state was maintained across time periods by using deepening instructions when necessary" (p. 94).

In their Discussion, the authors noted that "High-susceptible subjects in the hypnotized state have a significantly lower blink rate and presumably greater attentional focus than lows. Although the interaction was significant and in the predicted direction, it accounted for only a small portion of the overall variance, suggesting that trait differences are more robust than those for state" (p. 95).

1989

Holroyd, Jean; Maguen, Ezra (1989). And so to sleep: Hypnotherapy for lagophthalmos. American Journal of Clinical Hypnosis.

We used hypnosis to facilitate eye closure during sleep for a 44-year-old woman whose nocturnal lagophthalmos prevented use of a contact lens following cataract surgery and could have resulted in severe corneal damage. On three separate occasions the symptoms remitted following a very brief course of treatment. We discuss the results in terms of alternate theories of hypnotic performance.

NOTES

1:

The Discussion section notes, "There was an excellent correlation between the onset of hypnotherapy and the cessation of the recurrent corneal erosion secondary to nocturnal lagophthalmos. Healing of corneal erosion, disappearance of the superficial punctate keratopathy, and alleviation of ocular foreign body sensation occurred promptly following hypnotherapy (with two separate therapists)" (pp. 267-268).

The authors present the view that "heightened suggestibility, more vivid imagery, and more specific influence of thoughts upon organ systems probably came into play (Brown & Fromm, 1986; Holroyd, 1987). Social influence explanations (role taking, expectancy, compliance) seem less relevant as explanations. This highly motivated patient had not been able to keep her eyes closed during sleep despite her conscious efforts, her "good-patient" role, her positive expectations about the benefits of standard treatments, and respectful incorporation of the assistance provided by her ophthalmologist" (p. 268).

Miller, Scott D. (1989). Optical differences in cases of multiple personality disorder. Journal of Nervous and Mental Disease, 177 (8), 480-486.

Nine patients (aged 24-43 years) diagnosed with multiple personality disorder (MPD) and 9 control Ss role-playing MPD were given complete ophthalmological examinations to test whether the MPD Ss would show greater variability in visual functioning across alter personalities than would control Ss role-playing MPD. An analysis of variability of 8 optical measures in 4 prominent areas of vision was performed by comparing 2 covariance matrices for equality. Analyses showed that MPD Ss had significantly more variability across alter personalities than did their control counterparts on measures of visual acuity with correction, visual acuity without correction, visual fields, manifest refraction and eye-muscle balance. Ratings for clinical significance showed that the MPD Ss had 4.5 times the average number of changes in optical functioning between alter personalities of the control Ss.

1984

Murphy, Joseph K.; Fuller, A. Kenneth (1984). Hypnosis and biofeedback as adjunctive therapy in blepharospasm: A case report. American Journal of Clinical Hypnosis, 27, 31-37.

The efficacy of ophthalmologic, hypnotic, and biofeedback treatment procedures in a case of blepharospasm was evaluated. Manual eye rubbing and eye opening served as dependent measures which were assessed by the patient during treatment and a three month follow-up. Results indicated that ophthalmologic treatment had a limited effect. In contrast, brief hypnosis had a dramatic but short-lived effect and biofeedback had a moderate but sustained effect. Results are discussed in terms of the efficacy of psychological intervention, the limitations of the report, and the need for future research.

1982

Cunningham, Paul V.; Blum, Gerald S. (1982). Further evidence that hypnotically induced color blindness does not mimic congenital defects. Journal of Abnormal Psychology, 91, 139-143.

Six undergraduate women, highly skilled in hypnotic techniques, were trained under hypnosis with a color mixer to experience red, green, blue, and total color blindness and were then programmed for the same responses in the posthypnotic state under conditions of amnesia. After awakening they were shown pseudoisochromatic plates as a preliminary check on the efficacy of the prior hypnotic instructions. The experiment consisted of successive administrations of the Farnsworth-Munsell 100-hue test, initially under normal baseline viewing conditions followed by each of the color-blind conditions in turn. Results indicate that although the observers subjectively experienced the varieties of color blindness as instructed, their responses differed from specimen responses of individuals with congenital defects in color discrimination. Implications for interpreting hypnotic alterations of perception are discussed.

Sheehan, Eugene P.; Smith, Howard V.; Forrest, Derek W. (1982). A signal detection study of the effects of suggested improvement on the monocular visual acuity of myopes. International Journal of Clinical and Experimental Hypnosis, 30, 138-146.

2 groups of 8 Ss each, matched for suggestibility and degree of myopia, were assessed by a signal detection method in their ability to make a monocular spatial discrimination, both before and after 15 minutes of listening either to music or to taped suggestions that vision would improve. There was a significantly greater improvement in sensitivity on the part of the group of Ss listening to suggestions, and within this group, but not within the group of Ss listening to music, there was a significant negative correlation ( $r = -.67$ ) between S's initial sensitivity and the amount by which it increased. There was no significant difference between the

amounts by which the criterion changed in the 2 groups. In contrast with the results reported by Graham and Leibowitz (1972), there was no evidence in the present study to indicate that the amount of improvement shown by Ss depended upon either their suggestibility as measured by BSS or their refractive error.

NOTES

1:

"In contrast with the results reported by Graham and Leibowitz (1972), there was no evidence in the present study to indicate that the amount of improvement shown by Ss depended upon either their suggestibility as measured by BSS or their refractive error" (p. 144).

1972

Graham, Charles; Leibowitz, Herschel W. (1972). The effect of suggestion on visual acuity. International Journal of Clinical and Experimental Hypnosis, 20, 3.

NOTES

1:

In experiment one, all subjects participating attained the maximum score on the BSS. The subjects were hypnotized and post-hypnotic suggestions were given to the effect that the subject really knew how well they could see, and this was contingent upon relaxation. The patient was now given an opportunity to re-read the eye charts. It was found that in this experiment, myopic visual acuity was significantly improved through the use of hypnosis and positive suggestion.

In experiment two, subjects who scored the maximum and the minimum on the BSS were used. The same procedure was used as in number one except that the highly susceptible subjects were told that "various studies had demonstrated that being hypnotized was not a pre-requisite for obtaining improvement." The insusceptibles were told that "acuity improved under hypnosis, but like many other phenomena associated with hypnosis, improvement in vision was also well within the reach of the non-hypnotizable subjects, if they simply learned to relax their eyes." it was found that myopic visual acuity was significantly improved in the absence of a formal hypnotic induction. This improvement was for the highly hypnotizable subjects only, and did not transfer to outside the experimental situation.

In experiment three, subjects were used who scored the maximum on the BSS and the Harvard Group Scale. Testing was done in both the hypnotized and waking state. it was found that the rank order correlation between initial and final acuity levels was .98 ( $p < .001$ ), indicating the effect of suggestion was selective.

1969

Weitzenhoffer, Andre M. (1969). Eye-blink rate and hypnosis: Preliminary findings. Perceptual and Motor Skills, 28, 671-676.

Tests the validity and reliability of certain features of the outer appearance of hypnotized individuals which have long been popularly and clinically considered good indices of "hypnosis." The present report focuses on eye-blink rate. 19 Ss were administered a slight modification of the Stanford Scale of Hypnotic Susceptibility, Form A. Samples of their blink rates were obtained prior to the induction of

hypnosis and some time after the induction of hypnosis procedure had been terminated, but before the dehypnotization procedures began. The results support the popular and clinical belief that hypnotic-like behavior is accompanied by a decrement in blink rate to the extent that Ss scoring 6 or more points on the Stanford Scale showed a marked and statistically significant mean reduction in blink rate of over 60% following the induction procedure and some testing of their suggestibility. In contrast, Ss scoring 5 or less and presumably not hypnotized but merely suggestible to non-suggestible, did not show a statistically significant decrement. As a possible index of "hypnosis," such a decrease in rate was found to have a test-retest reliability of .86. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

## **FACTOR ANALYS**

**1993**

**Woody, Erik Z. (1993, October). Factors, facets, and fiddle-faddle. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.**

## **NOTES**

**The classic suggestion effect implies involuntary behavior. A theory by Norman & Tim Shallice (published in a book on cognitive neuropsychology by Shallice) explains the classic suggestion effect in terms of underlying control processes.**

There are 2 complementary systems: 1. contention scheduling (routine acts that don't require conscious control, activating schemas through environmental events and other schemas) for well learned habitual tasks. 2. supervisory attentional system - nonroutine actions in centralized processes, accessing unique information, operating only indirectly by modulating lower level control system, biasing their selection of schemas by system #1.

These two systems permit the sense of behavior being automatic or willed. The theory can be used to explain hypnotic nonvolition. For highs, hypnosis may partly disable System #2, dissociating lower levels of control and resulting in genuine changes in behavior because System #1 would be more enabled, triggered directly by co-active schemas and environmental stimuli. This increased dependence on a lower level of control would not rule out a wide range of behavior. It's mainly novel or very complex behaviors that would diminish, plus exercise of will.

The model also illuminates our understanding of behavioral rigidity and the tendency for thought/action to be triggered by [suggestions?]. Spontaneous voluntary behavior would be diminished. (See for example Orne's studies of the effect of apparent power outage during an experiment, in which high hypnotizable Ss did not move or leave the room but sat passively, whereas low hypnotizable simulating Ss simply got up and left.)

Also a weaker "supervisor" would lead to disinhibition of inappropriate or peculiar associations or behavior. In labs one sees few such triggers, although Hilgard observed drug flashbacks. The phenomena of hypnosis sequelae appear like a disinhibition of experiences.

Hypnotic analgesia follows this model too, an automatic and controlled processing of perceptual input.

Amnesia that follows hypnosis can be explained by this theory. Shallice has a model of how memory is affected: memory is a higher control system, enabling the handling of non-routine situations. Confronted by a nonroutine memory problem, the supervisory system formulates a model of what [the information] should look like, pulls out memories, and compares the model. If hypnosis interferes with the supervisor function it should interfere with memory (the description and verification phases) leading to [hypnotic amnesia?]. [With hypnosis one would predict]: 1. Poor access to memories requiring description (not overlearned material). Recall should demonstrate good cued memory but poor free recall. [It has been observed that] hypnotic amnesia selectively impairs free recall rather than recognition recall. 2. Hypnotized Ss should show poorer verification (the ability to discriminate irrelevant from correct associations). Many studies have shown this, with impoverished verification (e.g. the "discovery" of elaborate previous lives).

A dissociated control theory of hypnosis is thus possible, emphasizing a loss of control of supervisory system processes. It would implicate changes in frontal lobe processing. The essence of hypnosis, according to this approach, is the bypassing of executive control, and the frontal lobe is viewed as a center of executive control.

There are several ways that hypnosis suggests inhibition of frontal lobe functioning: 1. impoverishment of self initiated behavior 2. other-directedness 3. frontal amnesia (unable to distinguish true memories from irrelevant memories; prone to

confabulation, especially when probed with false information) 4. poorer in temporal or sequential organization in memory.

How do we proceed to make this theoretical approach useful? We should do more neuropsychological studies, as Helen Crawford does. They emphasize the inhibition of frontal lobe functions.

Testable hypotheses arise: 1. Hypnotizable Ss should show the same kind of problem solving problems as frontal lobe patients. 2. Memory of hypnotized Ss should be like patients with frontal amnesia.

1992

Balthazard, Claude G.; Woody, Erik Z. (1992). The spectral analysis of hypnotic performance with respect to 'Absorption'. *International Journal of Clinical and Experimental Hypnosis*, 40, 21-43.

In factor analyses of the hypnosis scales, the essential result is that the items form a continuous, 2-dimensional fan-shaped pattern. This continuum is referred to as the "spectrum of hypnotic performance." "Spectral analysis" is introduced as an exploratory procedure which makes use of this notion of continuum or spectrum. Spectral analysis consists of a graphical display of the level of latent correlation between a variable and individual hypnotic performances when the latter are arranged according to their position in the spectrum. The spectral analysis of hypnotic performance with respect to absorption is illustrated using data from a sample of 160 Ss. The results indicate that absorption is more strongly related to difficult hypnotic performances than to easy ones. In particular, illustrative item characteristic curves are presented to show that although easy hypnotic performances do not require the processes tapped by individual differences in absorption, a certain level of absorption is necessary to pass difficult hypnotic items. In addition, a high level of absorption may be sufficient in and of itself for difficult hypnotic performances. These results are discussed in light of some speculations by Shor, M. T. Orne, and O'Connell (1962) and Tellegen (1978/1979) concerning the differential contribution of ability components to performance on difficult hypnotic suggestions. The results are also related to a variety of work in social psychological models of hypnotic performance.

#### NOTES

Spectral analysis "consists of a graphical display of the level of latent correlation between a variable and individual hypnotic performances when these hypnotic performances are arranged according to their position in the spectrum---which is indexed by item difficulty" (p. 25). Difficulty (the proportion of Ss that pass a given item) is on the X-axis; the degree of latent correlation is on the Y-axis. "It is necessary to differentiate between the manifest and the latent relationship of a variable to a dichotomously scored hypnotic performance. The manifest relationship is given by the point biserial correlation and the latent relationship is given by the biserial correlation. ... By inspecting the overall pattern of these biserial correlations as a function of item difficulty, it is possible to overcome the difficulty-content

confound, because the biserial correlations are not affected by item difficulty" (p. 25).

"Throughout the easy and middle ranges [of item difficulty], the biserial correlation of hypnotic performance with absorption remains slightly above .2, then it rises sharply in the difficult range--beginning roughly where only one in four Ss can pass the item--to a value slightly above .5 " (p. 27). "In essence, the proportion of Ss that pass a particular hypnosis suggestion given a particular score on the absorption scale is being plotted" (p. 30).

In their discussion, the authors relate their position to that of other theorists. Shor, Orne, & O'Connell (1962) proposed that both ability and nonability components contributed to hypnosis, with ability being the primary determinant of hypnotic performance at deeper levels. Shor et al. found a correlation between depth ratings and a questionnaire that tapped 'hypnotic-like experiences' to be .45; the correlation was .84 when computed for only the Ss who became deeply hypnotized, but only .17 for Ss who were only lightly or medium-level hypnotized. They concluded that their questionnaire predicted hypnotizability only for the "deeper region" of hypnosis.

Tellegen (1978/1979) proposed a two-factor model, one factor being genuine responsiveness and the other being compliance . He suggested that various hypnosis test items draw on the two factors in differing degrees. Tellegen's genuine responsiveness factor would be similar to Shor et al.'s ability components, and Tellegen's compliance factor would be similar to Shor et al.'s non-ability components. (The Shor model goes farther than Tellegen in positing a gradual shift in the relative contributions of the two components as one moves from easy to difficult items, and this gradualness is part of the authors' spectrum model.)

The two-factor model is different from the general factor (plus special factors) model suggested by E. R. Hilgard (1965)); Hilgard's general factor would probably correspond better to the Tellegen genuine responsiveness factor and the Shor et al. ability component than to the compliance factor or nonability component, which probably would correspond more to the easier items on hypnotizability scales.

Spanos et al. (1980) suggested that cooperativeness and expectation might be more important with ideomotor and challenge suggestions, and ability to treat imaginings as real (i.e. absorption) more important for more difficult cognitive items. Sarbin (1984) developed a typology with two types of individuals--those who respond to the hypnosis context by "joining the game" and knowingly create an illusion that their response is involuntary (the compliance kind of response), and those who convince themselves and others that their response is involuntary (the genuine responsiveness factor kind of response).

[Speaking of the context effects observed but not replicated 100% of the time, on the correlation between absorption and hypnotizability.] "It is possible that context effects may depend on the difficulty of the hypnotic suggestions and the latent abilities of the sample used. For relatively good hypnotic Ss performing relatively difficult suggestions, the correlation of absorption with hypnotizability may be stable across different contexts; however, for less able Ss performing relatively easy suggestions, the correlation, depending more on the 'non-ability' component, may be quite responsive to context manipulations. It might also be mentioned parenthetically that details of the instructions used to introduce the particular

hypnosis scale employed may differentially pull for one kind of component or the other" (p. 39).

**Brentar, John P.; Lynn, Steven J. (1992, August). The Post-Hypnotic Experience Scale: Validity and reliability. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, DC.**

**This paper describes the development of the Posthypnotic Experiences Scale (PES), a 57-item scale comprised of four subscales labeled Pleasant, Somatic- Kinesthetic, Irritability/Anger, and Anxiety. It was derived by way of an initial factor analysis using 444 subjects and refined by a second factor analysis using 288 subjects. In three data collection phases, the subscales were found to be internally consistent and to exhibit low to moderate test-retest reliabilities. The PES was also found to evidence excellent content, convergent, and discriminant validity, as measured by indices of hypnotizability, positive affect, depression, anxiety, hostility, sensation seeking, dysphoria, social desirability, perceptual aberration, absorption, and physical symptomatology. Behavioral validity was demonstrated in so far as subjects who were willing to volunteer for a second experiment, without reimbursement, scored higher on the Pleasant subscale than did nonvolunteers. (ABSTRACT from the Bulletin of Division 30, Psychological Hypnosis, Fall, 1992, Vol. 1, No. 3.)**

**Frischholz, Edward (1992, October). The dimensionality of hypnotic performance. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.**

#### **NOTES**

**A 1985 article by Balthazar & Woody in Psychological Bulletin is the best I have read on this topic, and on how factor analysis can be used fruitfully.**

**Many people using the same data sets have arrived at difference conclusions. My results are based on two data sets: Balthazar & Woody's, in which they created a unidimensional scale. (If you factor analyze a simplex matrix you obtain a 3 factor matrix; yet you knew it was unidimensional. They pointed out the 2nd factor correlated with item difficulty, and the 3rd factor had a U-shaped correlation with item difficulty.)**

**Factor analysis may not be best way to demonstrate unidimensionality.**

**I decided to use non metric multidimensional analysis to confirm unidimension. By this, Form A appears to be multidimensional. The same holds true for Stanford Form C scale.**

**Interpretability of the different dimensions? I agree with Dr. Stone: unidimensions are better for interpreting tests. But you should start out by constructing one in the first place.**

**I argue that Form C is unidimensional, because the items were selected by using item/full score correlations, hence a first component was built into it. But what does the scale measure? The only way to know is to correlate it with external measures,**

like Woody does. There are no studies using factor analysis showing that different factors on hypnotizability tests have different correlations with external measures (e.g. Factor 1 doesn't correlate differently with Absorption than Factor 3).

We might better start with a theory if we are going to construct new hypnotizability scales. Don't just use item total correlations. It would be better to find items representing different dimensions, scale the items, then correlate them with different external referents.

Then when we do collect data, make sure the items are unidimensional representations.

Third, we should appropriately validate these dimensions.

Stone, Mark H. (1992, October). Rasch scaling of hypnotizability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

The author calibrated responses to the Stanford Scales of hypnotizability, which have not been used much by clinicians. Much of the data collected by Hilgard and Weitzenhoffer on the development of those scales was not published.

Rasch measurement techniques analyzed item data taken from the individual Form A and B manuals.

The Rasch measurement involves natural Log odds, adjusted by variance of the respective persons. Thorndike's text explains this procedure taken from Wright & Stone, 1979, Best Test Design.

The calibration of items on Forms A and B of the Stanford scales indicates they differ greatly on difficulty and order of items. Items 1, 2, 3 are among the most difficult. Yet, items should follow item difficulty order.

For practicing clinicians, the mean and SD are inadequate to guide treatment. The practitioner wants to know how the patient responds to each item, compared with what would be expected (Like a Chi square). When data from misfit analysis is combined with clinical observation, we would get more understanding [of the patient's capabilities].

Not only are the 12 items not in order of difficulty, but there is redundancy. We could shorten the scale by selecting only items that span the same range of item difficulty: 4, 8, 10, 11, 2, 1 or 7, and 3. This would give a screening scale with wider range measured, more finely graduated, better suited to diagnosing misfit. We could connect seemingly disparate scale items.

Form C has a perfect correlation between order of difficulty and order of administration, except for 12 which must be administered earlier.

Forms I and II [the Profile scales] deviate from the administration order and the difficulty order.

Only Form C seems to be located in the way the author would want, a Guttman type scale (which is Like Rasch's analysis).

Woody, Erik Z.; Oakman, Jonathan; Drugovic, Mira (1992, October). Fleshing out a two-component view of individual differences underlying hypnotic responsiveness. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

Balthazar and I pointed out that different psychological processes are implicated in hypnotizability scale items, depending on the difficulty of the item. One process is more important on easy items, the other on difficult items.

We correlated an external variable as a function of difficulty of the items. Used the Absorption scale as the non-hypnotic measure for the latent correlation (biserial correlations). As item difficulty increases, the correlation with Absorption increases (from .2 to .5).

This suggests a high level of Absorption is needed to pass difficult items on the hypnotizability scale. We argued that Absorption is connected to true hypnotic responsiveness.

Now we are looking for indicators of easy item responsiveness. Last year I tried to explain anomalies in the data, anomalies that disappeared with a full complement of Ss.

Another possible external variable to correlate with item difficulty is a social compliance type of attribute, but in the history of hypnosis those variables are not found. Therefore we used a model from alcohol research that investigates an expectancy type of suggestion.

In that model, Ss drank two drinks that were alcohol free, but one drink purportedly had alcohol. Ss were told that large amounts of alcohol affect changes in perception, and that we were testing whether small amounts did. They were tested for "feeling of sluggishness in limbs," etc. They rated a list of experiences they might be having. The 109 Ss had been tested on Harvard A scale in separate research.

Ratings in the alcohol model had high internal consistency; this suggestion score correlated with hypnotizability in .2-.3 range.

The pattern of latent correlations would be predicted to be a graph with a negative slope, which the researchers obtained.  $R = -.77$

The easier the hypnosis item, the stronger the correlation with the expectancy measure. The easiest Harvard A scale items tap little more than those expectancy effects, and the hardest items have almost nothing to do with the expectancy effect.

What does this mean? We thought it was evidence of a social influence factor. Further work suggests we need to be more specific.

We measured the other putative variables: 1. Compliance Questionnaire (Gudjonsson, 1989); it evaluates the tendency to comply with requests, and to obey instructions; e.g., "I tend to go along even when someone is wrong." It has correlated with a measure of social conformity. 2. Suggestibility Questionnaire (which we developed). Items were based on interviews in which Ss told about everyday suggestible things--e.g. "When I hear about an illness I tend to get it. When someone tells me they smell something, I tend to also."

These Compliance and General Suggestibility tests correlated .12 and .07 respectively with the alcohol expectancy measure; nor did they correlate with each other. They do not measure the same trait. Also, though they correlated .18 and .26 with hypnotizability, neither variable showed the spectral pattern on latent correlation analysis.

Thus, we need to be more specific in linking the alcohol expectancy measure to hypnosis.

Most items on Harvard A scale are motor items of either direct suggestion or inhibition (challenge) type. The relationship of alcohol expectancy to direct motor items is strong; the relationship is weaker with motor challenge items (for which another process must be important).

We can think of will vs automatic control of behavior, as in the theory presented by Normal and Shallice. For well-learned behavior there are two levels of control: 1. low level - doesn't require conscious attention and control 2. higher level - relevant to initiation of action, planning

Direct motor suggestion response requires little attentional effort and the role of will is not important. There exists ambiguity for indeterminacy of the role of will and attention. Ambiguity offers an opportunity to attribute one's action to hypnosis. What happens in alcohol expectancy is different, but an ambiguous experience is happening due to "alcohol" in the drink--ambiguous experience is interpreted according to the context.

This differs from the neodissociation theory explanation, according to which the suggested behavior is enacted voluntarily but the voluntary aspect is separated from consciousness. To me, for simple motor acts the causality is inferred rather than perceived. For simple motor acts, no such higher level control is needed.

Motor challenge items have instructions to "try" to overcome; S must exert will. "Try to raise your arm" is different from "Raise your arm." The S could remain role consistent and not try; ambiguity is maintained and the S could look to the context for an explanation.

In the Normal and Shallice model, hypnosis weakens the higher system relative to the lower system. The S might be trying to exert will but experience it as less [influential] than in the normal state. Such capacity would not be tapped by an alcohol expectancy measure.

We think of individual differences in hypnotizability as multiple processes, like a tree that consists of more than one healthy branch but has plenty of dead wood to be pruned out.

Ross, Colin A.; Joshi, S.; Currie, R. (1991). Dissociative experiences in the general population: A factor analysis. *Hospital and Community Psychiatry*, 42, 297-301.

The 28-item Dissociative Experiences Scale was administered to a stratified cluster sample of 1055 respondents in a general population of Winnipeg. Dissociative experiences were common in the sample and were not related to socioeconomic status, sex, education, religion, or place of birth, although they declined with age in both sexes. A principal components analysis identified three factors accounting for

47.1% of the combined variance of scores. The first factor, absorption-imaginative involvement, is composed of common, benign experiences such as missing part of a conversation, being able to ignore pain, staring into space, absorption in a television program or movie, not being sure if you did something or only thought about it, and remembering things so vividly one seems to be reliving it. The other two factors, activities of dissociated states and depersonalization-derealization, composed of less common experiences such as not recognizing friends or family members and not recognizing one's own reflection in a mirror, may be powerful predictors of DSM-III-R dissociative disorders.

1990

Fischer, Donald G.; Elnitsky, Sherry (1990). A factor analytic study of two scales measuring dissociation. *American Journal of Clinical Hypnosis*, 32, 201-207.

The present study was designed to investigate the construct validity of dissociation. We administered the PAS and the DES to 507 male (48%) and female (52%) undergraduate students. Factor analysis on each scale separately showed that neither the PAS nor the DES adequately measures the three dimensions hypothesized to underlie dissociative experience. For both scales, a single factor emerged as replicable and reliable. Use of the scales, in their present form, therefore, should be limited to a single dimension representing disturbances in affect-control in the case of the PAS and disturbances in cognition-control if the DES is used at least with normal populations. Analysis of the combined items showed that the scales are measuring conceptually different but statistically correlated dimensions of dissociation. Further development of both scales is desirable, and further research should investigate the effect of different response formats on the internal structure of the scales. NOTES 1: NOTES: The stated purpose of this study was to investigate the internal structure of the Perceptual Alterations Scale (PAS) and the Dissociative Experiences Scale (DES) using a large sample from a normal population.

"Sanders (1986) conceived of dissociation as a personality trait that is characterized by modification of connections between affect, cognition, and perception of voluntary control over behavior, as well as modifications in the subjective experience of affect, voluntary control, and perception. She chose items from the MMPI to represent this trait. Bernstein and Putnam (1986), utilizing the DSM-III definition of dissociation, constructed items from information derived from interviews with patients and clinicians to represent a number of different types of dissociative experiences" (0. 202).

"The PAS (Sanders, 1986) is a 27-item scale; subjects respond by checking one of the following categories using a 4-point Likert format: never, sometimes, frequently, almost always. The items related to modifications of regulatory control, changes in self- monitoring, concealment from self and others, and modifications of sensory, perceptual, and affective experiences.

"The DES (Bernstein & Putnam, 1986) contains 28 items. Subjects indicate the percentage of time they experience the feelings or behavior described by the items on a 10- point scale. The items related to the experience of disturbances in identity,

memory, awareness and cognition, and feelings of derealization or depersonalization" (pp. 202- 203).

Results were as follows. The one-factor solution for the PAS accounted for 18.5% of the total variance.; 11 of the 28 items did not load significantly on the factor. The one-factor solution for the DES accounted for 26.3% of the total variance; 7 of the 28 items did not load significantly on the factor.

"The 3-factor solution obtained by Sanders (1986) for the PAS was not replicated. An obvious reason for the different is that principal factor extraction was used in the present study, whereas principal components extraction was utilized by Sanders. ... Even when principal components analysis is performed on the present data, however, there are difficulties with the 3-factor solution" (pp. 204-205).

"All of the criteria suggest that a single factor best represents the latent structure of dissociative experience as measured by the PAS and DES. Although the total amount of variance accounted for is low, the one-factor solutions for both scales are interpretable, replicable, and have high internal consistency. The items for the PAS appear to represent primarily the affect and control dimensions, whereas those for the DES represent the cognitive dimension" (pp. 205-206).

"Overall, both scales contain similar items, although the DES has more items relating to disturbances in memory and altered perception of time (i.e., cognition), whereas the PAS has more items reflecting specific disturbances in identity and control. It appears, therefore, that the scales are measuring conceptually separate but statistically correlated dimensions of dissociation" (p. 206).

Kihlstrom, John F.; Register, Patricia A.; Hoyt, Irene P.; Albright, Jeanne Sumi; Grigorian, Ellen M.; Heindel, William C.; Morrison, Charles R. (1989). Dispositional correlates of hypnosis: A phenomenological approach. *International Journal of Clinical and Experimental Hypnosis*, 37, 249-263.

Attempted to construct and validate a questionnaire measure of hypnotic- like experiences based on Shor's (1979) 8-dimension phenomenological analysis of hypnosis. Separate item pools were developed to measure each disposition: Trance, Nonconscious Involvement, Archaic Involvement, Drowsiness, Relaxation, Vividness of Imagery, Absorption, and Access to the Unconscious. Based on preliminary testing (total Number - 856), a final questionnaire was produced containing 5 items measuring normal, everyday experiences in each domain. Results from a standardization sample (Number - 468) showed that each of the subscales, except for Archaic Involvement, possessed satisfactory levels of internal consistency and test-retest reliability. Factor analysis indicated that 6 subscales loaded highly on a common factor similar to the absorption construct (Tellegen & Atkinson, 1974), while items pertaining to Relaxation and Archaic Involvement formed separate factors. Validation testing on 4 samples receiving the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962) (total Number = 1855) showed that the Absorption and Trance dimensions correlated most strongly with HGSHS:A; the correlations with Drowsiness, Relaxation, and Nonconscious Involvement approached 0. The scales derived from Shor's analysis,

however, did not improve the prediction of hypnotizability over that obtained with the absorption scale (Tellegen & Atkinson, 1974).

**McConkey, Kevin M. (1983). Behaviour, experience, and effort in hypnosis. Australian Journal of Clinical and Experimental Hypnosis, 11, 73-81.**

**Subjects were administered the Harvard Group Scale of Hypnotic Susceptibility, Form A, and were afterwards asked to rate the degree to which they experienced the items; subjects also scored their behavioural performance on the items. Data were analyzed to explore the relationships among behaviour, experience, and effort. Findings indicated a significant positive relationship between behaviour and experience on all of the HGSHS:A items, a significant negative relationship between behaviour and effort on the ideomotor items, and a significant positive relationship between behaviour and effort on the cognitive items. A similar pattern was observed between experience and effort. Also, subjects of varying HGSHS:A responsivity differed in terms of overall experience of the scale but not in terms of the overall amount of effort that they expended. Implications of the data are discussed in terms of the factors influencing subjects' experiential response and behavioural performance as well as the attributions that they make concerning effort during hypnosis.**

**Burns, Ailsa (1977). The distribution and factor structure of hypnosis scores following intervention. International Journal of Clinical and Experimental Hypnosis, 25, 192-201.**

**An intervention procedure was found to produce significant gains in hypnotic performance in a sample of 90 Ss. It was argued that the postintervention scores could be regarded as a measure of asymptotic rather than average hypnotizability. The distribution and factor structure of these scores were then considered to see whether these differed from what is generally found when average hypnotizability is measured. Using Orne and O'Connell's (1967) Diagnostic Rating Scales, a trimodal distribution was obtained with the modes falling at the top of the ideomotor passive range, the bottom of the cognitive range, and the middle of the "classic somnambulist" range. Analysis of subscale scores based on this distribution indicated the presence of a trait of general hypnotic competence. A 3-factor solution gave a strong general hypnotic factor, best represented by challenge items, a second ideomotor passive factor, and a third factor which could represent either a difficulty or a dissociation dimension. A 4-factor solution reduced the generality of the first factor, gave it more the appearance of a challenge factor, and introduced a strong imagery factor along with a passive ideomotor and a posthypnotic suggestion/negative hallucination factor. The size of the unrotated first factor was found to compare favorably with that obtained in other studies: this could be interpreted as meaning that the effect of training is to increase the size of the general factor in hypnotic performance. It is suggested that the 3 modes may represent 3 hierarchically arranged "ideal types" of hypnotic response, and that the effect of training has been to push members of the 3 classes closer towards their paradigm.**

**Spiegel, Herbert; Aronson, Marc; Fleiss, Joseph L.; Haber, Jerome (1976). Psychometric analysis of the Hypnotic Induction Profile. International Journal of Clinical and Experimental Hypnosis, 24, 300-315.**

**Psychometric analyses of the Hypnotic Induction Profile (HIP) of Spiegel (1974a), a sixteen point test designed to measure hypnotic capacity, are presented herein. Briefly summarized are the sequential phases of trance experience as monitored by the HIP. On the basis of a factor analysis of individual items entering into the HIP's of 1674 patients, two distinct factors emerged. One is defined largely by up-gaze and**

eye-roll, the other by some of the subsequent items. Two methods for scoring the HIP, a configurational method involving both factors (profile scoring) and an actuarial method using only items from the second factor (induction scoring), are defined. As expected from the factor analysis, eye-roll is little related to the HIP graded by either scoring method. The correlation of induction scoring with the eye-roll is .22 in a sample of 1023 patients. Such a correlation is significant, although it accounts for only 5% of the variance that eye-roll and induction scoring have in common. That the low correlation may be a function of the relationship of hypnotizability to psychopathology is shown by a highly significant correlation ( $r = .52$ ) between eye-roll and induction scores in a population selected as non-psychotic. The usefulness of the HIP in relation to psychodiagnosis has been demonstrated elsewhere and is not the subject of this paper. Evidence is presented bearing on the reliability of the profile and induction scores, both yielding satisfactory reliabilities. Some validity information is given through satisfactory correlations with existing standardized scales. The HIP and Stanford Hypnotic Susceptibility Scale (Weitzenhoffer & Hilgard, 1959) correlate .55.

Greenleaf, Eric (1969). Developmental-stage regression through hypnosis. *American Journal of Clinical Hypnosis*, 12, 20-36.

Twenty subjects serving as their own controls were given four developmental tasks under conditions of hypnotic regression (R) and hypnotic simulation (S). Scored interview data were correlated with performances under R and S. Findings: (a) The Ss' pattern of responses is best conceptualized as a 'mixed' regression rather than 'true' developmental regression. (b) Even when Ss are used as their own controls, the R condition is productive of a greater mean number of childlike responses than is the S condition, disregarding response patterns. (c) The S condition scores provide measures of a set of relatively independent, the R condition of a set of relatively unitary performance variables; this in the same Ss. (d) Factor analysis yielded three orthogonal factors: 'outcome by test performance,' a personality constellation and a factor describing interpersonal actions. The specific situational

variable with greatest impact on test performance was the subject's ability to pretend.

1962

As, Arvid; Lauer, Lillian W. (1962). A factor analytic study of hypnotizability and related personal experiences. *International Journal of Clinical and Experimental Hypnosis*, 10 (3), 169-181.

To throw further light on the exclusivity of "primary suggestibility" as reported by other investigators, a factor analysis was performed in a sample of 102 female college students on the basis of the intercorrelations of 23 items of personal experiences earlier shown to be related to hypnotizability, and 19 items from 2 hypnosis scales. No simple factor structure emerged. 2 factors were interpreted: the 1st as a hypnotic factor with special emphasis on the capability to sustain the effect of suggestion over time, and the 2nd as a combination of psychological changeableness and social influencibility. A brief discussion was given of the composite picture of hypnotic susceptibility emerging from the fact that many hypnotic items loaded on both factors. ## FALSE MEMORY

2002

Gravitz, M.A. (2002). The search for Bridey Murphy: Implications for modern hypnosis.. *American Journal of Clinical Hypnosis*, 45, 3-10.

The 1956 publication of "The Search for Bridey Murphy" was a noteworthy event in the history of hypnosis. This internationally best selling book, written for lay readers, described several recorded sessions of alleged time-regression to a prior life nearly two centuries before 1956. While subsequent investigations disproved that claim, there were a number of important implications for the science and practice of hypnosis. Although it was concluded that the Bridey Murphy interviews were products of cryptomnesia, the book was a significant factor associated with a resurgence of public and professional interest in the modality.

## NOTES

The author notes that the hypnotist was a layman who did no mental status evaluation prior to the hypnosis. The author also considers and rejects several alternative hypotheses (reincarnation or regression to past lives; fraud or hoax; monetary motivation on the part of the hypnotist; and development of a dissociated identity, i.e. multiple personality disorder. He concludes, "Tighe's expectancies, her prior hypnotic experiences with Bernstein, her compliance, transference, acquiescence, and heightened suggestibility, could have set the stage for the subsequent behavior of both the hypnotist and subject in a nonconscious interrelationship in which both parties accepted their beliefs as reality" (p. 7).

Scorborja, Alan; Mazzoni, Giuliana; Kirsch, Irving; Milling, Leonard S. (2000, August). Evaluating the exclusions: Comparing influences of hypnosis and leading questions on memory reports. [Paper] Presented at the annual meeting of the American Psychological Association, Washington, D. C..

Recall and memory distortion were assessed in a sample of 50 highly hypnotizable participants, using a modified form of the Gudjonsson Suggestibility Scale. After listening to a story, half of the participants were asked a series of leading questions, and the others a corresponding series of nonleading questions. Half of the participants in each condition were asked the questions following a hypnotic induction, and the other half in a nonhypnotic context. All participants were then asked nonleading questions without hypnosis. No increases in correct responses were found. Both leading questions and hypnosis resulted in increased error rates

and a decrease in "don't know" responses. Implications of the findings regarding the per se exclusion of post-hypnotic testimony are discussed. [Abstract in Psychological Hypnosis: Bulletin of Division 30, Volume 10 Issue 1, Winter-Spring 2001.]

Stern, Clara; Stern, William (1999). Recollection, testimony, and lying in early childhood. Washington, DC: American Psychological Association. (First published in 1909, in German.)

NOTES

This book, previously unavailable to American readers, describes a seminal study by William and Clara Stern, first published in Germany in 1909, documenting their own children's abilities to recollect, recount, testify, and distinguish truth from falsehood" (from publisher statement). Contents: Recognition as the basis of recall; The chronological development of recall and testimonial ability; False testimony-- Mistaken recollections, pseudo-lies, and lies; Recognition; Correct recollection; Purposive recall; Mistaken recollections; Experimental studies of testimony in early childhood; The falsification of testimony through fantasy; Pseudo-lies and lies; Educating young children to report on their experiences; The origins of lying and its prevention; The capability of small children as witnesses in legal proceedings.

1997

Karlin, Robert (1997). Illusory safeguards: Legitimizing distortion in recall with guidelines for forensic hypnosis - two case reports. International Journal of Clinical and Experimental Hypnosis, 45, 18-40.

Two amnesic automobile accident victims remembered the information needed for their ongoing lawsuits during hypnosis. Meeting the recording requirements of the Hurd safeguards led to the admission of hypnotically influenced testimony in court in one case, whereas failure to record led to exclusion in the other. In both cases, closed-head trauma almost certainly prevented long-term memory consolidation. Thus adherence to guidelines for forensic hypnosis legitimized distortions in recall instead of preventing them. Hypnosis used to facilitate hypermnesia alters expectations about what can be remembered, makes memory more vulnerable to postevent information, and increases confidence without a corresponding increase in accuracy. Distortion of recall is an inherent problem with the use of hypnosis and hypnotic-like procedures and cannot be adequately prevented by any set of guidelines.

1996

Perry, Campbell; Orne, Martin T.; London, Ray William; Orne, Emily Carota (1996). Rethinking per se exclusions of hypnotically elicited recall as legal testimony. International Journal of Clinical and Experimental Hypnosis, 44 (1), 66-81.

In 1993, Boggs argued for a rethinking of the per se exclusion of hypnotically elicited testimony. This article analyzes the Minnesota v. Mack (1980) case that

initiated this exclusion and the two Illinois cases Boggs cites in favor of her position. The scientific data on the effect of hypnosis on memory do not support Boggs's position. Rather than providing reasons for rethinking this per se position, these data suggest that it should be retained.

Lynn, Steven Jay; Martin, Daniel J.; Frauman, David C. (1996). Does hypnosis pose special risks for negative effects? A master class commentary. International Journal of Clinical and Experimental Hypnosis, 44 (1), 7-19.

#### NOTES

The authors review evidence in both experimental and clinical hypnosis situations. They conclude that "the available data do not justify the conclusion that hypnotherapy is any more dangerous, or ultimately less effective, than other psychotherapy and relaxation procedures" (p. 13). However, negative effects do sometimes occur in clinic or in laboratory. They indicate that the following situations and factors suggest need for particular care or vigilance:

Increased Psychopathology

Intensified Transference

Misconceptions About Hypnosis

Suggestions May Instigate or Reveal Unexpected Affect

Difficult or Inappropriate Suggestions

Direct Suggestions to Relinquish Symptoms

Countertransference Reactions

Suggestive Procedures and False Memory Creation

Inadequate Training in Psychology and Psychotherapy

Maestri, D.; Perry, C.; Laurence, J.-R. (1996, August). Children's memory for a special event: Exploring the effects of repeated questioning on recall, suggestibility, and photo lineup identification. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.

Recollections of a visit at the Montreal Olympic Stadium from two groups of children (4.5- and 5.5-year-old) were elicited on four occasions with free recall, direct questions, and misleading questions. Recall was evaluated in terms of correct, incorrect, neutral, repeated, omitted, and attributional responses. To study the possibility of children choosing one type of suggestion more readily than the other, the misleading questions were further evaluated in terms of the type of suggestion implied. A photo lineup recognition task of familiar and unfamiliar faces present during the visit was also included. Children displayed high degrees of acquiescence to the misleading questions and a clear preference for the suggestion that did not involve their own person. In the photo lineup identification task, 21-37 percent (across trials) of the children mistakenly judged familiar and unfamiliar faces as having been present at the event. Results were discussed in a legal context. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1996, Vol. 5, No. 3.)

1995

8025, Ruehle & Zamansky, 1995

Neodissociation theory proposes that hypnotic suggestions are performed relatively automatically, whereas sociocognitive theories suggest that effortful cognitive strategies are necessary. To distinguish between the predictions derived from the two theories, we gave hypnotized subjects the suggestion to forget the number eight, and asked them to solve a series of addition problems using that number. It is a well-established finding in cognitive psychology research that subjective estimations of time depend on the amount of cognitive effort expended during that time. Increases in cognitive effort are associated with decreases in subjective time. Accordingly, if hypnotic subjects carry out a suggestion relatively automatically, they should perceive the time taken as longer than if they carry it out using effortful cognitive strategies. Highly hypnotizable subjects under hypnosis and low hypnotizable subjects instructed to simulate hypnosis were given the suggestion to forget the number eight and to replace it with nine. They were then given a page of addition problems, many of which included eights in the solutions, and were instructed to do the problems as quickly and accurately as possible. They were also informed that they would be asked to estimate the time spent completing the problems.

Subjects completed the addition problems and then gave their time estimates. As a control for changes in time estimation brought about simply by being hypnotized, all subjects also completed a series of addition problems without the amnesia suggestion, and again estimated the time. The order of the two conditions (i.e., with and without the amnesia suggestion) was counterbalanced across subjects.

Results showed that the simulators, who intentionally avoided the number eight in their solutions to the problems, perceived the time spent doing these problems as shorter than the time spent doing problems normally, without the suggestion to forget the number eight. The increase in cognitive effort therefore resulted in decreased subjective time, as expected. The hypnotized subjects, on the other hand, showed no difference in their time estimations under the two conditions. The two groups did not differ in their time estimates without the amnesia suggestion, but with the suggestion, the hypnotized group perceived the time as longer than did the simulators. The results, then, are consistent with neodissociation theory, since the hypnotized subjects appeared to expend relatively less cognitive effort in carrying out the amnesia suggestion.. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1995, Vol. 4, No. 3.)

Orne, Emily Carota; Whitehouse, Wayne G.; Dinges, David F.; Orne, Martin T. (1996). Memory liabilities associated with hypnosis: Does low hypnotizability confer immunity?. International Journal of Clinical and Experimental Hypnosis, 44 (4), 354-369.

Retrospective analyses of data from the authors' program of research on hypnosis and memory are presented, with special emphasis on effects observed among low hypnotizable individuals. In Experiment 1, participants completed seven forced-

recall trials in an attempt to remember a series of pictures that had been shown 1 week earlier. For half the participants, the middle five trials were carried out using hypnotic procedures; the remaining participants performed all recall attempts in a motivated waking condition. Hypnosis failed to enhance correct recall for either high or low hypnotizable participants beyond the hypermnesia and reminiscence effects associated with repeated retrieval attempts over time. However, whereas high hypnotizable participants produced substantial numbers of confident recall errors (i.e., intrusions) independent of the use of hypnosis, low hypnotizable participants exposed to hypnotic procedures reported significantly more intrusions than their counterparts in the waking condition. In Experiment 2, participants were asked to identify whether specific recollections, reported during two forced-interrogatory recall tests conducted 1 week earlier, had originated in the first or second of those tests. A general bias to misattribute previously reported recollections to the first of two recall occasions was observed; however, the effect was greatest among low hypnotizables who had undergone the second recall attempt in hypnosis. The findings imply that highly hypnotizable individuals are not unique in their vulnerability to distortions of memory induced by hypnotic techniques. Individuals of lesser hypnotic capacity also manifest memory alterations when exposed to such procedures. -- Journal Abstract

American Medical Association Council on Scientific Affairs (1995). Report on memories of childhood abuse. International Journal of Clinical and Experimental Hypnosis, 43 (2), 114-117.

#### NOTES

The AMA considers the technique of 'memory enhancement' in the area of childhood sexual abuse to be fraught with problems of potential misapplication" (p. 114). "Most controversial are those 'memories' that surface only in therapy and those from either infancy or late childhood (including adolescence)" (p. 114).

Dywan, Jane (1995). The illusion of familiarity: An alternative to the report-criterion account of hypnotic recall. International Journal of Clinical and Experimental Hypnosis, 43 (2), 194-211.

Hypnosis increases the likelihood that participants will report incorrect material at higher levels of confidence. One interpretation of such data is that hypnosis induces individuals to lower the criterion they use to make memory reports. A lowered report criterion could account for the increase in items that participants are willing to report as memories but not for the increase in confidence that typically accompanies hypnotic retrieval. Although some participants may indeed lower their report criterion, this alone should not result in the highly confident confabulation so often observed. An alternative perspective is that for some participants, hypnosis alters the experience of retrieval such that items generated during retrieval attempts are more likely to have the qualities (e.g., perceptual fluency, vividness) usually associated with remembering. This illusion of familiarity would account for the

higher levels of confidence that are so frequently observed in hypnotic recall, and adopting this perspective should lead to even greater caution in the use of hypnosis as an aid to retrieval.

Levitt, Eugene E.; Pinnell, Cornelia Mare (1995). Some additional light on the childhood sexual abuse-psychopathology axis. International Journal of Clinical and Experimental Hypnosis, 43 (2), 145-162.

This exposition is an attempt to unravel the complexities of the relationship between childhood sexual abuse and adult psychopathology. Four facets of the relationship are examined in some detail: (a) the extent of childhood sexual abuse; (b) the probability that sexual abuse in childhood will result in psychopathology in the adult; (c) the reliability of early life memories in later life; and (d) the role of recovered memory of trauma in the healing process. The conclusions of this logico-empirical analysis are that first, government statistics tend to underestimate the extent of childhood sexual abuse, whereas independent surveys tend to overestimate it. Estimating prevalence is further complicated by variations in the definitions of key terms. Possibly the only safe conclusion is that true prevalence cannot be reliably determined. Second, empirical investigations of childhood sexual abuse conclude that not all victims are emotionally injured. A substantial number of these investigations find that a majority of victims suffer no extensive harm. Other variables such as family dynamics are involved; there may be only a few cases in which emotional harm results from sexual abuse as a single factor. Third, memory research suggests that memory in general is a dynamic, reconstructive process and that recall of childhood events is particularly vulnerable to distortion. Memory cannot dependably produce historical truth. Last, there is some clinical evidence that abreaction of a traumatic event in adulthood may have a remediative effect. Similar evidence for childhood trauma is lacking. The belief in the healing effect of recalling and reliving a childhood trauma depends on the therapist's orientation.

Nagy, Thomas F. (1995). Incest memories recalled in hypnosis -- a case study: A brief communication. International Journal of Clinical and Experimental Hypnosis, 43 (2), 118-126.

Accuracy of repressed memories recovered in hypnosis cannot be reliably determined with any greater certainty than non-hypnotically recalled events. Therefore, the practice of therapists' accepting hypnotically enhanced memories as veridical, absent corroborating evidence, is not advocated. A 52-year-old woman with a 27-year history of panic attacks and sleep disorder inadvertently recovered incest memories in hypnosis. Photographs and remembered events by other family members were thought by the patient to provide general support although they did not constitute actual proof of abuse. Implications are discussed.

Sarbin, Theodore R. (1995). On the belief that one body may be host to two or more personalities. International Journal of Clinical and Experimental Hypnosis, 43 (2), 163-183.

The belief in the validity of the multiple personality concept is discussed in this article. Two scaffolding constructions are analyzed: dissociation and repression. As generally employed, these constructions grant no agency to the multiple personality patient. The claim is made that the conduct of interest arises in discourse, usually with the therapist as the discourse partner. In reviewing the history of multiple personality and the writings of current advocates, it becomes clear that contemporary users of the multiple personality disorder diagnosis participate in a subculture with its own set of myths, one of which is the autonomous actions of mental faculties. Of special significance is the readiness to transfigure imaginings into remembering of child abuse, leading ultimately to the manufacture of persons. The implications for both therapy and theory of regarding the patient as agent in place of the belief that the contranormative conduct is under the control of mentalistic faculties are discussed.

1994

Ceci, Stephen J.; Loftus, Elizabeth F.; Leichtman, Michelle D.; Bruck, Maggie (1994). The possible role of source misattributions in creation of false beliefs among preschoolers. International Journal of Clinical and Experimental Hypnosis, 42 (4), 304-320.

In this article the authors examine one possible factor in the creation of false beliefs among preschool-aged children, namely, source misattributions. The authors present the results from an ongoing program of research which suggest that source misattributions could be a mechanism underlying children's false beliefs about having experienced fictitious events. Findings from this program of research indicate that, although all children are susceptible to making source misattributions, very young children may be disproportionately vulnerable to these kinds of errors. This vulnerability leads younger preschoolers, on occasion, to claim that they remember actually experiencing events that they only thought about or were suggested by others. These results are discussed in the context of the ongoing debate over the veracity and durability of delayed reports of early memories, repressed memories, dissociative states, and the validity risks posed by therapeutic techniques that entail repeated visually guided imagery inductions.

Frankel, Fred H. (1994, October). On patients remembering abuse when it in fact may not have occurred. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

The concept of hidden memories has supported the profession of psychotherapy for a century. This process can only occur if there is a mechanism to support it. Bowers says, if memory is not reliably accurate, it is not reliably inaccurate either.

"Ideas passing as descriptions lead us to equate the tentative with [the factual.]" - Gould.

Three studies purporting to establish repression: 1. Briere & Comte sampled 450 adults who reported abuse. They asked, "Was there ever a time when you couldn't remember the forced experience?" How does respondent understand the question? Clients were all in therapy. 2. Herman and Schatzow (1989) "verification of abuse" study. 53 Ss in a survivor's group. Reports percentages who had no or little recall. Authors don't acknowledge that the group discussion and the attitude of therapist may have shaped the response. It is also not clear how many Ss who claimed to have "verified" their accounts were among those who had severe amnesia for the event. They could be Ss who had never lost the memory in the first place. 3. Williams interviewed women who earlier were in Emergency Rooms because of abuse being suspected. 38% did not report childhood abuse when questioned, and author concluded it was due to repression. Significant numbers of adults cannot remember things even past the age of 5.

Problem with wording of questions. Some of the women interviewed might have preferred not to report the event. This was not investigated in the study.

Frankel, Fred H. (1994). The concept of flashbacks in historical perspective. International Journal of Clinical and Experimental Hypnosis, 42, 321-336.

A computer search of the literature for papers indexed under "flashbacks" produced a list of 70 references, many found in publications on the topics of substance abuse and trauma. Several of these were letters or papers written in languages other than English. In all, the author reviewed 55 papers. Although most of these papers contained comments that addressed the subject matter to some extent as recurrences or reminiscences of past happenings, the variability in the use of the term leaves many unresolved questions regarding the veridicality of the imagery. Nothing in the presentations reviewed by the author clearly demonstrates the unidimensional nature of flashbacks nor any recognizable neurophysiological correlate. The content of a flashback appears to be at least as likely to be the product of imagination as it is of memory.

Ganaway, George K. (1994, October). The thin line: Reality and fantasy in hypnotically facilitated memory retrieval during psychotherapy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

## NOTES

Historical review: Every hundred years there has been a peak in interest in altered states--a fin de cicle zeitgeist. It is the Brigadoon effect, i.e. something materializing for one day every 100 years. The theories developed then suffer from "paradigm grandiosity." In hypnosis, we can refer back to:

1694 Salem witch trials

1790s Gaussner's exorcism (see Ellenberger); in a 1775 showdown between him and Mesmer, there occurred the turning point between exorcism and psychotherapy.

1880s Charcot at Salpêtrier 'demonstrated' that hypnosis was an organic, pathological condition. Ultimately this contributed information about the plasticity

of hypnotized people. (In the 1880s Bernheim thought it wasn't pathological and thought that suggestion was the important element in hypnosis.)

Recent historical contributions have influenced our views of MPD. Spiegel and Kardiner published book about hypnosis and war neuroses. Cheek & LeCron developed ideomotor questioning, which ignores the contribution of unconscious fantasy. Jacob Arlow's metaphor for MPD is two movie projectors aiming at a screen from two different sides. The subjectively known experiential world thereby combines external reality and the person's internal, motivated perceptions. The author presented a case study of female therapist, who had been previously diagnosed as MPD, who presented with dissociative symptoms that she thought were due to abuse by her grandmother. She fabricated the memories in order to get the holding and physical nurturing from her therapist for being courageous and remembering the abuse.

Maintenance of professional boundaries is very important in treatment.

Garry, Maryanne; Loftus, Elizabeth F. (1994). Pseudomemories without hypnosis. International Journal of Clinical and Experimental Hypnosis, 42 (4), 363-378.

Hypnosis is often colloquially associated with "the power of suggestion"; however, some cognitive memory researchers believe that suggestions have power even without hypnosis. A well-known phenomenon in cognitive psychology is the "misinformation effect," in which subjects who are misled about previously witnessed events often integrate that inaccurate postevent information into their accounts of the event. In the present article, we review the misinformation literature in four major rounds according to the nature of the memory distortion. The first three rounds are studies of memory suggestibility for observed events; by contrast, the fourth (and newest) one deals with personal or autobiographical memory. Considered collectively, these four rounds of research provide compelling evidence that it is not hard at all to make people truly believe they have seen or experienced something they have not -- without any hypnosis at all. Finally, we discuss the tragic implications for the unquestioned acceptance of all recovered memories.

Kihlstrom, John F. (1994). Hypnosis, delayed recall, and the principles of memory. International Journal of Clinical and Experimental Hypnosis, 42 (4), 337-345.

This article reviews the seven principles of memory function that set limits on the degree to which any attempt to recover a long-forgotten memory can succeed: encoding, organization, time dependency, cue dependency, encoding specificity, schematic processing, and reconstruction. In the absence of independent corroboration, there is no 'litmus test' that can reliably distinguish true from false memories, or memories that are based on perception from those that are based on imagination. Practicing clinicians should exercise great caution when using hypnosis or any other technique to facilitate delayed recall.

Lynn, Steven Jay; Nash, Michael R. (1994). Truth in memory: Ramifications for psychotherapy and hypnotherapy. American Journal of Clinical Hypnosis, 36, 194-208.

In this article we address a number of issues relevant to the practice of psychotherapy and hypnotherapy: How reliable is memory? How are therapists' and clients' beliefs and expectancies related to pseudomemory formation? Are certain clients particularly vulnerable to pseudomemory creation? Does hypnosis pose special hazards for pseudomemory reports? What are the variables or factors that mediate hypnotic pseudomemories? In addition to reviewing the literature on these topics, we intend to sensitize the clinician to the potential pitfalls of critical reliance on the patient's memories, as well as uncritically accepted clinical beliefs and practices.

Lynn, Steven. Jay; Rhue, Judith W.; Myers, Bryan P.; Weekes, John R. (1994). Pseudomemory in hypnotized and simulating subjects. International Journal of Clinical and Experimental Hypnosis, 42 (2), 118-129.

High hypnotizable (n = 23) and low hypnotizable simulating (n = 13) subjects received pseudomemory suggestions. High hypnotizable and low hypnotizable simulating subjects were equally likely to pass the target noise suggestion during hypnosis and were also equally likely (high hypnotizables, 47.83%; low hypnotizable simulators, 64.29%) to report pseudomemories when tested for pseudomemory after instructions to awaken. As in previous research with task-motivated subjects, pseudomemory rate (high hypnotizables, 47.48%; low hypnotizable simulators, 46.25%) was not reduced by informing subjects that they could distinguish fantasy and reality in a nonhypnotic state of deep concentration. At final inquiry, after deep concentration, high hypnotizable and low hypnotizable simulating subjects' pseudomemories remained comparable (43.48% and 38.46%, respectively). Unlike previous research, high hypnotizable subjects did not report more unsuggested noises and more pseudomemories of novel sounds than did awake low hypnotizable simulating subjects. Pseudo-memory reports were generally consistent with subjects' ratings of whether the hypnotist expected them to believe the sounds were real or imagined.

Nash, Michael R. (1994). Memory distortion and sexual trauma: The problem of false negatives and false positives. International Journal of Clinical and Experimental Hypnosis, 42 (4), 346-362.

Logically, two broad types of mnemonic errors are possible when adult psychotherapy or hypnosis patients reflect on whether they were sexually abused or not as a child. They may believe that they were not abused when in fact they were (false negative error), or they may believe they were abused when in fact they were not (false positive error). The author briefly reviews the empirical evidence for the occurrence of each of these types of errors, and illustrates each with a clinical case. Further, in considering the incidence, importance, and clinical implications of these

errors, the author contends that clinical efficacy in no way assures that a false negative or a false positive has been avoided. A plea is made for theorists and researchers to acknowledge that both categories of errors can occur and to conduct future clinical and laboratory research accordingly.

Nash, Michael R. (1994, October). Reports of early sexual trauma: The problem of false negatives and false positives. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

The problem of false positives and problem of false negatives are distinct and should be treated differently. The question involves pseudomemories vs repression.

Evidence for false positives: 1. Memory research 2. Developmental psychopathology 3. Contemporary psychoanalytic theory 4. Clinical field studies

No laboratory researcher has produced false memories that are as gravid, or as emotionally loaded as early abuse.

Evidence for repression: 1. "Repressor Personality" research (Weinberger & Schwartz, who view it as a trait rather than a state). 2. Implicit memory research 3. Hypnosis research on memory (see Nash chapter in Fromm & Nash book on research in hypnosis) 4. Clinical field studies

Ofshe, Richard; Singer, Margaret T. (1994). Recovered memory and robust repression: Influence and pseudomemory. International Journal of Clinical and Experimental Hypnosis, 42, 391-410.

A subset of the psychotherapists practicing trauma-focused therapy predicate their treatment on the existence of a newly claimed, powerful form of repression that differs from repression as used in the psychoanalytic tradition and from amnesia in any of its recognized forms. Recovered-memory specialists assist patients to supposedly retrieve vast quantities of information (e.g., utterly new dramatic life histories) that were allegedly unavailable to consciousness for years or decades. We refer to the hypothesized mental mechanism as 'robust repression' and call attention to the absence of evidence documenting its validity and to the differences between it and other mental mechanisms and memory features. No recovered-memory practitioner has ever published a full specification of the attributes of this mechanism. That is, the properties it would have to have for the narratives developed during therapy to be historically accurate to any significant degree. This article reports a specification of the properties of the robust repression mechanism based on interviews with current and former patients, practitioners' writings, and reports to researchers and clinicians. The spread of reliance on the robust repression mechanism over the past 20 years through portions of the clinical community is traced. While involved in therapy, patients of recovered-memory practitioners come to believe that they have either instantly repressed large numbers of discrete events or simultaneously repressed all information about abuse they may have endured for as long as a decade. Patients' therapy-derived accounts are thought by some social influence, memory, and clinical specialists to be

inadvertently created iatrogenic effects: inaccurate pseudomemories and confabulations produced due to patient-therapist interaction, the use of leading, (sic) suggestions, hypnosis, and the mismanagement of the dependent relation of the patient on the therapist. Three cases are reported which illustrate how new life accounts predicated by robust repression can develop during therapy with a recovered- memory practitioner.

Schefflin, Alan W. (1994). Forensic hypnosis: Unanswered questions. Australian Journal of Clinical and Experimental Hypnosis, 22, 25-37.

Many courts have mistakenly identified hypnosis as more suggestive than eyewitness testimony or leading questions, and therefore these courts have applied unnecessarily restrictive rulings on hypnosis. The dangers of suggestion in eyewitness and interrogation cases pose reliability problems that are equally as great. In all situations, pre-trial evidentiary hearings on admissibility of 'suggestive' testimony is essential. Expert testimony should be available to assist the judge. The forensic rules to date have failed to clarify some hard cases. In resolving these cases, courts are encouraged to adopt a case-by-case analysis rather than a total prohibition on hypnotically refreshed recollection. Courts have assumed conclusions about hypnosis that the laboratory experiments suggest are incorrect - juries are not overly persuaded by hypnosis testimony, there is no inevitable concreting effect and witnesses do not become impervious to cross-examination. Thus, the restrictive per se disqualification rules for hypnotically refreshed recollection are too severe.

Spiegel, David; Schefflin, Alan W. (1994). Dissociated or fabricated? Psychiatric aspects of repressed memory in criminal and civil cases. International Journal of Clinical and Experimental Hypnosis, 42 (4), 411-432.

During the last decade, clinicians, courts, and researchers have been faced with exceedingly difficult questions involving the crossroads where memory, traumatic memory, dissociation, repression, childhood sexual abuse, and suggestion all meet. In one criminal case, repressed memories served as the basis for a conviction of murder. In approximately 50 civil cases, courts have ruled on the issue of whether repressed memory for childhood sexual abuse may form the basis of a suit against the alleged perpetrators. Rulings that have upheld such use underscore the importance of the reliability of memory retrieval techniques. Hypnosis and other methodologies employed in psychotherapy may be beneficial in working through memories of trauma, but they may also distort memories or alter a subject's evaluation of their veracity. Because of the reconstructive nature of memory, caution must be taken to treat each case on its own merits and avoid global statements essentially proclaiming either that repressed memory is always right or that it is always wrong.

Spiegel, David (1994, October). On patients not remembering abuse when it in fact may have occurred. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

## NOTES

False memories and false non-memories may be two sides of the same coin. What is the evidence for repression?

If people are abducted by extraterrestrials, why don't they just keep them? [Joke!]

It seems counter-intuitive that people would forget important, arousing things that happen.

The three main components of hypnosis (suggestibility, absorption, and dissociation) are also aspects of memory: 1. Absorption relates to encoding (narrowing attention); also happens during traumatic events (Loftus' "gun memory" which is so clear, while they don't encode what gunman's face looks like). 2. Dissociation relates to memory storage (compartmentalization of information). Traumatized people have symptoms of dissociation, depersonalization. If you are in an unusual mental state, you may watch the event; the memory is stored without the usual network of associations. 3. Suggestibility relates to retrieval. The way questions are asked influences one's response. But hypnosis is not an infinite influencer; the main damage to memory contributed by hypnosis is "confident errors" (McConkey).

We did research one week after the Loma Prieta earthquake, and found significant cognitive alterations, memory alterations, etc. In our sample, 1/4 of the people felt detached from their body or from the ground right after the earthquake.

Memory alterations were compared with data from other studies after other traumas. Difficulties with memory occurred in 29% of our sample.

The disorganization of memory can follow even just witnessing trauma (e.g. the recent slaying of 8 people in the law office in San Francisco) And people who witnessed the execution of Harris. They were in no danger themselves, yet the level of dissociative symptoms were as high in the former.

The Briere & Cone and Herman & Shatzow studies are based on self report of earlier trauma, and that is a problem in research. But Williams' study does have the age of people when they were abused as children; see her article in Journal of Consulting and Clinical Psychology.

## COMMENTS FROM THE AUDIENCE

Dabney Ewin: Sex abuse trauma differs from earthquakes because the abuser says, "If you tell anybody I'll kill you." This is like a post hypnotic suggestion, which is carried out compulsively when given to the victim during fear.

Dale: How do we account for the vigor in the attempts of each side to convince the other. The people who have been real victims of sexual abuse need to be able to talk with the people who are victims of False Memory Syndrome. The impact on a family is just as traumatic as the sexual abuse itself.

Response by D. Spiegel: I wouldn't recommend that combination, but the point you make about damage to the falsely accused is relevant. Their lives are shattered but remember the damage done throughout life by sexual abuse.

Yapko, Michael D. (1994). Suggestions of abuse: True and false memories of childhood sexual trauma. New York, NY: Simon & Schuster.

## NOTES

From the section titled "A Note to Therapists:"

"I would encourage you not to (1) preclude open communication at all times among family members; (2) act as your client's 'hired gun'; (3) act as if corroboration of allegations of abuse were unnecessary; (4) jump quickly to the conclusion abuse occurred simply because it is plausible; (5) suggest a history of abuse to someone who is not your client; (6) refer a client out for hypnotic confirmation or disconfirmation on the false premise that hypnosis is some kind of lie detector; (7) ask leading or suggestive questions; (8) assume repression is in force when someone does not have much memory from childhood; (9) rely on your memory of the interaction. Tape your investigative sessions and review them later for any evidence of possible unintentional contamination of your client's recollections" (p. 217).

London, Ray William (1993, October). Refreshed adult memories: Abuse survivor or therapeutic victim?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

## NOTES

The author addresses four areas: 1. public policy 2. psychological issues 3. legal issues (evidence) 4. how to properly deal with it

A definition of sexual abuse is being applied to behaviors that for years were not considered out of bounds (e.g. entering a bathroom where someone else is). Furthermore, using the word "survivor" for abused people equates patients with survivors of concentration camps, who do not present with repressed memories typically. National incidence of child abuse remains unclear estimates are 6 to 60% of females. In Florida, only 13% of cases reported are confirmed.

Some therapists who specialize in this area in surveys indicate that they have false beliefs regarding memory and effects of trauma.

[These represent only partial notes on a lengthy and substantial paper.]

1993

Nadon, Robert (1993, October). Nomothetic and idiographic approaches to hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

## NOTES

Scientists and practitioners are not benefitting from each other's contributions. The central contribution to hypnosis, both basic and applied, is the logic and validity of study designs. The false memory issue is an example. Clinicians supply an answer the public likes, but scientist provide data based on nomothetic (group average) models that are not useful here.

Most of my own work is nomothetic, but it can work together with case study approach. We use a synergistic model: the combined effects of traits, cognitive,

social, and affective factors are investigated. Interactions are tricky to detect, but we need a spirit of enquiry that encourages designs sensitive to interactions.

One example is Radke & Spanos' study that used a scale rating whether subject was hypnotized and another indicating degree of absorption-and-hypnotized vs absorption-and-not-hypnotized. Nadon's reanalysis showed a scale by Ss interaction: mediums were different on the 7 point scale but highs were not. (Highs were less manipulated by the scale manipulation).

Jean-Roche Laurence and Nadon replicated the interaction. Then Nadon did a study to test the idea that highs were less affected by scale manipulation because they relied more on subjective experience. They measured Absorption in a different context and hypothesized that the highs here would be less affected on the 7 point scale in the other context; it was validated. There seemed to be a linear absorption by a quadratic hypnotizability interaction.

Another simple example of interaction at work: there are different lines predicting hypnotic ability based on the Absorption scale, representing need for control on the scale. Those low in need for control have a stronger prediction of hypnotizability from Absorption scale. With high need for control, Absorption doesn't predict hypnotizability. This may explain why the correlation isn't stronger between Absorption and hypnotizability.

Nadon investigated how level of relaxation could be affected by an interaction. Measured muscle tension of masseter (?) while listening to music (half of Ss) or focusing on relaxing (50%). In an experiential condition there was a negative correlation between Absorption and muscle tension (highs relaxed more); in an Instrumental condition it was the opposite. So both high and low Absorption people were capable of relaxation, but to get the best relaxation you would have to know their Absorption score.

A second study hypothesized that predispositions for certain kinds of affect (Tellegen's positive affect, like extroversion) and negative affect (like neuroticism). High Absorption extraverts low in neuroticism worked best with music; and [missed words]. This supports Tellegen's hypothesis re the effects of positive and negative affect and Absorption.

Now we can discuss individual characteristics that suggest which relaxation strategy will benefit. The practical implications can be validated by case studies.

**Sheehan, Peter W.; Garnett, Michelle; Robertson, Rosemary (1993). The effects of cue level, hypnotizability, and state instruction on responses to leading questions. International Journal of Clinical and Experimental Hypnosis, 41, 287-304.**

Two sessions were conducted in which independent groups of 86 high- and 85 low-susceptible subjects, responding individually under waking or hypnotic instruction, answered high- and low-cued leading questions about a video event that depicted shooting at an airport. The two sessions were separated by 1 week, and the same questions were asked in both sessions. It was predicted that highly susceptible subjects responding under hypnotic instruction would show the most evidence of accepting false information via strongly cued leading questions. Results showed general effects for leading questions and level of susceptibility but no firm support

for the involvement of hypnosis. Data are discussed in terms of both the linguistic and social factors that appear to have operated on subjects in the study, results overall highlight the strong influence of level of susceptibility on subjects' acceptance of false information.

1992

Faller, Kathleen Couborn (1992, Summer). Can therapy induce false allegations of sexual abuse?. The Advisor (Published by American Professional Society on the Abuse of Children), 5 (3), 3-6.

#### NOTES

Concern about the impact of therapy on children's accounts of sexual abuse should be understood in the context of two phenomena: (1) the adult need to deny that children are sexually abused, and (2) adult identification with the alleged abuser. These phenomena operate at both individual and societal levels" (p. 3).

"Research related to impact of stressful situations on children's ability to recall provides mixed results, some studies finding children are less accurate if the event is traumatic (Peters, 1991) and others finding they are not (Goodman, Reed, & Hepps, 1985).

"Research reveals that it is rare for children to falsely allege that they have been touched in their private parts. In one study, a substantial proportion of children who experienced genital and anal touch during a physical examination by a doctor did not volunteer this information when asked general questions about the examination. The majority of children in the study revealed genital and anal touch only when they were asked specific questions like, "Did the doctor touch you there?" (Saywitz, Goodman, Nicholas, & Moan, 1991)" (pp. 3-4).

"Clarke-Stewart and her colleagues (1989) have demonstrated that children's interpretation of ambiguous events can be manipulated and altered by an authority figure who insists upon a particular interpretation (see also Lindberg, 1991)" (p.4).

"In sum, the research suggests that older children are likely to provide more complete unassisted disclosure than younger children. Younger children may need more memory cues in the form of specific questions than older children. Therapists are much more likely to find false negatives than false positives. Finally, therapists should be aware of the possibility the child may identify the wrong person. ... Generally, however, the research indicates that concern about the contaminating effects of therapy on children's recollections of sexual abuse is exaggerated" (pp. 4-5).

"Research indicates that the proportion of fabricated reports may be higher in the divorce scenario than in other contexts (Faller, 1990; Jones & Seig, 1988). Studies suggest most false reports are made by adults, not children (Jones & McGraw, 1987; Jones & Seig, 1988)" (p. 5).

"Clinical research (Sorenson & Snow, 1991) and experience (Faller, 1988) indicate that for most children, revealing sexual abuse is a process which occurs over time. A typical pattern is one in which children begin with the least overwhelming experience and gradually disclose more and more as their accounts are accepted and believed" (p. 5).

"[In conclusion]... therapists should be aware of the findings from research on children's memory and suggestibility. This research indicates that there are vulnerabilities which should be taken into account during therapy" (p. 6).

Lynn, Steven Jay; Rhue, Judith W. (1992, October). Memory. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

## NOTES

[Author presented a dramatic case report of patient who recalled specific events that subsequently he and the patient investigated and disproved. What the patient thought they saw could not possibly have been seen.]

The experimental literature on memory gives us some things to think about. Therapy relies highly on memory, and the therapist shapes the contours of the memory by validating the memories, which are rarely doubted. Tacit acceptance of memories as historical facts is part of the contract of therapy.

Memory studies challenge the idea of accurate storage. Some people are unduly confident of their memory. Bartlett's research demonstrated distortion according to schema, interpretations, embellishments, etc. Jacobi et al indicate people's theories about what happened shape memory.

One theory is that trauma leads to amnesia, repression, dissociation. But research does not show inability to recall early life events indicates presence of a traumatic history. Repression is not prima facie evidence of abuse. The *Courage to Heal* book states that merely thinking you were abused is evidence that you probably were.

How do vague ideas crystallize? Loftus finds if inability to remember isn't attributed to ordinary forgetting, the person may look for memories, thereby creating them.

Studies of persons who confess to crimes, unsure whether they did or didn't do them, indicate that these people are easily coerced. Doubt in a memory's accuracy can be reframed by a therapist.

Hypothesis: Therapists who confidently state a view risk implanting pseudomemories. Therapists must be cautious.

Clients can confuse sources of information that they receive. Different sources of information can be integrated into a single memory (e.g. what occurred to them and what occurred to siblings can be integrated into a pseudomemory). Some limited evidence that early life experience memories could be implanted has been presented by Loftus.

Certain client characteristics contribute to false memories: 1. Present mood state (mood congruent memory). This effect is reliable when people are clinically depressed. Though clinicians may say it indicates early childhood abuse, the memory might be selective or biased. 2. History of fantasy-proneness. In childhood this type of person might have had problems distinguishing fantasy from reality. LaBelle et al found absorption made it difficult to distinguish sounds in hypnosis from what really occurred, creating pseudo- memories. With this population it is essential to avoid suggesting abuse.

Lynn was successful in implanting an idea of abuse in an alter called Person. He used the Orne technique (from the BBC film "Hypnosis on Trial") to ask a patient what she had told him about her dog during the hypnosis; he did this to convince her of the importance of exploring her amnesic episodes.

Does hypnosis foster a literal re-experiencing of childhood events? NO. Nash, in an exhaustive review, failed to find correspondence between information from hypnotic age regression and childhood events. He notes that literal reliving is not possible. It is possibly an expression of primary process thinking. Hypnosis doesn't ameliorate memory problems; and it may exacerbate memory problems.

Lynn views primary process thinking observed in hypnosis as due to the demand of hypnosis to fantasize and relinquish critical thinking or objectivity. This plus Therapist and Patient expectancies may foster tenacious beliefs that events occurred.

Many hypnotic suggestions may interfere with memory. The AMA 1985 report suggests that hypnosis can influence confidence in a 'memory' with no actual improvement in accuracy.

The effects aren't limited to hypnosis however. Simulators and controls also generate pseudomemories. Repeated questioning of Ss who are led to believe that questioning helps distinguish memories from fantasies, actually diminishes the accuracy of memories.

Hypnotizability is correlated with pseudomemory occurrence. We should evaluate a client's hypnotizability when evaluating for pseudomemories.

Perceived verifiability rate is important, as pseudomemories are higher where you can't verify the reported memory, it is thought. Therefore, approach with caution. Make every effort to corroborate memories.

Subjective reports may tell narrative truths even though inconsistent with the historical record, and could be useful independent of historical accuracy. I agree that those 'memories' could be important, just as age progression or past life regression material could be useful in therapy. But should we base our interpretations or conclusions on events that are not confirmed? A patient's belief in abuse by their parent has enormous implications for a family.

Therapists should understand the dynamics of a request for using hypnosis to recall forgotten memories before using uncovering techniques. Ask yourself, "Why is this being requested?" Also ask other questions: 1. Is the person fantasy prone, dissociative, suggestible, a high hypnotizable? 2. Is the person stabilized enough to focus on an abreaction? 3. Is there conscious or unconscious motivation to avoid responsibility for one's own behavior? 4. Is there a wish to arrive at a facile solution, a magic cure, the royal road to the unconscious; or is there an attempt to control the treatment hour, to avoid issues, to test the therapist? 5. Is therapy stalled, not moving forward? 6. Am I angry with the client because they expect to uncover more?

Instead of using hypnosis to retrieve memories, I may focus on the issues to which I answer 'Yes' in the forgoing list.

I do not believe current research is sufficiently persuasive to throw out hypnosis for retrieving memories. The dangers of pseudomemory are endemic to therapy.

**Incorporating hypnosis into a broader frame of therapy depends on the skill of the clinician. However, we must use hypnosis with great caution**

#### **COMMENTS FROM AUDIENCE**

**Joseph Dane: In 75% of cases that could be verified, they found corroborating evidence: what should you look for as an index that the memory recalled in hypnosis is more likely to be accurate?**

**Lynn: Many instances of abuse are corroborated. No one questions the veracity of all memories. To my knowledge there are no ways of corroborating genuine from false memories. We know subjective conviction is not sufficient, and clients' affective experience can be very misleading. Since my experience [in the case study reported at the beginning of this presentation] I have talked with many therapists who have had similar experiences.**

**David Spiegel - the problem is not the hypnosis: patients go in and out of hypnosis all the time, momentarily. The problem is, how do I explore the material in psychotherapy? There is no substitute for corroboration if you can get it. But you have to be sensitive to the vulnerability of those people.**

**Howard Hall: What is a genuine memory? No memory is undistorted. More importantly, can we verify significant events that might have had long term consequences, like abuse? We should try to verify memories when we base treatment programs on them. The only memories in the literature that have a reputation of being accurate are highly traumatic events that stand out, and these reports are anecdotal in nature.**

**Murrey, Gregory J.; Cross, Herb J.; Whipple, Jim (1992). Hypnotically created pseudomemories: Further investigation into the 'memory distortion or response bias' question. Journal of Abnormal Psychology, 101 (1), 75-77.**

**In order to study whether pseudomemories represent actual memory distortions or are a result of response bias, 60 highly hypnotizable subjects and subjects from the general population were divided into 4 experimental groups and were tested for pseudomemory manifestation after receiving a false suggestion. Of the 4 groups of subjects, 3 were offered a monetary reward as a motivation to distinguish false suggestion from the actual occurrence. Pseudomemory manifestation was found to be significantly higher among subjects not offered a reward than among subjects who were offered such a reward. The implications of these findings are discussed.**

#### **NOTES**

**The article contains a review of the literature through 1989. The study tested the hypothesis that when it is important to distinguish fantasy from reality in a hypnosis experiment, subjects can do so--a position presented by Spanos and McLean (1986). They used a verifiable event to test for pseudomemory production, as in research published by McCann and Sheehan (1988). Subjects were 30 high hypnotizable and 30 unselected students.**

**Subjects were shown a videotape of a mock robbery scene. The next week, Groups A, B, and C heard audiotapes "to enhance memory," but in addition to motivating**

statements about "trying to remember" certain details, the tapes included misleading information (e.g. "Remember the color of the hat the robber was wearing" when in fact there was no hat on the robber). Subjects in these groups were 'influenced.'

"Both highly hypnotizable subject groups (Groups A and B) listened to the audiotape after being administered a 10-min hypnotic induction procedure (modified from that of Barber, 1969). Subject Group C listened to the audiotape without hypnosis. The control group, Group D, did not listen to the audiotape and was, therefore, classified as 'uninfluenced.'"

A week later subjects responded to multiple-choice and yes-no or true-false questions about the robbery scene. The yes-no question about whether the robber was wearing a hat served as the dependent variable, a measure of pseudomemory. "To motivate subjects to report the truth rather than to follow any perceived expectations of the experimental or social context, we offered subjects in Groups B, C, and D a monetary reward if they achieved the most correct answers on the quiz (according to the videotape). The reward was offered just before administration of the quiz to ensure that no collusion between the subjects could occur. Group A was not offered any such reward" (p. 76).

"The number of subjects in Group A (hypnotized, influenced, no reward) who reported the false information at posttest (12) was significantly greater than that of Group B (hypnotized, influenced, offered reward.... However, the difference in incidence of pseudomemory between Group B and the control group, Group D (not hypnotized, uninfluenced, offered reward), was nonsignificant" (p. 76).

Table 1 Incidence of Pseudomemory Per Group -----

	Group A	Group B	Group C	Group D
False suggestion	(n=15)	(n=15)	(n=15)	(n=15)
Accepted	12	6	7	3
Rejected	3	9	8	12

---- Note. Group A = hypnotized, influenced, not offered reward.

Group B = hypnotized, influenced, offered reward.

Group C = not hypnotized, influenced, offered reward.

Group D = not hypnotized, not influenced, offered reward.

In the Discussion, the authors wrote, "Because the only variable among these groups was the reward, a reasonable conclusion from the findings is that pseudomemories manifested by the subjects were (for the most part) not actual memory distortions. Presumably, the reward provided the subjects in Group B an incentive to 'report the truth' and a disincentive to give biased reports on the basis of the perceived expectations of the social or experimental context. Thus these data suggest that pseudomemory effects or the occurrence of the pseudomemory phenomenon among highly hypnotizable subjects can be minimized by providing a motivation to subjects to give unbiased reports.

"A major implication of these findings is that researchers should control for response bias resulting from perceived social demands or from leading test designs when they conduct pseudomemory research. Of further concern is the fact that a

number of researchers contend that hypnotic interrogation of eye-witnesses can greatly facilitate the creation of pseudomemories (Levitt, 1990; Loftus, 1979; Orne, 1979; Putnam, 1979), and therefore hypnosis either should not be allowed in the courtroom or should be strictly controlled. Yet in light of our findings, response bias may be a confound in pseudomemory research, and thus researchers need to be cautious when making inferences to specific situations from data obtained in an experimental setting.

"Despite the existence of a confound of (unmeasured) differences in hypnotizability between the two groups, there was no significant difference between Group B and the control group (Group D). This suggests that if response bias is controlled for, there may not be significant differences in manifestation of pseudomemories between highly hypnotizable subjects and subjects representative of the general population. However, further research is needed in order to address this question" (pp. 76-77).

Ofshe, Richard J. (1992). Inadvertent hypnosis during interrogation: False confession due to dissociative state; mis-identified multiple personality and the satanic cult hypothesis. International Journal of Clinical and Experimental Hypnosis, 40, 125-156.

Induction of a dissociative state followed by suggestion during interrogation caused a suspect to develop pseudo-memories of raping his daughters and of participation in a baby-murdering Satanic cult. The pseudo-memories coupled with influence from authority figures convinced him of his guilt for 6 months. During this time, the suspect, the witnesses, and all the evidence in the case were studied. No evidence supported an inference of guilt and substantial evidence supported the conclusion that no crime had been committed. An experiment demonstrated the suspect's extreme suggestibility. The conclusion reached was that the cult did not exist and the suspect's confessions were coerced- internalized confessions. During the investigation, 2 psychologists diagnosed the suspect as suffering from a dissociative disorder similar to multiple personality. Both psychologists were predisposed to find Satanic cult activity. Each concluded that the disorder was due to "programming" by the non-existent Satanic cult.

Sheehan, Peter W.; Statham, Dixie; Jamieson, Graham A. (1991). Pseudomemory effects over time in the hypnotic setting. Journal of Abnormal Psychology, 100 (1), 39-44.

Highly (n=36), moderately (n=26), and low (n=48) susceptible Ss were administered either hypnosis or waking instruction to examine the hypothesis that pseudomemory will occur for hypnotic Ss as long as 2 weeks after suggestions are given for accepting false events. Accuracy and confidence of memory were measured for all ss, and memory was examined for free recall, structured recall, and recognition. Results indicated persistence of pseudomemory for the 2-wk period for both highly and moderately susceptible ss. Data highlighted the multifaceted operation of skill,

contextual, and state instruction factors, and a hypothesis that ambiguity of communication when suggestion is delivered plays a part in the maintenance of pseudomemory over time is offered for further testing.

**Supreme Court of the United States (1990). Vickie Lorene Rock, Petitioner v. Arkansas, on writ of certiorari to the Supreme Court of Arkansas [June 22, 1987]. International Journal of Clinical and Experimental Hypnosis, 38 (4), 219-238.**

#### **NOTES**

The popular belief that hypnosis guarantees the accuracy of recall is as yet without established foundation and, in fact, hypnosis often has no effect at all on memory" (p. 232). "Three general characteristics of hypnosis may lead to the introduction of inaccurate memories: the subject becomes 'suggestible' and may try to please the hypnotist with answers the subject thinks will be met with approval; the subject is likely to 'confabulate,' that is, to fill in details from the imagination in order to make an answer more coherent and complete; and, the subject experiences 'memory hardening,' which gives him great confidence in both true and false memories, making effective cross-examination more difficult" (pp. 232-233). "The inaccuracies the process introduces can be reduced, although perhaps not eliminated, by the use of procedural safeguards" (p. 233). "The more traditional means of assessing accuracy of testimony also remain applicable in the case of a previously hypnotized defendant. Certain information recalled as a result of hypnosis may be verified as highly accurate by corroborating evidence. Cross-examination, even in the face of a confident defendant, is an effective tool for revealing inconsistencies" (p. 234). "We are not now prepared to endorse without qualifications the use of hypnosis as an investigative tool; scientific understanding of the phenomenon and of the means to control the effects of hypnosis is still in its infancy. Arkansas, however, has not justified the exclusion of all of a defendant's testimony that the defendant is unable to prove to be the product of prehypnosis memory. A State's legitimate interest in barring unreliable evidence does not extend to per se exclusions that may be reliable in an individual case. Wholesale inadmissibility of a defendant's testimony is an arbitrary restriction on the right to testify in the absence of clear evidence by the State repudiating the validity of all posthypnosis recollections" (p. 234).

**Udolf, R. (1990). Rock v. Arkansas: A critique. International Journal of Clinical and Experimental Hypnosis, 38 (4), 239-249.**

Rock v. Arkansas is the first United States Supreme Court decision that addresses the conflict between a criminal defendant's right to testify in his or her own behalf and a state's right to impose a restrictive rule of evidence barring hypnotically refreshed testimony. The present critique describes the operative facts in Rock v. Arkansas and the majority and minority decisions. It also highlights some of the psychological and legal issues involved and speculates on what Rock v. Arkansas may portend for the broader issue of the admissibility of hypnotically refreshed testimony in general.

**Pinizzotto, Anthony J. (1989). Memory and hypnosis: Implications for the use of forensic hypnosis. Professional Psychology: Research and Practice, 20 (5), 322-328.**

#### **NOTES**

The author reviews arguments regarding hypnosis in forensic investigations, offers procedures of a nonhypnotic nature to enhance memory recall, and suggests guidelines for hypnosis in criminal cases. The effects of hypnosis on memory, as well as the concomitant dangers regarding those effects, are discussed.

#### **1989**

**Sanders, Glenn S.; Gansler, David A.; Reisman, Stephen Jr. (1989). The effects of hypnosis on eyewitness testimony and reactions to cross-examination. American Journal of Forensic Psychology, 7, 33-60.**

Investigative hypnosis has been a widely used and valuable police technique, but recent court rulings have expressed reservations about the admissibility of hypnotically related testimony. The proposed research is the first directly relevant evaluation of the most serious of the courts' reservations: the allegation that hypnosis produces excessive and unshakable levels of confidence in witnesses, thereby effectively denying opposing counsel the right of cross-examination. Volunteers from the community witnessed a simulated crime, and were then interviewed by a professional police investigator to obtain evidence and testimony. Two-thirds of these witnesses were randomly assigned to have their memory refreshed by one of two hypnotic induction techniques. All witnesses were subsequently examined and cross-examined by a pair of practicing criminal lawyers, and their videotaped testimony was evaluated by another volunteer sample of community residents serving as jurors. On both objective and subjective measures, hypnotized witnesses provided more complete and internally consistent testimony. However, neither form of hypnotic induction led to greater witness confidence, credibility, or resistance to cross-examination. Our results generally replicate previous findings in a more realistic investigative simulation. The discussion considers artifactual explanations of the confidence null effects, and explores theoretical and policy implications of the data.

#### **NOTES**

People responding to a newspaper ad asking for volunteers who would be paid for participating in psychology research at the State University were later asked to undergo hypnosis. Of 45 who responded to the ad, six (13%) declined to have hypnosis. This rate of refusal has relevance to research on clinical hypnosis that requires paid volunteer participants.

**Waxman, David (1989). Nothing but the truth? Commentary on the 1988 Home Office Circular No. 66. [Comment/Discussion] .**

#### **NOTES**

The Commentator agrees with views expressed in the Home Office Circular and

suggests that if hypnosis is used in an investigation, the following guidelines should be observed.

" 1. The subject must be entirely willing to undergo hypnosis. Signed and witnessed consent should be obtained.

2. No accused person or suspect should be hypnotized in an attempt to obtain information.

3. Immunity from prosecution should never be offered to the person being hypnotized.

4. Hypnosis should be carried out by a physician or psychologist with knowledge in this field, experience in its clinical use and special training in the use of forensic hypnosis.

5. The hypnotist must be an independent specialist, with no responsibility either to the prosecution or the defence.

6. His opinion must be entirely unbiased. Therefore he should only be given some basic and known facts of the case. He should have no knowledge of the suspect so that he may remain impartial.

7. A full medical and psychiatric evaluation of the subject must be made by the specialist before commencing hypnosis. He must be satisfied that the subject is a fit person to undergo hypnosis.

8. Tape recordings and video-tape recordings covering the entire area of the room in which the hypnosis is to take place should be made. The subject should be informed that the interview is being recorded. The tapes should be opened as the subject enters the room by the police officer in charge of the case, with venue, date and time duly stated and sealed again after all discussion is concluded.

9. Only the specialist and the subject should be in the interview room during the examination in order to avoid inadvertent cueing of the latter by other persons.

10. There should be no prompting or cueing of the subject at any time during the interview.

11. The subject's general practitioner should be informed of the interview having taken place if considered advisable by the specialist. The latter should be available to undertake follow-up if required.

12. Information obtained under hypnosis should not be regarded as irrefutable evidence in a court of law. Corroborative evidence should always be obtained by the police. The corollary is that information obtained at the interview cannot be used to corroborate other information for which there is no evidence" (pp. 45-46).

1988

Council, James R.; Loge, D. (1988). Suggestibility and confidence in false perceptions: A pilot study. British Journal of Experimental and Clinical Hypnosis, 5, 95-98.

Subjects received audiotaped instructions implying that they would perceive increases in odor or heaviness while comparing stimuli in a sensory-judgment task. Stimuli were actually indiscriminable. Subjects pretested as higher or lower in hypnotizability performed the task in either hypnotic or non-hypnotic conditions. In both treatments, greater hypnotizability was associated with more perceived

changes in the stimuli and greater confidence in the reality of those perceptions. Results support a general factor underlying suggestibility in hypnotic and nonhypnotic situations. The findings are discussed in relationship to false confidence effects reported in hypermnesia research.

Perry, Campbell (1988, November). An interactionist position on hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

#### NOTES

Context makes differential contributions across items on scales, e.g. amnesia depends mostly on individual differences. Yet in the 19th Century it occurred almost inevitably, spontaneously, because of expectancy of therapist and patient.

Success in pain reduction is much greater in clinic (Crasilneck; Melzack et al; Cedercantz - skull injury) than in lab (Hilgard's studies of highs and lows).

Central to the disagreement about special state/socio-behavioral theories is the question, "What are the origins of beliefs about hypnosis?" The beliefs can be modified by experience, which is mediated by individual differences.

Author suggests trying to predict which individual will respond to which hypnosis item. Since there are at least 3 factors in hypnotizability scales, one needs a number of variables to do this type of research. Nadon et al (Journal of Personality and Social Psychology 1987) predicted hypnotizability with PICS (an imagery control test) and Absorption scale plus Evans' Sleep Questionnaire subscale plus Belief in [paranormal events] subscale: predictions were 63% correct. PICS (as compared with other imagery tests) reflects imagery as a preferred mode of thinking. Now, can we predict who will make highly confident errors when asked to remember details of a crime? Who is more vulnerable when told a pseudomemory is veridical? In a test of this question, mimicking a field setting, the authors weren't able to predict the people who would make errors, who functioned at the same level following neutral instructions ("We don't know what we'll find") and Reiser-type instructions ("You can use a zoom lens to see the scene up close") in hypnosis. Also, the effect of an increase in confident errors was greater for highs than for lows. People with high hypnotizability and low PICS made the most errors. N.B. Since lows also increased in errors, one should be cautious in any case.

Creation of pseudomemory research: Using SHSS:C and PICS one can predict 81% of those who accepted and reported the implanted pseudomemory.

Pettinati, Helen M. (1988). Hypnosis and memory. New York and London: Guilford Press.

#### NOTES

From a review in British Journal of Experimental and Clinical Hypnosis, 7, 175-178, by Vernon H. Gregg]:

Book has 5 sections: 1. method, theory 2. mechanisms of memory enhancement 3. hypnotic and other forms of reversible amnesia 4. clinical uses of hypnosis for increasing accessibility of memories and fantasies 5. Summary

The chapter by Martin Orne et al presents a comprehensive review. Perry, Lawrence, d'Eon and Tallant contribute a lively assessment of age regression procedures in the elicitation of inaccessible memories. They provide a description of procedures, a brief historical review, and discuss problems of confabulation and creation of pseudomemories. Their account is illustrated by clinical and forensic examples and gives an interesting account of belief in reincarnation in terms of source amnesia.

Section 3 has Hollander's chapter on hysteria and memory, which illustrates the concept of reversibility of amnesia with two types of hysterical conditions: one of these types, the dissociative disorders, has the potential for amnesia to be reversed but the other, histrionic personality disorders, is characterized by no reversibility.

In the section on clinical studies of memory enhancement Frankel and Kolb both accept that uncovering repressed memories and fantasies is therapeutically beneficial and that the faithfulness of recovered memories is often not important for therapeutic success. Frankel illustrates the usefulness of hypnosis with several case studies. But he thinks that clinical issues are dealt with too briefly in this book. In her summary chapter Pettinati points to the dearth of systematic research into the effectiveness of hypnosis in clinical settings.

Sheehan, Peter W. (1988). Memory distortion in hypnosis. International Journal of Clinical and Experimental Hypnosis, 36, 296-311.

This paper presents data from a programmatic series of studies that varied the range of conditions affecting potential increase of recall, memory distortions, and distortions of confidence during and following hypnosis. All the studies used a paradigm that exposed Ss to misleading information some time before memory was tested and applied procedures in the hypnotic setting to analyze memory performance in both recognition and free recall. Results from the program failed to demonstrate any increment in accurate memory due to hypnosis, and the accuracy of memory reports in hypnosis was at times significantly reduced. Further, hypnotic recall was distinctively distorted when false information was introduced after, rather than before hypnosis. Results were discussed in relation to the role hypnotic as opposed to contextual variables may play in explaining Ss' memory test performances, and some legal implications are drawn from the data.

#### NOTES

This article investigates 3 major questions: 1. whether hypnosis makes recollections more susceptible to error 2. whether hypnosis reliably enhances recall 3. whether hypnosis alters certitude of what is remembered, independent of accuracy

The author reviews earlier literature, noting that different methodologies lead to different, sometimes conflicting, results. He uses Loftus' methods, which "allows for systematic exposure to specific information that is erroneous and examines the after- effects of that exposure on subsequent attempts to remember" (p. 298). The Ss are tested initially for memory of an incident, with subtle introduction of false information; then retested in way that probes for correct recall/recognition by presenting the incorrect information as an alternative for response. (Loftus has

presented the position that misinformation is incorporated into waking memory, and this examines whether the addition of hypnosis--especially with Ss who are highly hypnotizable--increases the effects.)

Sheehan reports six studies that varied type of memory test (free recall, recognition); type of instruction (hypnotic, waking, simulating); and level of hypnotizability (high, low). Each study dealt with the same incident that depicted an apparent robbery and three false pieces of information about the incident were presented to Ss in the misleading condition. The studies have been published elsewhere as: --Study 1 Sheehan & Tilden, 1983: High and low hypnotizable Ss tested under hypnosis & waking conditions. False information is given before hypnosis. --Study 2 Sheehan & Tilden, 1984: Real & simulating Ss presented with false information prior to hypnotic induction. --Study 3 Sheehan & Tilden, 1986: High hypnotizable and motivated low hypnotizable Ss presented with false information prior to hypnosis. --Study 4 Sheehan, Grigg, & McCann, 1984: Real & simulating Ss presented with false information after hypnotic induction. --Study 5 Sheehan & Grigg, 1985: High hypnotizable and motivated low hypnotizable Ss presented with false information after hypnotic induction --Study 6 (this article reports): High and low hypnotizable Ss tested under hypnosis and waking conditions. False information is given after hypnosis. Scene shown is described by hypnotist in a congruent (robbery) or incongruent (friendly encounter) way

Ss tended to give incorrect responses along the lines of the false cues, but this effect was not greater when hypnosis occurred after the leading information had been given. In two experiments (#4 and #5) the effect was associated with hypnosis. Thus, when Ss are hypnotized they are more likely to be misled by false information. Study 6 did not demonstrate the incorporation of false information into memory, possibly because there was a longer delay between presentation of the information and the memory test itself. This weakening effect of delay has also been shown by Loftus et al. (1978). High hypnotizable Ss in the hypnosis condition showed more distortion than lows not hypnotized in 4 of the 6 studies evidencing distortion.

The authors note that "confidence may be maintained in the hypnosis setting despite the presence of substantial inaccuracy. ... Simulating Ss performed just as confidently as real Ss ... raising the question that context may determine the results for confidence among real Ss. ... Where expectations were out of phase with stimulus events [Study 6], confidence effects involving hypnosis did not emerge" (pp. 304-305).

"Overall, data indicated that hypnotic instruction may be more reliably associated with confidence than level of hypnotizability, though both variables are associated with confidence at one time or another. What is not clear, however, is whether hypnosis itself is at issue or the context of which hypnosis forms a part. That context, of course, may include the belief of Ss brought to the formal test situation that hypnosis increases memory. ... Simulating Ss reported higher confidence levels than real Ss when results were analyzed just for the hypnotic setting ..., for recognition testing in Study 4; simulating Ss were not distinct from hypnotic Ss under waking conditions of testing. It seems that the hypnotic setting itself, or expectations about it, obviously communicated that an expression of strong conviction was required. Collectively, results demonstrated that simulating Ss

believed that a hypnotized person would be more confident, and they therefore reported greater confidence levels during their act of pretense" (pp. 305-306).

In their discussion, the authors note that there was more evidence for mis-reporting than for accuracy, but that hypnosis did not produce more error unless false information was given during hypnosis. High hypnotizable Ss produce many errors with a high level of confidence, but since simulators feign hypnosis by reporting high levels of confidence, it may be expectations about the ability of hypnosis to improve recall that influences these results. "Such expectations may influence hypnotic recall for all Ss, but this would not explain differential levels of confidence between high and low hypnotizable Ss when both are tested in exactly the same way--that is, when task demands are held constant" (p. 306).

"One major implication of the data is that future research should move away from focusing only on the truth validation or distorting influence of hypnosis to emphasize the role contextual features may play in accentuating memory distortion effects" (p. 307). "The one clear finding across all of the studies in the program was that hypnosis does not increase memory, and the findings provide no basis to justify the forensic application of hypnosis given that the point of forensic application is that hypnosis will help memory. Data also indicate that when leading questions are asked under hypnosis, they are likely to be more effective in distorting memory reports than when such questions are asked without hypnosis. Low resistance to misinformation was present among both hypnotic and waking Ss, but separated the two groups when the false information was given in hypnosis.

"One of the major inferences ... is that the most substantial risk to using hypnosis may lie not only with the tendency to mis-report itself, but with the tendency for hypnotic Ss to be convinced in their reporting no matter what the accuracy of their statements. This effect was pervasive enough that it may offer sufficient grounds for restricting how hypnosis should be used forensically" (p. 308).

Whitehouse, Wayne G.; Dinges, David F.; Orne, Emily C.; Orne, Martin T. (1988). Hypnotic hypermnesia: Enhanced memory accessibility or report bias?. Journal of Abnormal Psychology, 289-295.

Laboratory studies of hypnotic hypermnesia have yielded inconsistent evidence of memory enhancement, and the process responsible for the occasional positive findings have eluded identification. The present experiment assessed delay recall for filmed material under conditions in which subjects were required to answer all questions, by guessing if necessary. They also rated confidence in the accuracy of each response. After an initial wake-baseline forced-recall test, subjects were randomly assigned to hypnosis or waking conditions for a second forced-recall test. Both groups of subjects recalled additional correct details on the second test, but the magnitude of this hypermnesia was no greater for subjects exposed to the hypnosis treatment. Hypnotized subjects did, however, exhibit a significantly greater increase in confidence for responses designated as "guesses" on the prior waking test--a finding consistent with the view that hypnosis engenders a shift in the subjective criterion for what constitutes a "memory". Implications of these findings for the use of hypnosis in forensic situations are discussed. McCann, Terry; Sheehan, Peter W.

(1987, October). Pseudomemory creation and confidence in the experimental hypnosis context. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Los Angeles.

After watching a video-tape of a bank robbery incident, 34 out of 40 highly hypnotizable subjects displayed pseudomemory reports subsequent to the administration of false memory suggestions given after hypnotic induction instructions. Incorporation of elements of pseudomemory into recall reports was accompanied by increased confidence ratings, but confidence ratings for those subjects displaying most pseudomemory distortion at recall fell appreciably when subjects were confronted with the reality constraints associated with recognition testing. Data imply that pseudomemories associated with hypnotic suggestion are not always accompanied by increased conviction or certitude, nor are they resistant to change in the face of contrary evidence. Data further indicate that subjects adapt both accuracy and confidence responses to the stimulus conditions of testing, implying that accuracy and confidence ratings may covary meaningfully.

1987

Register, Patricia A.; Kihlstrom, John F. (1987). Hypnotic effects on hypermnesia. International Journal of Clinical and Experimental Hypnosis, 35, 155-170.

The effects of hypnotic suggestions for improved memory were explored using procedures known to produce hypermnesia in the normal waking state. In Experience 1, 64 trait adjectives were randomly assigned to orthographic, phonemic, semantic, and self-referent orienting tasks in an incidental learning paradigm. These were presented to 40 Ss classified as low, medium, high, or very high in hypnotizability, followed by a series of 3 recall trials: immediately after the study phase, following a hypnotic suggestion for enhanced memory, and after termination of hypnosis. There were significant effects of both encoding condition and repeated trials on incidental recall. However, the hypermnesia effect observed in other experiments was not obtained, and there were no memory effects attributable to hypnosis. In Experiment 2, 60 line drawings of common objects were presented to an overlapping sample of 40 Ss, followed by the same recall procedure employed in Experiment 1. There was a significant hypermnesia effect of repeated trials, but again no effects attributable to hypnosis. In Experiment 1, the hypnotic procedure seemed to interfere with the normal waking hypermnesia effect; in Experience 2, hypnosis failed to enhance it. These results fail to support the use of hypnosis to enhance the memories of eyewitnesses in forensic investigations.

#### NOTES

The designs for Experiments 1 and 2 are complex and detailed, so they are not summarized here. The DISCUSSION follows, however:

"The present study concerned the effect of hypnotic suggestions on hypermnesia for words presented under conditions of incidental learning (Experiment 1) and for pictures studied under conditions of intentional learning (Experiment 2). Experiment 1 failed to produce a hypermnesia effect; in fact, recall decreased on the second trial, after hypnosis was induced, though these memories were recovered on a subsequent waking recall trial (for contrary findings, see Shields & Knox,

1986). This loss of memory was not a specific effect of hypnosis, because the extent of loss was not associated with S's hypnotizability. Experiment 2 succeeded in producing hypermnesia, but the effect was not a function of hypnotizability. These findings are consistent with those of Nogrady et al. (1985). Apparently hypnosis does not enhance waking hypermnesia effects.

"Dywan and Bowers (1983), who also embedded hypnosis in the waking hypermnesia paradigm, obtained somewhat different results. They observed a significant improvement in memory in hypnosis over and above what had been produced by waking hypermnesia. Moreover, they observed a significant increase in false recall on the hypnotic trial. These differences may have been due to the instructions given to Ss. Following the forced-recall procedure employed by Erdelyi and Becker (1974), Dywan and Bowers (1983) required their Ss to produce 60 items (the number of stimuli that had been presented during the study phase), even if they had to guess or respond randomly in order to do so. By contrast, neither Experiment 2 nor that of Nogrady et al. (1985) employed this forced-recall procedure. In addition, the instructions in Experiment 2 stressed accuracy in recall.

"The implication of these three studies taken together is that there is a high correlation between two products of hypnotic hypermnesia: any increase in accurate recall resulting from hypnotic procedures may be offset by a corresponding increase in false recollections. When Ss are not urged to produce more or new memories, hypnosis may not increase false recollection, but it will not increase accurate recall either. When hypnotized Ss are strongly encouraged to guess, as in Dywan and Bowers (1983), or in forensic situations, they may improve their levels of accurate recall, but this will be at the price of an increase in false recall. In fact, a study of normal waking memory by Roediger and Payne (1985) found that forced-recall instructions--in which Ss were asked to guess after they had exhausted their confident recall--increased intrusions tenfold over a condition in which Ss were warned 'not to guess wildly [p. 4]'--although there were no differences in correct recall. Although Roediger and Payne did not collect confidence ratings, we can assume that their Ss were able to distinguish between wild guesses and accurate memories (Johnson, 1985). Hypnotized Ss, however, appear to be poor at making this distinction (Dywan & Bowers, 1983; Nogrady et al., 1985).

"In the final analysis, hypnosis may encourage Ss to guess, but it does not appear to improve memory per se. Interestingly, hypnotized Ss do not seem to realize that they are guessing. Overall, their confidence levels tend to increase with no corresponding increase in accuracy (Dywan & Bowers, 1983; Nogrady et al., 1985). These Ss appear to confuse memories of prior guesses with those of the actual experience. For this reason, although cautionary instructions are likely to yield nothing new, instructions to guess are much more likely to produce misleading results when given to hypnotized individuals. This suggests that hypnosis is an unreliable technique for enhancing memory, and it should be used in forensic and other applied settings only with the utmost caution (for some guidelines see American Medical Association, 1985; M. T. Orne, 1979; M. T. Orne, Soskis, Dinges, & E. C. Orne, 1984). Other psychological techniques for improving memory may not possess these liabilities, and they may prove more suitable for use in field settings (Geiselman et al., 1985)."

1986

Nash, Michael R.; Drake, Stephen D.; Wiley, Stephen; Khalsa, Sahib; Lynn, Steven Jay (1986). Accuracy of recall by hypnotized age regressed subjects. Journal of Abnormal Psychology, 95 (3), 298-300.

Investigated the accuracy of the factual recall of highly hypnotically susceptible undergraduates both during and after the hypnotic procedure. Third-party verification (parent report) of the accuracy of recall was obtained for 2 S groups: 14 hypnotized Ss and 10 postsimulation control Ss. Results indicate that, despite the similarity to children in their way of relating to transitional objects, hypnotic Ss were significantly less able than control Ss to correctly identify the specific transitional objects actually used. Furthermore, all recollections obtained during hypnosis were incorporated into posthypnotic recollections, regardless of accuracy. Clinical implications are discussed.

Sheehan, Peter W.; Tilden, Jan (1986). The consistency of occurrences of memory distortion following hypnotic induction. International Journal of Clinical and Experimental Hypnosis, 34, 122-137.

The present study examined a range of circumstances for their effects on the vulnerability of hypnotic Ss to memory distortion. 26 high and 26 low hypnotizable Ss were tested individually in a design in which Ss received information that was either misleading or not misleading about a series of events depicting an apparent robbery. The information was presented prior to Ss being given hypnotic instructions, and low hypnotizability Ss were especially motivated for positive response in the session. Memory for the robbery was studied across a range of measures that included forced choice recognition, free recall, and response to leading questions. Results demonstrated predictably variable effects. The 2 groups performed appreciably differently in free recall, for example, while in recognition testing, data indicated that high and low hypnotizable Ss both incorporated misleading information into their memories to the same degree. Some implications of the data for the forensic context are discussed.

#### NOTES

56 Ss were prescreened with Harvard Group Scale of Hypnotic Susceptibility, Form A, defining highs = 9-12, lows = 0-3. Used Loftus materials for testing memory (wallet snatching sequence, on a series of slides). Errors were classified as errors of fact, of inference, or conjectures. Highs had more intrusions that were errors of fact than lows did ( $p < .05$ ), confirming the earlier results published by Sheehan & Tilden, 1984. There was no significant association between hypnotizability level and intrusion of central detail (description of robber and victim), but 57% of highs and only 18% of lows intruded peripheral objects incorrectly into their own narrative reports (i.e. descriptions given of the surroundings),  $p < .01$ .

There were trends for high hypnotizable Ss to recall more objects correctly than low hypnotizable Ss during narrative reporting ( $p < .06$ ) and to recall more central

objects ( $p < .06$ ), but not more peripheral objects. There may have been a loosening of criteria for memory among high hypnotizables, because they appeared to produce both greater accuracy and inaccuracy in recall of certain types of detail.

During the recognition testing, high hypnotizables exhibited significantly greater confidence in their responses than low hypnotizable Ss, but there was no group difference for accuracy. "Results for both tests of integration then (recognition and free recall) confirmed the prediction that hypnotic Ss incorporate false information into their memory, and the effect did not differentiate high from low hypnotizable Ss" (p. 131).

When a leading question implied that traffic lights were present in the scene, 34% responded in some way to that suggestion, and 20% said that they could see the lights in their minds eye; but 14% said that "although they could not see the lights, they nevertheless remembered they were there" (p. 132). Response to the leading question did not differ between high and low hypnotizable Ss.

In their discussion, the authors note that hypnosis did not enhance memory in this study. "Results overall suggest that hypnotic induction lowers the correspondence between confidence and accuracy. In the present study, hypnotic Ss were confident about their recall when the degree of accuracy of their reports suggested they should have been quite uncertain. Hypnotic instruction itself would appear, then, to establish conditions that spuriously facilitate a high degree of confidence in the reports that Ss produce.

"A major point to be made about the present study is that both general distortion and confidence effects observed here cannot necessarily be attributed to hypnosis. There was no independent comparison condition, for example, to contrast results for hypnotic Ss with results for Ss receiving no induction procedures. Effects, then, could be attributed to the hypnotic context as much as to the effects of induction per se, and context rather than state may be responsible for the vulnerability of hypnotic Ss that has been observed. The influence of context is seen at least in the clear evidence for an interaction between situational factors and hypnotizability. In free recall, hypnotizable Ss were more prone to distortions than un hypnotizable Ss, while in recognition, hypnotizable and un hypnotizable Ss were equally prone. Mode of testing is, therefore, a major contextual variable that is related to the nature of the distortion and confidence effects that can be observed. Present data further indicate that the hypnotic context is associated with memory distortion even in Ss who have little capacity for being hypnotized, but who are instructed to believe that they can, in fact, experience much of what is being suggested" (pp. 133-134).

Forensic implications need to be tempered because of difference between laboratory and real life, but practitioners nevertheless should be cautious. "While it is not true that hypnotized persons, by virtue of their hypnotizability level, will always distort their reports more obviously than nonhypnotic Ss, so as to bring their recollections into line with what is implied or suspected, parameters do exist that clearly increase the risks of distortion that can occur after hypnotic instruction. This is evidenced, for example, by the distinctive distortion effects that have been demonstrated for high hypnotizable Ss when they are given induction instructions and later requested to tell their story in their own way. Overall, the present data imply that the law needs to closely evaluate the impact of the different settings in which hypnosis takes

place and the different ways in which misleading information can be communicated to persons who are later asked to testify. The potential risks of hypnosis--as well as its utility--will depend critically on how that information has been conveyed, and the way in which Ss' memories are tested" (pp. 134- 135).

Wilson, L.; Greene, E.; Loftus, Elizabeth F. (1986). Beliefs about forensic hypnosis. International Journal of Clinical and Experimental Hypnosis, 34 (2), 110-121.

The beliefs people hold about hypnosis have an impact on the behavior of a witness who is hypnotized and on juries who hear these witnesses and weigh hypnotically influenced testimony. Students in Experiment 1 and registered voters from the community in Experiment 2 responded to questions about forensic hypnosis. Over 70% of the students as compared to about 50% of the community members were favorable toward the use of hypnosis by police for memory enhancement. In both groups, however, twice as many people reported that they would put less faith rather than more faith in the testimony of someone who had been hypnotized. A substantial portion of the students affirmed common myths about the effects of hypnosis on memory and behavior.

Stager, Gordon L.; Lundy, Richard M. (1985). Hypnosis and the learning and recall of visually presented material. International Journal of Clinical and Experimental Hypnosis, 33, 27-39.

To examine the effect of hypnosis on the learning and recall of visually presented material, high and low hypnotizable Ss were presented, under hypnotized or awake conditions, with a short, entertaining movie followed by questions about the movie. 2 week later Ss, hypnotized or awake, were again asked questions concerning the movie. The principal finding was that high hypnotizable Ss in the hypnotic induction condition increased accurate recall without increasing inaccurate recall. Neither hypnotizability nor hypnotic induction at learning affected recall. The major finding of the present study is that hypnosis during recall of previously learned material is facilitative, but that hypnosis during that previous learning is not.

Thornton, P. (1985). Use of hypnosis by the police in the investigation of crime. Which way should the pendulum swing?. British Journal of Experimental and Clinical Hypnosis, 2 (2), 125-127. (National Council for Civil Liberties' opinion about the Home Office's proposed guidelines on use of hypnosis by the police in the investigation of crime)

## NOTES

### "Conclusions

20. The dangers of using hypnosis in the criminal process are clearly demonstrated from a civil liberty point of view.
21. Inaccurate and misleading information supplied under hypnosis could lead to the investigation and arrest of innocent parties.
22. A witness who had undergone hypnosis could innocently yet confidently give false evidence.
23. Magistrates or juries may tend to rely on answers given under hypnosis as being more reliable than those given in the waking state simply because of the mystery surrounding the process.
24. A witness could be unfairly yet effectively cross-examined on the video-recording of the hypnotic state.
25. Hypnosis should not be used even as a last resort in the investigation of crime" (p. 127).

## 1984

Orne, Martin T.; Dinges, David F.; Orne, Emily Carota (1984). On the differential diagnosis of multiple personality in the forensic context. International Journal of Clinical and Experimental Hypnosis, 32 (2), 118-169.

The problems of diagnosing multiple personality disorder in a forensic context are discussed, and illustrated by the case of State v. Kenneth Bianchi (1979), a defendant who was both charged with first degree murder and suspected of having the disorder. Because of the secondary gain (e.g., avoiding the death penalty) associated with the diagnosis of multiplicity in such a case, hypotheses had to be developed to permit an informed differential diagnosis between multiple personality and malingering. If a true multiple personality disorder existed, then (a) the structure and content of the various personalities should have been consistent over time, (b) the boundaries between different personalities should have been stable and not readily altered by social cues, (c) the response to hypnosis should have been similar to that of other deeply hypnotized subjects, and (d) those who had known him over a period of years should have been able to provide examples of sudden, inexplicable changes in behavior and identity, and evidence to be the case. Rather, the content, boundaries, and number of personalities changed in response to cues about how to make the condition more believable, and his response to hypnosis appeared to reflect conscious role playing. Further, the life history indicated a persistent pattern of conning and deliberate deception. It is concluded that Mr. Bianchi was simulating a multiple personality and the diagnosis of Antisocial

Personality Disorder with Sexual Sadism was made. Differential diagnoses and the clinical aspects that appeared to account for his behavior are discussed.

Sheehan, Peter W.; Tilden, Jan (1984). Real and simulated occurrences of memory distortion in hypnosis. Journal of Abnormal Psychology, 93 (1), 47-57.

79 undergraduates were prescreened for high or low susceptibility to hypnosis (Harvard Group Scale of Hypnotic Susceptibility--Form A) and tested individually to examine memory distortion in hypnosis. Independent groups of Ss were allocated to a 2 x 2 factorial design in which S grouping (hypnotic or simulating) was crossed with an information condition that either misled or did not mislead Ss about a series of scenes depicting an apparent robbery. It was hypothesized that memory distortion would characterize the performance of hypnotic Ss when memory was examined in unstructured, narrative recall. Results show that real Ss were differentiated appreciably from simulating Ss in the extent to which they incorrectly intruded uncued errors (i.e., errors not arising from misleading information) into their memories but not in their intrusion of cued errors (i.e., errors arising from misleading information). Real Ss remembered correctly more detail of a peripheral kind but also distorted more with respect to the same kind of detail. Results overall negate the view that earlier memory traces are revived in hypnosis, thereby leading to more accurate retrieval, and suggest that hypnotic Ss bring distinctive styles of information processing to bear on their recollections of complex, socially meaningful events

Sheehan, Peter W.; Grigg, Lyn; McCann, Terry (1984). Memory distortion following exposure to false information in hypnosis. Journal of Abnormal Psychology, 93 (3), 259-265.

92 Ss preselected for hypnotic responsiveness on the Harvard Group Scale of Hypnotic Susceptibility--Form A were tested in strict application of the real-simulating model of hypnosis to examine the hypothesis that hypnotic Ss distinctively incorporate false material into their memories when that material is introduced after, rather than before, hypnotic induction. Both real (n = 46) and simulating (n = 46) Ss were either exposed or not exposed to misleading information after receiving induction instruction. Procedures for testing were otherwise identical to those adopted in an earlier study by the 1st author and J. Tilden (see PA, vol 71:14147) in which false information was presented prior to hypnosis. Results confirm the hypothesis and show that hypnotic Ss differed appreciably from simulating Ss by incorporating more misleading material into their memory. Findings highlight the possibility of distinctive processing in hypnosis and implicate lowered critical assessment by hypnotic Ss of information they confidently accepted in the hypnotic context (20 ref)

Flatt, Jennifer R. (1983). What makes therapy work? Thoughts provoked by a case study. Australian Journal of Clinical and Experimental Hypnosis, 11 (2), 63-72.

The case described is offered as illustrating the doubt common to introspective therapists: what did cure the patient? "Francesca's" presenting problem and the object of the short-term psychological intervention described here, was a fairly circumscribed set of fears related to enclosed spaces. The therapeutic approach adopted was primarily hypnobeavioural, with hypnotically-assisted systematic desensitization and "in vivo" exposure being the main components of the planned programme. However, at the client's suggestion, one hypnotic session with content planned by the therapist as age regression produced rather dramatic and unexpected results claimed by the patient to effect complete cure.

#### NOTES

The therapist suggested that "her mind would take her back to a time that was important in understanding her fears and that she would be able to stay calm and relaxed while this past event was revealed to her" (p. 69). She subsequently imagined being in a cave, peaceful and calm. "On being roused from hypnosis, Francesca eagerly described her cave image. She was enthusiastic about the significance of this experience, claiming that it was evidence that in a previous life she had died from being locked into a cave as some sort of punishment and that this experience made her fear of enclosed places rational and comprehensible to her" (p. 69).

**Karlin, Robert (1983). Forensic hypnosis--two case reports: A brief communication. International Journal of Clinical and Experimental Hypnosis, 31 (4), 227-234.**

Two criminal cases are briefly described. In these cases, hypnosis was used to "refresh the recollection" of the victim. In each case, the victim's unsupported identification of a perpetrator, produced through hypnosis, was the sole evidentiary basis of the prosecution. There was considerable evidence that both identifications were based on confabulation.

1981

**Zelig, Mark; Beidleman, William B. (1981). The investigative use of hypnosis: A word of caution. International Journal of Clinical and Experimental Hypnosis, 29 (4), 401-412.**

The purpose of the present experiment was to determine the efficacy of hypnosis for enhancing the recall of Ss exposed to a stress provoking motion picture. This stimulus, which vividly displayed several workshop accidents, was selected to provide an analog to witnessing an actual crime. After viewing the film, Ss were questioned in either hypnosis or in a waking state and responded to a questionnaire which contained leading and nonleading questions. Dependent measures included the number correct, number of errors, and the average confidence rating given to their responses. Analyses of these data revealed that waking Ss were significantly more accurate on leading questions. No significant differences were observed when Ss' responses to nonleading questions were examined. Post hoc correlational analyses across both hypnotic and waking conditions revealed that hypnotic

susceptibility and confidence ratings were positively correlated while susceptibility and the number of correct responses were not significantly correlated. These findings are compared with previous research and the resulting implications for hypnotically conducted interrogations are discussed.

1979

Ault, R. L. Jr. (1979). FBI guidelines for use of hypnosis. International Journal of Clinical and Experimental Hypnosis, 27 (4), 449-451.

The Federal Bureau of Investigation uses hypnosis as a tool for investigative purposes in selected cases where further leads are needed and witnesses or victims are willing to participate in a hypnotic interview. All sessions are tape recorded, preferably by video. A hypnotic interview cannot necessarily provide accurate leads, and therefore careful investigative work is done to verify the accuracy of any information obtained in hypnosis. Psychiatrists, psychologists, or physicians specially trained in hypnotic techniques have been employed to add protection for the witnesses or victims being questioned under hypnosis.

Hilgard, Ernest R.; Loftus, Elizabeth F. (1979). Effective interrogation of the eyewitness. International Journal of Clinical and Experimental Hypnosis, 27 (4), 342-357.

Eyewitness reports have been investigated in the psychological laboratory from time to time ever since 1900. Specimen studies from the early period and from the last decade indicate that free reports are consistently more accurate but less complete than reports obtained through specifically directed inquiry. The optimal combination is free report followed by the asking of specific questions. The wording of those questions, however, can have a substantial effect on the answers given. Furthermore, the wording of questions put to a witness can distort the witness's memory for the previously experienced event. These techniques and findings have implications for the study of other "retrieval" techniques such as hypnosis. Although laboratory-type control cannot be expected in practical settings, scientific validation of interrogation methods as practiced can be obtained if recording is complete and accurate, if processes of memory restoration or amplification are studied as they occur in the course of interrogation, and if outcome studies are fully reported, including both successes and failures to gain new information or to substantiate existing information.

Orne, Martin T. (1979). The use and misuse of hypnosis in court. International Journal of Clinical and Experimental Hypnosis, 27, 311-341.

The various forensic contexts in which hypnosis has been used are reviewed, emphasizing its advantages and pitfalls. The technique may be helpful in the context of criminal investigation and under circumstances involving functional memory loss. Hypnosis has no utility to assure the truthfulness of statements since, particularly in a forensic context, subjects may simulate hypnosis and are able to willfully lie even

in deep hypnosis; most troublesome, actual memories cannot be distinguished from confabulations either by the subject or by the hypnotist without full and independent corroboration. While potentially useful to refresh witnesses' and victims' memories to facilitate eyewitness identification, the procedure is relatively safe and appropriate only when neither the subject, nor the authorities, nor the hypnotist have any preconceptions about who the criminal might be. If such preconceptions do exist -- either based on information acquired before the hypnotic procedure or on information subtly communicated during the hypnotic procedure -- hypnosis may readily cause the subject to confabulate the person who is suspected into his "hypnotically enhanced memories." These pseudomemories, originally developed in hypnosis, may come to be accepted by the subject as his actual recall of the original events; they are then remembered with great subjective certainty and reported with conviction. Such circumstances can create convincing, apparently objective "eyewitnesses" rather than facilitating actual recall. A number of minimal safeguards are proposed to reduce the likelihood of such an eventuality and other serious potential abuses of hypnosis.

Putnam, W. H. (1979). Hypnosis and distortions in eyewitness memory. International Journal of Clinical and Experimental Hypnosis, 27 (4), 437-448.

An experiment was conducted to determine whether eye-witnesses questioned under hypnosis are more likely to answer leading questions incorrectly than eyewitnesses questioned in a normal waking state. Ss viewed a videotape-recording depicting a car-bicycle accident and were questioned about the details of the accident. Half of Ss were questioned under hypnosis and half of Ss were questioned in a normal waking state and in each of these conditions, half of Ss were questioned 15 minutes after seeing the videotape-recording and half were questioned after a 24-hour delay. The results revealed that Ss in the hypnosis condition made significantly more errors on leading questions (questions that suggested an incorrect answer) than Ss in the normal waking condition. There were no significant differences between the groups of Ss on objective, non-leading questions. The results are discussed in terms of their implications for the use of hypnosis in police investigations.

Worthington, T. S. (1979). The use in court of hypnotically enhanced testimony. International Journal of Clinical and Experimental Hypnosis, 27 (4), 402-416.

The leading judicial decisions on the use of hypnosis on witnesses are presented. Emphasis is on the increasing use of hypnosis by the police or prosecution with witnesses in criminal cases. Hypnosis has proved to be a valuable tool to learn facts not otherwise available. There is, however, a potential for abuse when the information learned is used directly as evidence in court or when the subjective certainty of the witness is increased to the point where cross-examination becomes ineffective. Safeguards are needed to prevent abuse.

1958

Conn, Jacob H. (1958). Meanings and motivations associated with spontaneous hypnotic regression. Journal of Clinical and Experimental Hypnosis, 6 (1), 21-44.

## NOTES

### "Summary

"The motivational influences and meanings associated with spontaneous regression have been discussed. It is postulated that when a patient spontaneously regresses he has the wish to recreate a previous life situation --one in which he was completely helpless. The clinical material indicates that the patient can be brought out of regression without any attempt being made to re-orient him to the present, and during spontaneous regression the patient can discuss topics which are subsequent to the regressed age level. The patient does not revive old memories but 'memory romances' which are rationalizations and wish fulfilling fantasies.

"The patient in the hypnotic trance is not passive, but is an active agent, who uses the therapist as a means of restoring the patient's feeling of mastery and control. A painful, baffling life situation which formerly had been the source of conflict, guilt or self-depreciation is in this manner mastered, so that the patient can start all over again as if he were 'reborn,' and can go on to a normal, healthy way of life.

"This is in keeping with Whitehorn's view (16) that 'symptoms have meaning in a motivational sense, that morbid patterns of reaction are part of an adaptational struggle, that one of the main tasks in psychiatric work is to conduct an individualized study of each patient to point up the main recurrent theme of dissatisfaction and conflict and to assess the individual's currently unused potentialities for dealing with this issue ...'" (p. 42).

## FAMILY

1995

Guyer, Charles G. II; Van Patten, Isaac T. (1995). The treatment of incest offenders -- a hypnotic approach: A brief communication. International Journal of Clinical and Experimental Hypnosis, 43 (3), 266-273.

Incest has become more prominent in public awareness over the past 15 years. The major focus of this interest has been on the incest survivor. The incest offender has received less attention. A hypnotic approach to treating incest offenders is outlined that involves a seven-stage approach. A case example is presented and future research directions suggested.

Levitt, Eugene E.; Pinnell, Cornelia Mare (1995). Some additional light on the childhood sexual abuse-psychopathology axis. International Journal of Clinical and Experimental Hypnosis, 43 (2), 145-162.

This exposition is an attempt to unravel the complexities of the relationship between childhood sexual abuse and adult psychopathology. Four facets of the relationship are examined in some detail: (a) the extent of childhood sexual abuse; (b) the probability that sexual abuse in childhood will result in psychopathology in the adult; (c) the reliability of early life memories in later life; and (d) the role of recovered memory of trauma in the healing process. The conclusions of this logico-empirical analysis are that first, government statistics tend to underestimate the extent of childhood sexual abuse, whereas independent surveys tend to overestimate it. Estimating prevalence is further complicated by variations in the definitions of key terms. Possibly the only safe conclusion is that true prevalence cannot be reliably determined. Second, empirical investigations of childhood sexual abuse conclude that not all victims are emotionally injured. A substantial number of these investigations find that a majority of victims suffer no extensive harm. Other variables such as family dynamics are involved; there may be only a few cases in which emotional harm results from sexual abuse as a single factor. Third, memory research suggests that memory in general is a dynamic, reconstructive process and that recall of childhood events is particularly vulnerable to distortion. Memory cannot dependably produce historical truth. Last, there is some clinical evidence that abreaction of a traumatic event in adulthood may have a remediative effect. Similar evidence for childhood trauma is lacking. The belief in the healing effect of recalling and reliving a childhood trauma depends on the therapist's orientation.

Nagy, Thomas F. (1995). Incest memories recalled in hypnosis -- a case study: A brief communication. International Journal of Clinical and Experimental Hypnosis, 43 (2), 118-126.

Accuracy of repressed memories recovered in hypnosis cannot be reliably determined with any greater certainty than non-hypnotically recalled events. Therefore, the practice of therapists' accepting hypnotically enhanced memories as veridical, absent corroborating evidence, is not advocated. A 52-year-old woman with a 27-year history of panic attacks and sleep disorder inadvertently recovered incest memories in hypnosis. Photographs and remembered events by other family members were thought by the patient to provide general support although they did not constitute actual proof of abuse. Implications are discussed.

Loftus, Elizabeth; Polonsky, Sara; Fullilove, Mindy Thompson (1994). Memories of childhood sexual abuse: Remembering and repressing. Psychology of Women Quarterly, 18, 67-84.

Women involved in out-patient treatment for substance abuse were interviewed to examine their recollections of childhood sexual abuse. Overall, 54% of the 105 women reported a history of childhood sexual abuse. Of these, the majority (81%) remembered all or part of the abuse their whole lives; 19% reported they forgot the abuse for a period of time, and later the memory returned. Women who remembered the abuse their whole lives reported a clearer memory, with a more detailed picture. They also reported greater intensity of feelings at the time the abuse happened. Women who remembered the abuse their whole lives did not differ from others in terms of the violence of the abuse or whether the violence was incestuous. These data bear on current discussions concerning the extent to which repression is a common way of coping with childhood sexual abuse trauma, and also bear on some widely held beliefs about the correlates of repression.

#### NOTES

In previous research, it was reported that violent or incestuous abuse is particularly susceptible to repression. This study differs from previous investigations in the definition of violence. In the present study, 'violence' is defined as any act involving vaginal, oral, or anal sex. Earlier research defined 'violence' as involving sexual assault with physical injury or fear of death.

Depending on the definition of repression, a sizeable minority (31% or almost 1/5) of this sample forgot their earlier abuse for a period of time. The authors state that this suggests there is little 'robust repression' in this sample. They cannot rule out the possibility that some women who were abused still, to this day, do not recall the experience; or that some who continue to have memory loss based on organic causes, including blackouts.

The authors suggest that future research in this area use more specific questions, including assessing whether Subjects respond to statements like: "There was a time when I would not have been able to remember the abuse, even if I had been directly asked about it," or "There was a time when I would not have been able to report the abuse because I had no idea that it had even happened to me." Also, when Subjects report that a memory had emerged after a period in which they had no recall, the Experimenter should enquire about how and when the recovered memory occurred. The authors conclude that remembering abuse is more common than forgetting it.

Lynn, Steven Jay; Myers, B.; Sivec, H. (1994). Psychotherapists' beliefs, repressed memories of abuse, and hypnosis: What have we really learned?. [Comment/Discussion] .

#### NOTES

The authors are responding to an article by Michael D. Yapko in the same issue of AJCH, "Suggestibility and repressed memories of abuse: A survey of psychotherapists' beliefs." They are of the opinion that "Yapko's research and data

analysis do not justify the conclusion that many, if not virtually all, therapists are naive, credulous, and out of touch with the scientific literature, although it is evident that certain therapists can be so described" (p. 184). They state that "Yapko's research is important insofar as it suggests that unfounded stereotypes of hypnosis persist even among Ph.D.- and M.D.-level clinicians" (p. 184).

1990

Rhue, Judith W.; Lynn, Steven Jay; Henry, Stephanie; Buhk, Kerry; Boyd, Patti (1990-91). Child abuse, imagination and hypnotizability. Imagination, Cognition and Personality, 10, 53-63.

Research was designed to provide a rigorous test of J. R. Hilgard's hypothesis that hypnotizability is related to a history of physical punishment and to imaginative involvements. College students who reported a history of physical abuse (N = 21) and sexual abuse (N = 23) were compared with control subjects who either lost a parent by way of death or divorce (N = 20) or who were from intact homes (N = 35), under test conditions that minimized the possibility that context effects would prejudice the findings. No support was found for the hypothesis that increased hypnotizability was associated with a history of physical or sexual abuse: All of the groups were indistinguishable on measures of objective and subjective response to hypnosis. However, consistent with Hilgard's hypothesis, physically and sexually abused subjects were found to be more fantasy-prone than subjects in both nonabused control conditions.

Somer, E. (1990). Brief simultaneous couple hypnotherapy with a rape victim and her spouse: A brief communication. International Journal of Clinical and Experimental Hypnosis, 38 (1), 1-5.

This paper presents a case involving a rape victim and her emotionally affected spouse. Although the assault occurred before the couple met, the husband was too upset to concentrate when the victim wanted to share her rape-related feelings, nor could he provide the much needed empathy and support. This, apparently, was due to his difficulties in handling his own rage. Simultaneous couple hypnotherapy was used to allow the victim to share her experience under conditions safe for both her and her spouse. As he imagined in trance the rape account described by his age-regressed wife, he learned to identify his emotions and experience them in a controlled manner. During subsequent sessions, the husband was encouraged to include himself in his wife's abreaction and reshape the traumatic scene for both of them. The husband's rescuing behavior and the expressions of violent anger towards the perpetrator had several positive consequences. Not only did they change the abandonment component of the victim's traumatic memory, but they also helped the husband deal in better ways with his own feelings of anger. It also provided the couple with a helpful coping mechanism they later effectively applied under different circumstances.

#### **NOTES**

**Describes history of Erickson's relationship to the Palo Alto group and family therapy practice (both strategic and interactional), and identifies seven philosophical and methodological realms which represent the incorporation of Ericksonian principles into strategic and interactional family therapy models.**

**1989**

**Wallace, Benjamin; Persanyi, M.W. (1989). Hypnotic susceptibility and familial handedness. Journal of General Psychology, 116 (4), 345-350.**

**The possible relationship between hypnotic susceptibility and familial handedness was examined. In a mass testing session of students enrolled in introductory psychology, subjects were administered the Harvard Group Scale of Hypnotic Susceptibility and were also required to complete a questionnaire that ascertained information on their dominant handedness and that of their immediate family relatives. Subjects who had immediate sinistral relatives scored significantly lower in hypnotic susceptibility compared to those who had a history of familial dexterity. When immediate relatives of the original subject pool were tested on hypnotic susceptibility level, sinistral relatives scored lower in susceptibility than dextral relatives. The important implication is that this may indicate the existence of a familial component in hypnotic susceptibility.**

**Brink, Nicholas E. (1986-87). Three stages of hypno-family therapy for psychosomatic problems. Imagination, Cognition and Personality, 6, 263-270.**

**In dealing with psychosomatic complaints it has been found useful and necessary to bring together three stages or techniques of psychotherapy. First, along with teaching relaxation, the therapist directs the client to define the symptom in a symbolic or figurative way describing size, shape, color, consistency, smell, and sound. These descriptors assess intensity and, over time, change in intensity of the symptom. Second, several hypnotic techniques are used to determine the dynamic pattern that has created the symptom. Such uncovered patterns have been found to invariably involve family dynamics. Third, hypnotic and family therapy techniques assist the client in changing the pattern. Examples are presented.**

**Miller, Arnold (1986). Hypnotherapy in a case of dissociated incest. International Journal of Clinical and Experimental Hypnosis, 34 (1), 13-28.**

**This case study describes hypnotherapy with a young woman who, in the course of treatment, began to remember her incestuous relationship with her alcoholic father. Her presenting symptoms included self-assaultive masturbation, suicidal fantasies,**

depression, impaired sexual functioning, and inability to resume her education. Different phases of treatment entailed uncovering work, mastering the incest experience with the help of emotionally corrective experiences, the use of part-selves to assist coping, and the integration of several part-selves into a more effective personality. After 4 years of treatment she has successfully resumed her education, has normal sexual functioning, and is no longer incapacitated by depression.

**1985**

Levitan, Alexander A. (1985). Hypnotic death rehearsal. American Journal of Clinical Hypnosis, 27 (4), 211-215.

Death rehearsal is a technique developed to help terminally ill patients and their families deal with anxieties about death. It has proven useful in demystifying the dying process by answering the question "What is it like to die?" Patients, who are able to hypnotically experience the death process, learn to deal with both grief and anxiety with the help of the hypnotherapist. - Author's abstract

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott; Frauman, David; Rhue, Judith (1985). Hypnotic age regression and the importance of assessing interpersonally relevant affect. International Journal of Clinical and Experimental Hypnosis, 33, 224-235.

The present study was undertaken to replicate an earlier experiment and to clarify which factors in this previous experiment (Nash, Johnson, & Tipton, 1979) were responsible for the obtained child-like behaviors of hypnotically regressed Ss. As in the previous study, 3 characteristics of the transitional object relationship (spontaneity, specificity, and intensity) were used as the primary criteria to investigate the effects of hypnotic age regression when Ss were regressed to age 3 and placed in 3 home situations. While in the previous study E suggested separation anxiety and isolation during the 3 home situations (mother-absent condition), the present study deleted all references to anxiety and isolation, and replaced them with suggestions of security and maternal proximity (mother-present condition). As expected, the mother-present versus mother-absent conditions led to similar hypnotized- simulating differences. In further accord with predictions, hypnotized Ss and simulating Ss requested a transitional object infrequently in the presence of mother. The importance of using dependent measures which index affective processes germane to interpersonal affect-laden experience is discussed.

Fung, E. H.; Lazar, B. S. (1983). Hypnosis as an adjunct in the treatment of von Willebrand's disease. International Journal of Clinical and Experimental Hypnosis, 31 (4), 256-265.

Hypnosis has been used to control bleeding, both in normals and hemophiliacs. Case material is presented to demonstrate how hypnosis was used as an adjunct to standard medical treatment of a boy and his mother with von Willebrand's disease,

initially to reduce anxiety and improve self-esteem and the parent-child relationship, and later, to reduce bleeding. This use of hypnosis illustrates the relationship between hemostatic control and psychological adaptation.

**1982**

Oliver, George W. (1982-83). A cancer patient and her family: A case study. American Journal of Clinical Hypnosis, 25 (2-3), 156-160.

In recent years, increasing numbers of mental health workers have been attempting to use techniques of psychotherapy to influence the course of malignant disease. This paper reviews in detail the course of treatment of one female patient with an inoperable malignancy and conveys a sense of the clinical experience of working intensively with a cancer patient and her family. It shows the complex levels of interaction within the patient herself, between the patient and her family, and between the therapist and her family and within the therapist himself during different phases of the therapeutic journey.

**1981**

Query, W. T. (1981). Family size, birth order and hypnotizability: A brief communication. International Journal of Clinical and Experimental Hypnosis, 29 (2), 107-109.

In 2 separate studies (N = 47 and 143), birth order and family size were found not to be associated with group-tested hypnotic susceptibility using the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962). The value of cross validation was demonstrated in the failure to verify the association that appeared between susceptibility and larger families for men in the initial study. Discussion focused on the developmental approach to hypnotizability, including birth order and family size as increasing hypnotic susceptibility in the family milieu. Family interaction influencing hypnotizability is immensely complicated and further studies are suggested.

**1976**

Call, Justin D. (1976). Children, parents, and hypnosis: A discussion. International Journal of Clinical and Experimental Hypnosis, 24, 149-155.

Ease of hypnotic induction in children depends on the setting, expectancies and nature of the relationship between the child, parent, and hypnotist. The capacity to center attention seems to be reflected in an increased alpha base rate. The capacity to suspend reality testing and to become subject to the authority of the hypnotist has its counterpart in the child's relationship with idealized authoritarian parents. Hypnotic induction utilizes the child's readiness for regressive object relations in which union of self and idealized parent imago is reactivated leading to high degrees of both suggestibility and feelings of omnipotence in the child. It is hypothesized that the child shares reality testing with the hypnotist as the infant did earlier with the all-powerful parent.

The fact that children can easily be hypnotized by the experienced hypnotist tells us nothing about indication for, dangers of, or potential success of treatment. Brief symptomatic improvement of single symptoms means little and proves nothing. Success of hypnotic treatment with children depends on appropriate articulation of hypnotic procedures with total need-systems of child and family.

Cooper, Leslie M.; London, Perry (1976). Children's hypnotic susceptibility, personality, and EEG patterns. International Journal of Clinical and Experimental Hypnosis, 24, 140-148.

19 boys and 16 girls, aged 7 to 16, were given the EEG and then the Children's Hypnotic Susceptibility Scale, while a parent watched. About 1 week later, after some separate tests and interviews, each child was given a puzzle to solve in the parent's presence, while Es recorded offers and requests for help. Hypnotic susceptibility was positively correlated with the alpha duration with eyes open, but not with eyes closed. Both susceptibility and alpha duration tended to be negatively correlated with age. Highly susceptible children tended to wait longer than low susceptibles before asking parents for help with the puzzle, and their parents tended to be more strict, anxious, and impatient than did the parents of low susceptible children.

Gardner, G. G. (1976). Childhood, death, and human dignity: Hypnotherapy for David. International Journal of Clinical and Experimental Hypnosis, 24, 122-139.

Hypnotherapy can be a significant part of the treatment of a dying child. A detailed clinical report illustrates how hypnotherapy was integrated with other treatment modalities to help a terminally ill child and his family cope effectively with problems and enhance their ability to use their own resources for personal growth and mastery throughout the dying process.

1969

Duke, J. D. (1969). Relatedness and waking suggestibility. International Journal of Clinical and Experimental Hypnosis, 17, 242-250.

Volunteering pairs of Ss took 9 waking tests (WT) of hypnotic susceptibility. Pairs included siblings, friends, and strangers. Concordance correlations from 20 sibling pairs were positive for 7 of the 9 WT, 2 significantly so. For 19 pairs of strangers, correlations were insignificant, 5 positive, 4 negative. Data reopen nature-nurture questions about the origins of individual differences in hypnotic aptitude. For 20 pairs of cross-sex friends, 7 of 9 correlations were negative, 1 significant, and 2 approaching significance. 6 of 9 concordance correlations from 16 spouse pairs were also negative, but none was significant. Nowlis, D. P. (1969). The child-rearing antecedents of hypnotic susceptibility and of naturally occurring hypnotic-like experience. International Journal of Clinical and Experimental Hypnosis, 17, 109-120.

Data pertaining to early and mid-childhood socialization experiences available from a sample of children and their mothers as studied earlier by R. R. Sears, E. E. Maccoby, H. Levin, and others were related to hypnotizability scores and scores of susceptibility to naturally occurring hypnotic-like experiences for a part of the same sample when the children reached late adolescence. As hypothesized by J. R. Hilgard and E. R. Hilgard (see 37:3) after retrospective interviewing with college-age hypnotic Ss, the present study, using a longitudinal method of investigation, indicated some relationship between firm parental discipline in childhood and subsequent susceptibility to hypnosis and hypnotic-like experiences in adolescence. Correlations, however, were low and the overall yield of significant data was judged to be meager. This was particularly true of hypnotizability scores in relation to the other variables available for analysis. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1968

Long, T. E. (1968). Some early-life stimulus correlates of hypnotizability. International Journal of Clinical and Experimental Hypnosis, 16, 61-67.

34 MALE COLLEGE SS WERE PLACED INTO 3 HYPNOTIZABILITY GROUPINGS WITH THE USE OF THE PASCAL TECHNIQUE OF HYPNOSIS. THE PASCAL-JENKINS BEHAVIORAL SCALES WERE USED TO INVESTIGATE STIMULUS SITUATIONS PRESENTED BY MOTHER AND FATHER DURING THE 1ST 10 YR. OF SS' LIVES. THE SPECIFICALLY DEFINED BEHAVIORAL VARIABLES OF ACTIVITIES WITH S AND DISPLAYS OF AFFECTION FOR THE FATHER STIMULUS CATEGORY AND THE VARIABLE VERBAL PUNISHMENT FOR MOTHER SIGNIFICANTLY DIFFERENTIATED THE HIGH HYPNOTIZABLE SS FROM THE COMBINED MIDDLE-LOW HYPNOTIZABLE SS. THE OTHER PHYSICAL CONTACT VARIABLES, WHICH INVOLVE INTIMATE CONTACT BETWEEN S AND THE PARENT, SHOWED CONSISTENT TRENDS IN THE SAME DIRECTION. THUS, EARLY LIFE FAMILY EXPERIENCES OF A MORE POSITIVE AND LESS DEVIANT NATURE SEEM TO BE ASSOCIATED WITH HIGHER SUSCEPTIBILITY TO HYPNOSIS. (SPANISH + GERMAN ABSTRACTS) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1962

Mellenbruch, P. L. (1962). The validity of a personality inventory tested by hypnosis. American Journal of Clinical Hypnosis, 5 (2), 111-114. (In Psychological Abstracts: 63, 5234)

NOTES

The authors found that administration of the California Test of Personality in the

waking and hypnotized state resulted in subjects describing themselves in a better light in the waking state than in the hypnosis condition. The differences were especially noted on the following scales: Self Reliance, Feeling of Belonging, Family Relations, and Occupation Relations. The scales least subject to distortion (in sense of presenting a good image) in waking state are Sense of Personal Worth and Freedom from Anti-Social Tendencies. J. Holroyd

**1960**

Schneck, Jerome M. (1960). Incest experience during hypnoanalysis. International Journal of Clinical and Experimental Hypnosis, 8 (3), 147-150.

#### **NOTES**

Author's Summary: "Whereas incest fantasies are not unusual and are mentioned during treatment along with more infrequent reference to actual past incest experience, the occurrence of an incestuous relationship while a patient is in treatment appears to be worth recording. Some of the pertinent facts regarding a sexual contact between brother and sister have been described in connection with the hypnoanalysis of the latter, and the manner in which the patient imparted information during hypnosis has been revealed by direct quotation" (p. 149).

**1959**

Wilcox, Warren; Faw, Volney (1959). Social and environmental perceptions of susceptible and unsusceptible hypnotic subjects. International Journal of Clinical and Experimental Hypnosis, 7 (3), 151-160.

#### **Summary**

1. The purpose of this study was to test the hypothesis that hypnotic susceptibility was positively related to the perception of fundamental aspects of the social and environmental milieu and, further, to consider the nature of hypnosis itself.
2. Ss for this study, 44 women and 36 men, were employed from a previous study (Faw and Wilcox, 1958). A mass hypnotic technique was used and susceptibility was operationally defined by the use of rating scales. The susceptible were found to have better personality adjustment than the unsusceptible.
3. New for this study were self-rating scales of the Ss' perception of parents, personal worries and problems, social activities as group or individually oriented, social activities in school, and physical care. The rating scales were administered several months prior to and independently of the hypnotic induction.
4. Interpretation of results support the hypothesis that the susceptible perceived their social and environmental milieu in more positive terms than did the unsusceptible. The susceptible perceived their parents in significantly stronger affectional and supportive relationships than did the unsusceptible. The susceptible were less concerned about adjustment to the opposite sex, not as worried about personal appearance, were more group oriented and more likely to engage in social activities than were the unsusceptible. Susceptible males were less frequently hospitalized than were unsusceptible males while susceptible females were more frequently hospitalized than were unsusceptible females.

5. Hypnosis was defined as a tendency to accept suggestions and to actualize, maintain and affirm them in the form of perceptual experiences activated by the stimulus situation as interpreted by the S and formulated by the hypnotist. The suggestions arouse expectancies or personal hypotheses which become a gauge to test the efficacy of the suggestions. Perceptualization is shaped by motives and past stimulation of the social and environmental milieu" (p. 158).

#### NOTES

Two experiments with young children explored the similarity between mothers' sleep inducing speech and hypnotic induction. The first group were six normal children ranging in age from 25 to 37 months. Author interviewed their mothers for details on their sleep inducing behavior. Then "we followed a procedure that as a rule consisted in leaning over the little one, dedicating all our attention to him, repeating the mother's own series of soothing diminutives in a softly-modulated voice, and stroking gently the child's hair, forehead, or arm. In four to thirty-five minutes, the children relaxed, stopped moving, let their eyelids droop, and showed a particularly placid facial expression. Their appearance was completely similar to that of a hypnotized person" (p. 83). Signs of catalepsy (e.g. following suggestions of holding a teddy bear more and more tightly) and concentration of attention to the exclusion of outside stimuli were taken to indicate the hypnotic state.

The second experiment involved infants 3 to 24 months old, lulling them into a state of quiet relaxation. "The difficulty does not consist in producing this special state, but in demonstrating that it is really hypnosis. However, if we consider the identity of the means employed in bringing it about, and the similarity of the results to those occurring at a slightly later age, it would be unreasonable to think that there is a certain reaction up to a certain age and a fundamentally different one from that age on" (p. 85).

The author relates her findings to those of investigators who studied populations of infants and children who, lacking "psychological mothering" failed to thrive or even died. She concludes that the "psychological mothering" in normal families "produces hypnotic states in the infant daily, from the moment of birth" (p. 88).

Erickson, Milton H. (1954). A clinical note on indirect hypnotic therapy. Journal of Clinical and Experimental Hypnosis, 2, 171-174. (Abstracted in Psychological Abstracts 55: 4292)

#### NOTES

Author describes treatment of a young married couple who presented with the problem of life-long enuresis. The treatment involved a prescription: "Each evening you are to take fluids freely. Two hours before you go to bed, lock the bathroom door after drinking a glass of water. At bedtime, get into your pajamas, and then

kneel side by side on the bed, facing your pillows and deliberately, intentionally and jointly wet the bed" (p. 172). (Hypnotic induction was not used.)

The author opines that the procedure was based upon an indirect use of hypnosis. "The instructions were so worded as to compel without demanding the inntent attention of the unconscious" (p. 173).

1053

Beigel, Hugo G. (1953). Prevarication under hypnosis. Journal of Clinical and Experimental Hypnosis, 1 (3), 32-40.

NOTES

Author describes three cases in which hypnosis was used to confirm or disconfirm information provided in the waking state. All three cases involved marital relationships and mistrust. "It is interesting that, awakened from the hypnotic state, none of the subjects made the slightest attempt to deny any of the admissions made" (p. 39).

FANTASY/ FANTASY PRONENESS

2003

Holroyd, Jean (2003). The science of meditation and the state of hypnosis. American Journal of Clinical Hypnosis, 46 (2), 109-128.

Two aspects of Buddhist meditation -- concentration and mindfulness -- are discussed in relationship to hypnosis. Mindfulness training facilitates the investigation of subjective responses to hypnosis. Concentration practice leads to altered states similar to those in hypnosis, both phenomenologically and neurologically. The similarities and differences between hypnosis and meditation are used to shed light on perennial questions: (1) Does hypnosis involve an altered state of consciousness? (2) Does a hypnotic induction increase suggestibility? It is concluded that a model for hypnosis should include altered states as well as capacity for imaginative involvement and expectations.

2002

Linden, Julie H. (2002). Playful metaphors. American Journal of Clinical Hypnosis, 45 (3), 245-250.

The inner world of the child is a community of archetypes potentially available for the child's healthy ego development. Many forces limit and prohibit their utility. Play therapy in the context of a hypnotic relationship can potentiate these archetypes into becoming "playful metaphors" for healing and strengthening ego development. In this article, the author describes her use of playful metaphors in her therapeutic work with two children and explores how metaphor in play therapy is able to connect the child with healing archetypal imagery. Sapp, Marty (2002). Implications of Barber's Three Dimensional Theory of Hypnosis [Abstract]. Sleep and Hypnosis, 4 (2), 70-76.

Recently, Barber has presented a three dimensional paradigm of hypnosis. He proposed that there are three types of hypnosis clients- the fantasy-prone, amnesic-prone, and positively-set. This paper discusses the major theoretical implications of this new paradigm, and, if Barber is correct, his new theory should bridge a gap between the special process (state) and nonstate theorists. Finally, only research will determine if Barber's new theory will actually unify the previous disagreements between the state and nonstate theorists.

1988

Gibbons, Don (1998). Suggestion as an art form: Alternative paradigm for hypnosis?. [Paper] Presented at annual meeting of American

Psychological Association, San Francisco. ([available online:] <ftp://members.aol.com/gibbonsdon/artform.txt>)

This paper proposes a change in the manner in which we think about suggestion-induced phenomena, moving from primary reliance upon a medical/counseling model to a concurrent view of suggestion as an art form and hypnosis as an artistic medium. the rationale for such an alternative paradigm is discussed, and a procedure for scripting suggestions within the new paradigm -- the Best Me technique -- is presented, along with a specific illustration of its application, possible implications for current clinical practice, and suggestions for transition to the new paradigm.

1995

Bryant, Richard A. (1995). Fantasy proneness, reported childhood abuse, and the relevance of reported abuse onset. International Journal of Clinical and Experimental Hypnosis, 43 (2), 184-193.

This study investigated the relationship between fantasy proneness and the age at which reported childhood sexual abuse occurs. Seventeen adult females who reported having been sexually abused before the age of 7 years, 20 females who reported having been abused after the age of 7 years, and 20 females who reported having never been abused were administered two measures of imaginative involvement (Tellegen Absorption Scale [TAS] and Inventory of Childhood Memories and Imaginings [ICMI]). Participants who were reportedly abused early in childhood obtained higher scores on the TAS and ICMI than participants who were reportedly abused later in childhood, who in turn obtained higher scores than the control participants. Findings are discussed in terms of factors that mediate fantasy proneness and reports of childhood abuse.

Gearan, Paul; Schoenberger, Nancy E.; Kirsch, Irving (1995). Modifying hypnotizability: A new component analysis. International Journal of Clinical and Experimental Hypnosis, 43 (1), 70-89.

The effects of the Carleton Skills Training Program (CSTP) on hypnotizability were compared to those of a modified training program in which instructions for physical enactment of the response were omitted. After training, subjects in the original CSTP reported an increase in the extent to which they intentionally enacted suggested behaviors. In contrast, subjects in the modified training program reported increased fantasy without voluntary physical enactment. Nevertheless, both training programs increased behavioral and subjective responsiveness to suggestion, and there were no significant differences in response enhancement between the two programs. Across conditions, increases in behavioral and subjective responses to suggestion were correlated with increased use of fantasy. In contrast, increases in enactment were correlated only with compliance. The modified training program is recommended as a means of enhancing suggestibility with less likelihood than the original CSTP of engendering compliance.

Malinoski, Peter; Martin, Daniel F.; Aronoff, Jodi; Lynn, Steven Jay; Gedeon, Scott (1995, November). Hypnotizability, individual differences, and interpersonal pressure to report early childhood memories. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

#### NOTES

Infantile amnesia is attributed to developmental issues before 24 months. This study indicates non-hypnotic influences can shape early memories that cross the amnesia barrier.

227 Ss completed Harvard Scale and personality measures in Session 1. In Session 2 182 completed a suggestibility scale. In Session 3 they were selected, as if independent of earlier sessions - 143 [may have misheard number] Ss.

Interviewers told the selected Ss that they were experiencing something like psychotherapy, and they were asked to recall their earliest memory (independent of photos, what people had told them, etc.) Then Experimenters probed for earlier memories; that continued until Ss denied any more memories after 2 consecutive probes. Then Ss were asked to close their eyes and get in touch with more memories. Then they were told most Ss can remember more, including sometimes their second birthday party. After 1 minute, Ss were asked about memories of their second birthday. Then they were asked to focus on even earlier memories, implying it was expected and receiving complements for reporting earlier memories. Finally, Ss completed a post-study questionnaire.

Memory report was a verbal description of an event, person, or object. Initial memory mean age was 3.7; it correlated with Openness to Experience Scale and with Fantasy Proneness. Mean age of the last earliest memory report before the close eyes instruction was 3.2 years. After receiving visualization instructions, 59% reported a memory of their second birthday. Compliance correlated .33 with this. Subjective response, nonvoluntariness, and [missed words] also correlated.

Compliance scores correlated .28 with at least one memory at or before age 24 months. Yielding to leading questions correlated also with memory for an event at or before 24 months.

Clarity of memories decreased between conditions of initial memory, earliest query, birthday, and earliest memory. Mean confidence rating on 5 point scale for second birthday memory was 3.3; mean confidence rating for earliest memory was 3.6. Mean accuracy rating was 4.0, and 94% said their memory reports were accurate to at least a moderate degree.

The post study questionnaire, totally anonymous, indicated Ss did not feel much pressure to recall (2.9 on scale of 1-5). Only 9.8% indicated they felt a lot of pressure. Subjects also usually denied that they made up memories to satisfy the experimenter. On average, the reports of memory under visualization conditions occurred two years earlier than their first reported memories.

**1994**

Csoli, Karen; Ramsay, Jason T.; Spanos, Nicholas P. (1994, August). Psychological correlates of the out-of-body experiences--a reexamination. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

**NOTES**

12% of population reports an out-of-body experience (OBE) sometime in their lives. They leave their body and can see self from the outside. Awareness is confined to the new point of view, not fragmented; there is unimpaired intellectual ability; feelings of detachment, completeness, well being, and profound relaxation. Can occur under stress or deep relaxation; not while driving a car.

Psychological correlates aren't known. Studies are inconclusive with respect to belief systems (religious, death anxiety, etc.); measures of absorption, hypnosis, imaginative ability, imagery controls. Recent Carlton study with 87 Ss (33 had OBE) got results we didn't expect. They completed questionnaires, were tested for hypnotizability, had an interview re OBE experience.

This study found the OBE-experiencing people had higher levels of anxiety, psychosomatic symptoms, and panic attacks. They were also higher on magical thinking, perceptual aberration, and Schizophrenia scores. They didn't differ on mysticism, levels of drug or alcohol use, or level of self esteem.

Lynn, Steven Jay; Pezzo, Mark (1994, August). Close encounters with aliens? Simulated accounts following a hypnotic interview. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

**NOTES**

A survey of 5900 adults regarding unusual experiences concluded that 1 of 50 Americans may have had UFO experiences.

This study resembles that of Lawson (1977), in which Ss were asked to imagine UFO experiences; their descriptions were difficult to distinguish from real reports. One problem with Lawson's research is that he provided the Ss with information (e.g. to imagine they were abducted by aliens).

Our study differs from Lawson's in that we didn't actually hypnotize subjects. Our Ss' task was to 'simulate hypnosis, in recovered memory research.' We manipulated cues provided to the Ss.

Ss were told their purpose was to role play an excellent hypnotic subject. Standard simulation instructions were given. Then they were told that hypnosis frequently is used to recover experiences that the Ss cannot remember.

Ss were given a description of a Scene: driving on a road in the country, no traffic, etc. They were told that they couldn't remember 2 hours of what happened. Then a second Experimenter used a pseudo hypnotic induction, and told them they were going to recall material regarding events that had happened.

Ss completed an Omni Magazine questionnaire developed by Hopkins, who is an advocate of UFO sightings. They received the questionnaire either after the experiment, before the experiment, or with specific cues.

4 of 21 (19%) of the minimal cue condition Ss identified lights in the sky as a UFO; at the end, 52% saw a UFO. Thus, even with minimal information, subjects report interactive behavior. Almost all medium cue Ss reported the UFO. 17% felt a loss of control, being floated or transported to the spaceship. Only one S said the aliens were cruel. Only one of the role players picked up the word "trondant," a word used by Hopkins to pick up simulators who are hypnotized.

Our findings present a conservative picture. When Ss thought they would be thrown out of the experiment if detected as simulators, they avoided talking about bizarre events. 15% who were told to role play a close encounter failed to do so!

Our findings do not imply that persons who report contacts are simulating; but the basis for such reports are widely available to college students.

Malinoski, Peter; Aronoff, Jodi; Lynn, Steven J.; Moretsky, Michael (1994, August). Hypnosis and early memories. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

## NOTES

We studied autobiographical memory in the college population, as manifested in the therapy situation, as a way of investigating an individual difference variable. Most people do not have recall before age 3 or 4 (and probably infantile amnesia begins before age 2).

Administered Autobiographical Memory Scale (AMS), and later in context of a hypnosis scale. 247 students were in phase 1, conducted as two separate experiments so that Ss wouldn't link the AMS to measures used in the second study.

First study was presented as a study of personal memories. Asked Ss to distinguish first five birthdays, circumstances around loss of first tooth, first day of high school. Also, they were asked about their earliest memory events, rated according to 3 scales (detail, vividness, accuracy of recall). Authors summed Ss' responses on these 3 ratings for the 8 item scale.

Part II. Administered various scales: Life Experiences, Fantasy Proneness, Wilson & Barber's scale, Imagery Control Scale, Global Psychopathology, 25 item scale of physical and sexual abuse, Brier's list of symptoms of abuse, and DES (Dissociative Experiences Scale). Imbedded were 12 items to test carelessness in responding (e.g. "I have never said Hello to anyone who wore eyeglasses.")

RESULTS. Phase 1. Two people indicated they had memories dating to before their first birthday; an additional 5% of Ss gave memories between 12-24 months. This

would probably be impossible. Another 14.4% described events between 24-36 months; 37.4% said their earliest memory was at age 3. Mean age for earliest memory was 3.4 years (which agrees with other surveys.) Only 1 subject stated his earliest memory was as late as the tenth year of life.

High intercorrelation was obtained, ranging .79 to .89, between ratings on any of the memory event ratings (as detailed, vivid, or accurate). There was a negative correlation of these ratings with age of recall. Ss who report more detail, vividness, and competence, were also likely to report earlier first memories.

Authors divided Ss into three groups based on age of first memory: 12 with first memory earlier than first year; those whose first memory was between 1-7 years; and those with a later first memory. The earlier memory group were more fantasy prone; and rated their memories as more reliable, vivid. This suggests there are persons who report memories that are covered by infantile amnesia, report them with greater detail, and are more fantasy prone than those who report memory events beginning later in life. This is consistent with Wilson & Barber's finding that fantasy prone people have vivid recall of early childhood events.

None of the memory reports correlated with psychopathology or dissociation. Dissociation (DES) was correlated with abuse indicators, however. Compared top and lowest 10% and middle range on DES on their memory scores and found no relationship. There was no support for the idea that report of early life events in dissociative people is compromised. Failure to recall early memories shouldn't suggest that people are dissociative (which some therapists tend to do).

All three memory measures were associated with Harvard Scale scores. The AMS was administered at the same time as the Harvard. Objective responding on the Harvard correlated with detail, vividness, and accuracy of recall. Also, involuntariness of response correlated with all 3 measures of the AMS. Finally, subjective involvement correlated with all three measures of AMS. At least when hypnosis is measured first, and explicit connection is suggested, there is a connection. Further research is needed to see if the relationship holds when measured in independent contexts. This may explain why High Hypnotizables are more prone to pseudo memories and leading questions. They may come to confuse them with historical reality.

The results suggest caution for early memory reports. They may be vulnerable to confusing fantasy and reality, as well as to biasing effects.

Newman, Leonard S.; Baumeister, Roy F. (1994, August). Who would wish for the trauma? Explaining UFO abductions. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

#### NOTES

UFO abduction reports are more frequent than ever before. 1979 200 1984 500 1988 5000 letters [to a magazine?] 1993 55,000 letters, with 200/wk still being sent Hopkins, Jacobs, & Westrum (1992) took a poll: 3.7 million abductees in U.S. were estimated.

These, I maintain, are motivated in attempt to accept the self; the phenomenon relates to masochism on a psychological level. I think we need a more psychological

explanation than other arguments being presented. The other arguments being made are: 1. People are actually being abducted. 2. Abductees are publicity seeking liars. 3. These people cannot distinguish between fantasy and reality (but there is no evidence for that).

The two key questions we should attempt to answer are: 1. Why would people claim to remember things that did not actually happen to them? Most of these reports emerge under hypnosis. They may be creating memories rather than retrieving memories. 2. Why would people claim to remember this in particular?

Maybe abductees are people with knowledge about reports of UFO experiences, with therapists who believe in paranormal experiences? Probably this is not the explanation.

In the '50's there were reports of space aliens who abducted people, taught them about peace, love, etc. and the need for intergalactic harmony. But stories today are very different.

They want to escape the self because the self is "me." They may have done something that makes them feel stupid, unlovable; or it is just because of constantly having to maintain a positive self image. This kind of anxiety pertains to people who have an over-inflated presentation of the self. If you can avoid thinking about the implications of your behavior (e.g. through drinking, vigorous exercise, or masochism) you don't have the anxiety.

Masochism is a bizarre way to obtain pleasure, but it underlines both of these things. It cancels out meaningful aspects of the self (thought, self reflection); and needs of control are denied (bondage); it negates esteem and dignity. People higher paid, in more responsible jobs, are more likely to engage in masochistic activity.

The main features of masochism also apply to abduction stories: 1. Pain 2. Loss of control 3. Humiliation 4. Demographics (abductees seem to come from higher socio-economic classes) 5. International pattern - mostly an American & British phenomenon 6. Concern with "selfhood" 7. Sexual differences. (There are male and female masochists, but the contents are different: females more often talked about humiliation involving display than men did. Abduction cases are the same: alien examination episode (display) are in 50% of male stories but 80% of female stories.)

1993

Elter-Nodvin, Sabette; Lynch, Gregory; Nash, Michael R. (1993, October). Is primary process mentation a feature of hypnotic responding?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

It is difficult to measure primary process; usually measures from Rorschach are used. Recently Steven Lynn and Ken Bowers have done interesting work.

From literary criticism, we took the newer method of lexical pattern analysis--like a fingerprint (e.g. of Shakespeare's language). Wanted to determine whether there are differences between High and Low hypnotizables; or a difference in waking and hypnotic state. Martindale has a measure based on a lexical dictionary.

In Martindale's method, you take a long verbal sample, transcribe it into computer text file (response to TAT cards, and 3 tasks like--"Imagine you are ascending a spiral staircase and see someone at the top; describe what you see"); then do word count.

Rhue, Judith W.; Lynn, Steven Jay (1993, October). Dissociation, childhood sexual abuse, and fantasy. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

## NOTES

We are reporting on part of an ongoing study, with results still being analyzed. We are looking at imagination, fantasy, and dissociation in abused and non-abused children. This focuses on the relationship between dissociation and fantasy and imagination.

For Janet, dissociation was the primary defense against trauma. [Quotes D. Spiegel also.] There is a body of research on trauma associated with the development of dissociation. 1. NIH found 97% of multiple personality patients reported trauma in childhood; 83% were sexually abused; 75% were repeatedly physically abused; 68% had both types of abuse. 2. Bliss - studied 70 MPDs and found same results. 3. Ross, Norton, and Noosney [?name] - found same results 4. Coombs & Milstein - same

The incidence of retrospective reports of abuse is much lower in other types of patients.

So, what is going on during child abuse? We wanted to look at children experiencing or who recently experienced abuse. Also looked at a children's scale of dissociation symptoms and validated other studies.

We studied 39 children referred to Ohio University College of Osteopathic Medicine; 12 had primary problem as sexual abuse (8 of whom were female). Non-abused Ss were either behavioral or adjustment disorders. 8 reported severe physical abuse. Parents concurred in presence of abuse. Physical abuse consisted of broken bones, burns, etc. Average age 9-10.

Ss were given the Beck Depression Scale, Children's Fantasy Inventory, Meyers' Children's Creative Imagination Scale, Children's Perception Alteration Scale, Figure Drawings, WISC-R, and 2-3 other measures. Research assistants administering the scales didn't know the children's diagnoses.

We found no support for the hypothesis that sexual abuse in childhood is associated with imagination, fantasy, or dissociative tendencies--not surprising considering that only 4 Ss were abused by their father or stepfather, 2/3 of Ss had fondling as the most severe abuse they had experienced; only 2 had intercourse; 2/3 were abused only 1-3 times. Sexual abuse that is not violent, severe, prolonged, or perpetrated by a parent may not lead to the same problems.

In a sample of women whose assaults were rape, only 25% reported it as rape.

On other hand, physical punishment was more reliably associated with dissociation (.47), imagination and fantasy in absorption scale (.41-.51 with question about using imagination to block awareness of punishment). Physical punishment was associated with increased dissociation.

Sample size is small and the trend is in the predicted direction, so later results may be significant.

**Conclusion:** measures of fantasy, dissociation, and imagination were correlated. Children's Perception Alteration Scale and the measures of fantasy and imagination were validated. Diverse measures of fantasy were highly correlated with one another.

We need a non-abused sample to add to this research.

The clinical sample had a higher dissociation score than Evers, Sanders, and Shostick's cutting score. We use 60 as a cutting score (for an abused sample) while they used 55.

#### **COMMENTS FROM THE AUDIENCE:**

**Jack Watkins:** the sexual abuse for the most part was not painful. Answer by Rhue: The group of sexual abuse cases includes very wide varieties of experiences; we need to examine that in our research. Also, trauma and the perception of trauma is an individual matter.

**Etzel Cardena:** We presented a paper at APA in which sexual abuse was a predictor of psychogenic seizures, and most important, the duration of the abuse.

**Phyllis Alden:** In a recent study in Germany, it was length of time for the abuse that predicted [dissociative symptoms?].

**1992**

**Barrett, Deidre (1992).** Fantasizers and dissociaters: Data on two distinct subgroups of deep trance subjects. *Psychological Reports*, 71, 1011-1014.

The study delineated two subgroups of highly hypnotizable subjects. The first subgroup (fantasizers) entered trance rapidly, scored high on absorption (mean of 34 on the 37-item Absorption Scale), and described hypnosis as much like their rich, vivid, and very realistic waking fantasy life. None of the fantasizers experienced unsuggested amnesia, and 5/19 failed to produce suggested amnesia. Only 2/19 fantasizers described hypnosis as very different from their other experiences. The earliest memories of fantasizers were all identified as occurring before age 3, and before age 2 for 11 of 19. The second subgroup (dissociaters) took time to achieve a deep trance (unlike Wilson and Barber's fantasy-prone subjects, but they did achieve as deep a trance as fantasizers), experienced hypnosis as different from any prior experiences, and were more likely to exhibit amnesia for both hypnotic experience and waking fantasies. None of the dissociaters described their waking imagery as entirely realistic, and the earliest memories in this group were all over the age of 3 (mean age - 5). Of the 15 dissociaters, 7 scored below the norm on the Absorption Scale (Mean - 26).

**Bowers, Kenneth S. (1992).** Imagination and dissociation in hypnotic responding. *International Journal of Clinical and Experimental Hypnosis*, 40 (4), 253-275.

A neodissociative model of mind is better equipped than a social-psychological model to deal with the complexities of hypnosis, and of human behavior generally. It

recognizes, as Coe's (1992) model does not, that behavior can be more automatically activated than strategically enacted. In particular, Coe's emphasis on human behavior as purposeful and goal directed does not distinguish between goal-directed behavior that serves a purpose, and goal-directed behavior that is performed on purpose. It is this distinction that permits goal-directed behavior to be dissociated from a person's conscious plans and intentions. In addition to offering a critique of Coe's "limited process" view of hypnosis, 4 main points are made in the interest of developing a slightly modified, neodissociation view of hypnosis. First, it is argued that goal-directed fantasies are more limited in their ability to mediate hypnotic responding than is commonly appreciated; as well, they do not seem to account for the nonvolitional quality of hypnotic responding. Second, it is argued that hypnotic ability is not unidimensional, with compliance and social influence more apt to account for the low than for the high hypnotizable's responsiveness to suggestion. Third, compared to low hypnotizables, the hypnotic responsiveness of high hypnotizables seems more likely to result from dissociated control. In other words, for high hypnotizables, hypnotic suggestions may often directly activate subsystems of cognitive control. Consequently, the need for executive initiative and effort to produce hypnotically suggested behavior is minimized, and such responses are therefore experienced as nonvolitional. Fourth and finally, while goal-directed fantasies typically accompany hypnotically suggested responses, they are in many cases more a marker of dissociated control than a mediator of suggested effects.

Kunzendorf, Robert; Carrabino, Carlene; Capone, Daniel (1992-93). 'Safe' fantasy: The self-conscious boundary between wishing and willing. Imagination, Cognition and Personality, 12, 177-188.

This experiment tested the hypothesis that a fantasy will impel people to 'act out' only if they fail to distinguish the fantasy from the anticipated reality. In the experiment, one task obtained a baseline measure of how long subjects could resist eating popcorn, then measured how long subjects could resist popcorn while fantasizing its taste. Another task instructed subjects to merge three circular images with three circular percepts of equal vividness, then presented subjects unexpectedly with only two of the three circular percepts. Some subjects thought that there were three circular percepts during the merger, and for these subjects, the length of resistance to popcorn was significantly shorter during the popcorn fantasy. But for subjects who self-consciously differentiated the two real circles from the three merging images, the normal 'boundary' between wishful fantasy and willful eating was intact. NOTES 1:

#### NOTES

This research investigated whether people can fantasize without acting out. The authors place the study in the context of theories proposed by Freud and William James. Kunzendorf's source monitoring theory of self-consciousness suggests that "self-consciousness \_that one is imaging\_ is the phenomenal consequence of neurally monitoring the central source of one's imaged sensations, and self-

consciousness \_that one is perceiving\_ is the subjective quality of neurally monitoring the peripheral source of one's perceived sensations" (p. 178).

The ability to carry out source monitoring varies. Those who have difficulty monitoring whether they are imaging or perceiving may also have trouble distinguishing wishful fantasy from anticipatory imagery, and therefore they might act on it.

This research "identified subjects with poor source monitoring--nondiscerners of reality--and investigated the effect of fantasy on their impulse control" (p. 179).

## **METHODS**

Subjects sat in front of a computer monitor for all tests; they completed Eysenck's seventh impulsivity questionnaire for measures of impulsivity, venturesomeness, and empathy, Marks' Vividness of Visual Imagery Questionnaire (VVIQ).

The study used a test in which subjects maintained in mental imagery a red, green, and yellow filled circle that had been on screen, with eyes closed; were instructed to open eyes and merge their 3 imaginary circles with the 3 on the screen (but when they opened eyes only 2 were there), and they were then asked questions about how many circles they saw when they opened their eyes.

Then they were given a taste of popcorn, told to resist eating any more (but could press a key to receive a little if they couldn't resist), and then were told to resist by imagining that they were eating popcorn.

**RESULTS.** Those who discerned the two real circles while imaging a third circle of equal vividness (the Discerners), could resist eating popcorn for 137 sec in the baseline condition and 132 sec in the fantasy condition. Those who could not discern two real circles while imagining a third (Nondiscerners) could resist eating popcorn for 127 sec in the baseline treatment but only 95 sec in the fantasy treatment.

Discerners could identify the missing circle as the red one, whereas nondiscerners could not do so with any certainty; there was no effect of "image vividness".

"Vivid imagers" whose imagery matched real yellow circles of greater illuminance, exhibited more vivid imagery on the VVIQ as well.

In their Discussion, the authors suggest that "fantasy impels people to 'act out' only if they fail to distinguish fantasized sensations from perceived sensations. ... [the theory] is applicable to sexual fantasy and aggressive fantasy as well. This theory--Kunzendorf's 'source monitoring' theory of self-consciousness--implies that fantasies of the sensory consequences of a behavior should not lead to the behavior, so long as the fantasies are self-consciously known to be imaginal and are not expected to be perceptual... But for people who cannot self-consciously distinguish between wishful images of pure fantasy and anticipatory images of perceptual reality, between wishing and willing, fantasies of gastronomical, sexual, or aggressive sensations are implicitly unsafe.

"Indeed, as Baars notes, 'the issue of voluntary control is at the very core of human psychopathology' [31, p. 254]. But recently, Baars' and others' theories of volition have emphasized the computer-metaphoric distinction between conscious 'willful' behavior and unconscious 'automatic' action [31, 39-40], and have neglected James' distinction between conscious willing and conscious wishing. Decades ago, when pre-computational theorists like Janet used the term 'automatism' to describe

psychopathological behavior, they meant that an abnormally behaving patient was \_consciously 'possessed' by a fantasy\_--a wishful image, a hypnotic suggestion, or a fantasized personality [41]. In reemphasizing the phenomena of wishing, willing, and possession by fantasies, the present article redefines the latter phenomenon as possession by 'unmonitored' fantasies, which are distinguishable from anticipatory images impelling action" (pp. 184-185).

Lynn, Steven Jay; Sivec, Harry (1992). The hypnotizable subject as creative problem-solving agent. In Fromm, Erika; Nash, Michael R. (Ed.), Contemporary hypnosis research (pp. 292-333). Guilford Press.

#### NOTES

These notes are taken only from the section of this chapter that deals with Hypnotic Responding, Imaginative Activity, and Expectancies, and they treat of the concept of nonvoluntary responding (pp 315-316). Other topics covered in the chapter include: Imagination, Fantasy, and Hypnosis Theories; The Hypnotizable Subject as Creative Problem-Solving Agent; Hypnosis and Subjects' Capability for Imaginative Activity; Goal-Directed Fantasy: Patterns of Imaginative Activity during Hypnosis; Hypnosis and Creativity; and a Conclusion.

Several studies manipulated expectancies re the relationship between imagination and involuntariness. When Ss were told that "good" hypnotic subjects could (or could not) resist suggestions, "this information affected their ability to resist the hypnotist and tended to affect subjects' report of suggestion-related involuntariness ... [Lynn, Nash, Rhue, Frauman, & Sweeney, 1984]. Furthermore, subjects who successfully resisted suggestions and subjects who failed to do so reported comparable levels of hypnotic depth and imaginative involvement in suggestions.

"Spanos, Cobb, and Gorassini (1985) conducted a similar experiment in which they found that hypnotizable subjects who were instructed that they could become deeply involved in suggestions and yet resist them successfully resisted 95% of the suggestions and rated themselves as maintaining voluntary control over their behavior. Thus, subjects are able to resist nearly all of the suggestions when resistance is facilitated by situational demands. It is worth noting that subjects in this research who resisted hypnotic suggestions rated themselves as just as deeply involved in the suggestions as Ss who failed to resist suggestions after being informed that deeply hypnotized subjects were incapable of resisting suggestions" (pp. 315-316).

Lynn, Snodgrass, et al. (1987). showed that hypnotizable Ss who were just "imagining" along with suggestions but instructed to resist responding to motoric suggestions acted the way hypnotized Ss did in their earlier countersuggestion research: imagining subjects tended to move in response to suggestion (that "good" Ss responded in certain ways), despite being instructed to resist. In this study, with instructions designed to increase the use of goal directed fantasies (GDFs), low and high hypnotizable subjects reported equivalent GDF absorption and frequency of GDFs. However, highs responded more and reported greater involuntariness than lows, even when their GDFs were equivalent.

"A number of other studies have examined the effects of expectancies on imaginings and hypnotic behavior. Spanos, Weekes, and de Groh (1984) informed subjects that deeply hypnotized individuals could imagine an arm movement in one direction while their unconscious caused the arm to move in the opposite direction. Even though subjects so informed moved in the opposite direction, they imagined suggested effects and described their countersuggestion behavior as involuntary" (p. 317).

1991

Oettingen, Gabriele; Wadden, Thomas A. (1991). Expectation, fantasy, and weight loss: Is the impact of positive thinking always positive?. Cognitive Therapy and Research, 15 (2), 167-175.

Investigated the impact of expectation and fantasy on the weight losses of 25 obese women participating in a behavioral weight reduction program. Both expectations of reaching one's goal weight and spontaneous weight-related fantasies were measured at pretreatment before Ss began 1 year of weekly group treatment. Consistent with the hypothesis that expectation and fantasy are different in quality, these variables predicted weight change in opposite directions. Optimistic expectations but negative fantasies favored weight loss. Ss who displayed pessimistic expectations combined with positive fantasies had the poorest treatment outcome. Expectation but not fantasy predicted program attendance. The effects of fantasy are discussed with regard to their potential impact on weight reduction therapy.

Rhue, Judith W.; Lynn, Steven Jay (1991). Storytelling, hypnosis and the treatment of sexually abused children. International Journal of Clinical and Experimental Hypnosis, 39 (4), 198-214.

The present article describes an assessment and therapy program for sexually abused children using hypnotherapeutic techniques which center on storytelling. Storytelling presents the therapist with an opportunity to use comforting suggestions, symbolism, and metaphor to provide the emotional distance necessary to deal with the trauma of abuse. Hypnotherapy proceeds in a stepwise fashion from the building of a sense of safety and security; to imaginative sharing; to the introduction of reality events; to the final step of addressing complex emotional issues of loss, trust, love, and guilt brought about by the abuse.

1990

Council, James R.; Huff, Kenneth D. (1990). Hypnosis, fantasy activity, and reports of paranormal experiences in high, medium and low fantasizers. British Journal of Experimental and Clinical Hypnosis, 7 (3), 9-15.

The personality construct "fantasy-proneness" (Wilson and Barber, 1983a) has important implications for theories of hypnosis, imagination, and paranormal phenomena. The present study compared characteristics of persons who received high, medium or low scores on a self-report measure of fantasy-proneness. Results

revealed that the three groups differed significantly on measures of absorption, daydreaming styles, and reports of paranormal experiences. However, although high fantasizers were significantly more hypnotizable than low fantasizers, they did not differ from the middle group. These results are used to further characterize fantasy-prone persons, and implications of extremely low fantasy-proneness are discussed.

Rhue, Judith W.; Lynn, Steven Jay; Henry, Stephanie; Buhk, Kerry; Boyd, Patti (1990-91). Child abuse, imagination and hypnotizability. Imagination, Cognition and Personality, 10, 53-63.

Research was designed to provide a rigorous test of J. R. Hilgard's hypothesis that hypnotizability is related to a history of physical punishment and to imaginative involvements. College students who reported a history of physical abuse (N = 21) and sexual abuse (N = 23) were compared with control subjects who either lost a parent by way of death or divorce (N = 20) or who were from intact homes (N = 35), under test conditions that minimized the possibility that context effects would prejudice the findings. No support was found for the hypothesis that increased hypnotizability was associated with a history of physical or sexual abuse: All of the groups are indistinguishable on measures of objective and subjective response to hypnosis. However, consistent with Hilgard's hypothesis, physically and sexually abused subjects were found to be more fantasy-prone than subjects in both nonabused control conditions.

1989

Ganaway, George K. (1989). Historical versus narrative truth: Clarifying the role of exogenous trauma in the etiology of MPD and its variants. Dissociation, 2, 205-220.

The author notes a current trend toward viewing multiple personality disorder (MPD) and its variants as a form of chronic post-traumatic stress disorder based solely on exogenous childhood trauma, and cautions against prematurely reductionistic hypotheses. He focuses on Kluft's Third Etiological Factor, which includes the various developmental, biological, interpersonal, sociocultural, and psychodynamic shaping influences and substrates that determine the form taken by the dissociative defense. He hypothesizes a credibility continuum of childhood and contemporary memories arising primarily from exogenous trauma at one end, and endogenous trauma (stemming from intrapsychic adaptational needs) at the other. The author offers alternative multidetermined explanations for certain unverified trauma memories that currently are being accepted and validated as factual experiences by many therapists. He describes some potentially deleterious effects of validating unverified trauma memories during psychotherapy, and recommends that the MPD patients' need for unconditional credibility be responded to in the same manner as other transference-generated productions.

Hoyt, Irene P.; Nadon, Robert; Register, Patricia A.; Chorny, Joseph; Fleeson, William; Grigorian, Ellen M.; Otto, Laura; Kihlstrom, John F. (1989).

**Daydreaming, absorption and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 37, 332-342.**

#### **NOTES**

**It appears that the consistent correlation between hypnotizability and positive-constructive daydreaming is carried largely by three subscales--Acceptance of Daydreaming, Positive Reactions to Daydreaming, and Problem-Solving. Number other subscales consistently correlated with hypnotizability.**

**When absorption was taken into account, daydreaming activity made no independent contribution to the prediction of hypnotizability. "The present results differ from Crawford's (1982) somewhat, however, in terms of the specific aspects of daydreaming activity that are associated with hypnosis. Crawford found that hypnotizability correlated consistently (i.e., in both men and women) with three subscales tapping imagery variables: the presence of visual and auditory imagery in daydreams and the hallucinatory vividness of daydream imagery. In the present study, the imagery subscale, including both visual and auditory items, did not correlate significantly with hypnotizability; unfortunately, the hallucinatory vividness subscale is not represented on the short form (SIPI) of the daydreaming questionnaire used in this study. Crawford (1982) did not find consistent correlations between hypnotizability and scales measuring acceptance, positive reactions, and problem solving--the subscales that consistently yielded significant correlations in the present study. Not too much interpretive weight should be given to any of the correlations between hypnotizability and daydreaming subscales, until a full replication with reliable subscale measurements (such as those provided by the long, original IPI) has been completed. The important point made by Crawford (1982), and confirmed in the present study, is that hypnotizability is related to positive-constructive rather than guilty-dysphoric daydreaming" (p. 338). The two studies agree that absorption and hypnosis are not correlated with daydreaming scales reflecting poor attentional control. Given the theoretical emphasis in both domains on the narrowing of attention and exclusion of potentially distracting input, negative correlations with this aspect of daydreaming might have been expected.**

**Rhue, Judith W.; Lynn, Steven Jay (1989). Fantasy proneness, hypnotizability, and absorption--a re-examination: A brief communication. International Journal of Clinical and Experimental Hypnosis, 37, 100-106.**

**In a previous study (Lynn & Rhue, Journal of Personality and Social Psychology, 1986) of fantasy-prone persons, "fantasizers" participated in an 8-10 hour, multi-session study. Group selection was based on scoring in the upper 4% of the college population on the Inventory of Childhood Memories and Imaginings (ICMI) of Wilson and Barber (1981) and conforming to the fantasy-prone personality syndrome (Wilson & Barber, 1981) during an interview. Fantasizers differed from nonfantasizers (lower 4% of population) and medium range scorers on measures of hypnotizability (Harvard Group Scale of Hypnotic Susceptibility, Form A, Shor & E. Orne, 1962) and absorption (Tellegen Absorption Scale, Tellegen, 1976). In the**

current study, Subject were selected on the basis of their ICMI scores and participated in a 1-session experiment. As in our first study (Lynn & Rhue, 1986), fantasizers differed from both comparison groups on the measure of absorption and from the nonfantasizers on the measure of hypnotizability. Further, the correlations among fantasy proneness, absorption, and hypnotizability were stable across studies. Fantasy proneness and absorption were not found to be truly discriminable constructs. Unlike our initial study (Lynn & Rhue, 1986), fantasy-prone and medium range Subjects were equally hypnotizable. Methodological differences across studies provide a plausible explanation for the disparate results obtained.

1988

Council, James R.; Greyson, Bruce; Huff, Kenneth D. (1988, November). Reports of paranormal experiences as a function of imaginative and hypnotic ability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

Wilson and Barber (1983) have suggested that some excellent hypnotic subjects ("fantasy prone" persons) may be more likely to report paranormal experiences than the rest of the population. Council and Greyson (1985), studying a sample of subjects who had reported near-death experiences (NDEs), found a significant relationship between fantasy-proneness and NDEs, and a much stronger relationship between fantasy- proneness and reports of paranormal experiences in general. This paper presents new data from the study of NDE reporters and a replication and extension of those findings with a sample not selected for NDEs. These data indicate a strong association between fantasy- proneness and reports of paranormal experiences. Hypnotic susceptibility bears a weaker relationship with such reports that appears dependent upon variance shared with measures of fantasy-proneness. Other data from these studies suggests that both imaginative ability and reports of paranormal experiences may be related to a history of stressful or traumatic childhood experiences.

LeBaron, Samuel; Zeltzer, Lonnie K. (1988). Imaginative involvement and hypnotizability in childhood. International Journal of Clinical and Experimental Hypnosis, 36, 284-295.

2 pilot studies assessed the relationship between hypnotizability in children and extent of involvement in fantasy-related activities during early childhood. The Stanford Hypnotic Clinical Scale for Children and a structured interview questionnaire regarding fantasy activities based on previous work by Singer (1973) were given to 30 medical patients aged 6-18 years in the first study and to 37 healthy children aged 6-12 years from a school population in the second study. In both studies, hypnotizability correlated moderately (.42 and .39, respectively) with extent of involvement in fantasy- related activities. Results support Hilgard's (1979) findings that hypnotizability is related in part to the development of imaginative involvement in childhood.

Lynn, Steven Jay; Rhue, Judith W. (1988). Fantasy proneness: Hypnosis, developmental antecedents, and psychopathology. American Psychologist, 43 (1), 35-44.

This article presents a summary of the findings of our ongoing research program on the fantasy-prone person. In seven studies, nearly 6,000 college students were screened in order to obtain five samples of 156 fantasy-prone subjects. Fantasy-prone subjects (fantasizers) were selected from the upper 2%-4% of the college population on a measure of imaginative involvement and contrasted with nonfantasizers (lower 2%-4%), and medium fantasy-prone subjects (middle range). General support was secured for Wilson and Barber's construct of fantasy proneness: Fantasizers were found to differ from nonfantasizers, and in many cases also from medium-range subjects, on measures of hypnotizability, imagination, waking suggestibility, hallucinatory ability, creativity, psychopathology, and childhood experiences. Differences in hypnotizability were most reliable when subjects participated in a multisession study and were screened not only with the screening inventory, but also with an interview that substantiated their fantasy-prone status. However, our findings indicated that less correspondence between fantasy proneness and hypnotizability exists than Wilson and Barber suggested. Hypnotic responsiveness is possible even in the absence of well-developed imaginative abilities, and not all fantasizers were highly hypnotizable. Fantasizers recollected being physically abused and punished to a greater degree than other subjects did and reported experiencing greater loneliness and isolation as children. Many fantasizers appeared to be relatively well-adjusted; however, a subset of fantasizers were clearly maladjusted based on self-report, Minnesota Multiphasic Personality Inventory (MMPI), and Rorschach test data. Because of the diversity inherent in the fantasy-prone population, it is misleading to think of individuals at the extreme end of the fantasy-proneness continuum as conforming to a unitary personality type.

1987

Lynn, Steven Jay; Rhue, Judith W. (1987). Hypnosis, imagination, and fantasy. Journal of Mental Imagery, 11, 101-112.

Considers three questions pertaining to the relationship between hypnotic responsiveness and imaginative processes: Are subjects' nonhypnotic imaginative involvements related to hypnotic susceptibility? Do some fantasy prone subjects share a unique constellation of personality attributes and experiences, including an ability to respond to hypnotic suggestions? What are the childhood developmental antecedents of persons who score at the extremes of hypnotic ability and measures of fantasy and imagination? Reviews literature.

1986

Lynn, Steven Jay; Rhue, Judith W. (1986). The fantasy-prone person: Hypnosis, imagination, and creativity. Journal of Personality and Social Psychology, 51, 404-408.

Experimenters selected subjects who ranged along the continuum of fantasy proneness and assessed hypnotizability, absorption, vividness of mental imagery (QMI; Sheehan, 1967), response to waking suggestion (Creative Imagination Scale), creativity, and social desirability (Crowne & Marlowe). Fantasy-proneness was evaluated with the Inventory of Childhood Memories and Imaginings (Wilson & Barber, 1981). Strong support was secured for J. R. Hilgard's construct of imaginative involvement and Wilson and Barber's contention that fantasy prone persons can be distinguished from others in terms of fantasy and related cognitive processes. Fantasizers were found to outscore subjects in both comparison groups on all of the measures of fantasy, imagination, and creativity, with social desirability used as a covariate. Low fantasy-prone subjects were no less creative or less responsive to hypnosis than their medium fantasy-prone counterparts.

1985

Kerry Buhk; Rhue, Judith; Henry, Stephanie; Lynn, Steven Jay (1985, November). Fantasy proneness: Are their word associations richer?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

#### NOTES

Experimenters screened 7000 students to get 6 samples of fantasy prone Ss (top 2.4% on Wilson and Barber's ICMI). They found less association between fantasy proneness and hypnotizability than did Wilson and Barber.

They had fantasizers hallucinate a second cup next to a first styrofoam cup. Results were that 87% of High fantasizers, < 50% Medium fantasizers, < 25% Low fantasizers could do it, but they didn't describe seeing the hallucinated cup "as real as real" as Wilson and Barber said they did.

Experimenters were concerned about context effects (expectancy) because the Creativity and Fantasy Proneness tests were run proximal in time, so they separated in time the administration of Fantasy Prone and Creativity tests and also looked at word associations.

23 High and 20 Low fantasy prone students selected by ICMI, which was administered to Subjects 18 mos before the creativity study. At the time of the creativity study, Ss were informed they were randomly picked. There were two 90' sessions, counterbalanced.

Sessions: 1. Hallucinate image of R.A. and of styrofoam cup. Other tests were administered for intelligence and personality: Shipley-Hartford, MMPI, Crowne-Marlowe, etc. 2. Creativity tests (Revised Art Scale, Hilgard's Alternate Uses; story production which was scored on detail, imagery and fantasy and on imagery nouns.) Results of this study which was independent of context (i.e. the tests being correlated were administered independently of each other, separated by time). 1. Fantasizers were more creative than low fantasizers on both Creativity Scales. 2. Fantasizers show more divergent thinking on Hilgard Alternate Uses test, but relationship between fantasy proneness and creativity were not strong,  $r = .30$ . 3. Fantasizers and non fantasizers did not differ on the story measures! This diverges from Wilson and

Barber's results. Fantasizers may have more vivid images, but storytelling does not capture that.

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott; Frauman, David; Rhue, Judith (1985). Hypnotic age regression and the importance of assessing interpersonally relevant affect. International Journal of Clinical and Experimental Hypnosis, 33, 224-235.

The present study was undertaken to replicate an earlier experiment and to clarify which factors in this previous experiment (Nash, Johnson, & Tipton, 1979) were responsible for the obtained child-like behaviors of hypnotically regressed Ss. As in the previous study, 3 characteristics of the transitional object relationship (spontaneity, specificity, and intensity) were used as the primary criteria to investigate the effects of hypnotic age regression when Ss were regressed to age 3 and placed in 3 home situations. While in the previous study E suggested separation anxiety and isolation during the 3 home situations (mother-absent condition), the present study deleted all references to anxiety and isolation, and replaced them with suggestions of security and maternal proximity (mother-present condition). As expected, the mother-present versus mother-absent conditions led to similar hypnotized- simulating differences. In further accord with predictions, hypnotized Ss and simulating Ss requested a transitional object infrequently in the presence of mother. The importance of using dependent measures which index affective processes germane to interpersonal affect-laden experience is discussed.

Neufeld, Victor; Lynn, Steven Jay; Jacquith, Leah; Weekes, John (1985, November). Fantasy style, imagination, and hypnotizability. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

#### NOTES

Authors discuss three fantasy styles: 1. Positive constructive daydreaming 2. Guilt / fear of failure 3. Poor attentional control. Fantasy style has been related to many personality variables, usually based on questionnaires.

They examined subjects in hypnosis and waking states using hypnotic dreams, Short Imaginal Processes Inventory, Tellegen Absorption, Betts QMI Imagery Vividness, Hypnosis (HGSHS and suggested dream) involvement, Wilson and Barber ICI, Nonvoluntary experience, Fantasy Proneness, Content of fantasies.

137 student volunteers participated in the study. 82 had HGSHS-A and hypnotic dream, and gave involuntariness ratings. Ss self-rated pleasant and unpleasant for hypnotic dreams. Experimenter rated dream for 1) positive emotion, 2) negative emotion, and 3) anxiety. Correlations were significant for female Ss, but not for male Ss.

**RESULTS.** Fantasy-style, at least of negative affect, was consistent for waking and hypnotic states. Positive constructive fantasy correlated to HGSHS but the other two fantasy styles did not. [Other results reported are not included in this brief summary.]

**Crawford, Helen J. (1982). Hypnotizability, daydreaming styles, imagery vividness, and absorption: A multidimensional study. Journal of Personality and Social Psychology, 42 (5), 915-926.**

**In 25 male and 31 female university student and staff volunteers, the interrelationships between the following measures were studied: hypnotic susceptibility (SHSS:A and C), imagery vividness (VVIQ), involvement in everyday activities (TAS), and daydreaming styles (28 scales of Singer & Antrobus's Imaginal Processes Inventory). Factor analysis produced a factor characterized as a positively vivid and absorptive imagination style. Hypnotic susceptibility, VVIQ, TAS, and positive-affect daydreaming styles all loaded on this factor. Two other factors were a dysphoric daydreaming style and a lack-of-attentional-control style. Stepwise multiple regressions suggested that males and females, at least within this sample, exhibit different relationships between hypnotic susceptibility and predictor variables. Similar differences were found for the VVIQ and the TAS and their daydreaming-scale predictor variables.**

**Singer, Jerome L.; Pope, Kenneth S. (1981). Daydreaming and imagery skills as predisposing capacities for self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 271-281.**

**A growing body of empirical literature suggests that daydreaming and related forms of waking reverie are natural-occurring, common experiences in normal individuals. Specific experiments relating daydreaming and the stream of ongoing thought as an alternative source of stimulation to external cues are described. It is proposed that everyday waking consciousness has many features of internal absorption in imagery and adaptive but non-sequential processes that resemble fantasy, hypnosis, and night dreaming. Experiments linking daydreaming, imagery vividness, and hypnosis are cited as suggesting that individuals may develop capacities for control over the stream of thought and that such capacities are closely similar to the skills needed for self-hypnosis.**

**Barrett, Deirdre (1979). The hypnotic dream: Its relation to nocturnal dreams and waking fantasies. Journal of Abnormal Psychology, 88 (5), 584-591.**

**A review of the literature in the area of hypnotic dreams suggests that physiological correlates of hypnotic dreams are better established than content characteristics. A study is also reported that examined the content of hypnotic dreams in relation to that of nocturnal dreams and daydreams from the same subjects. Subjects were 16 undergraduates divided into deep-trance and medium-trance groups. Deep trance subjects hypnotic dreams were similar to their nocturnal dreams and different from daydreams on a wide variety of characteristics including length, emotional themes,**

characters, setting, and amount of distortion. Medium trance subjects' hypnotic dreams were found to fall between their nocturnal dreams and daydreams on most of these measures.

**Sutcliffe, J. P.; Perry, Campbell; Sheehan, Peter W. (1970). The relation of some aspects of imagery and fantasy to hypnotizability. Journal of Abnormal Psychology, 76, 279-287.**

Studied relations between hypnotic susceptibility and some aspects of imagery and fantasy in a normal population of 95 undergraduates. Vividness of imagery was assessed by a reliable questionnaire adapted from procedures 1st devised by G. H. Betts; dreams were collected by a diary method which studied the incidence of distortion in dream content; and hypnotizability was assessed by the Stanford Hypnotic Susceptibility scale (Form C), a standardized scale devised by the authors, and a rating procedure based on both scales. Results show a positive, curvilinear relationship between vividness of imagery and hypnotic susceptibility, but no significant relationship for fantasy. Evidence suggests that both imagery and fantasy, considered conjointly, lead to a more accurate prediction of deep susceptibility than the imagery variable alone. (34 ref.) **Nowlis, D. P. (1969). The child-rearing antecedents of hypnotic susceptibility and of naturally occurring hypnotic-like experience. International Journal of Clinical and Experimental Hypnosis, 17, 109-120.**

Data pertaining to early and mid-childhood socialization experiences available from a sample of children and their mothers as studied earlier by R. R. Sears, E. E. Maccoby, H. Levin, and others were related to hypnotizability scores and scores of susceptibility to naturally occurring hypnotic-like experiences for a part of the same sample when the children reached late adolescence. As hypothesized by J. R. Hilgard and E. R. Hilgard (see 37:3) after retrospective interviewing with college-age hypnotic Ss, the present study, using a longitudinal method of investigation, indicated some relationship between firm parental discipline in childhood and subsequent susceptibility to hypnosis and hypnotic-like experiences in adolescence. Correlations, however, were low and the overall yield of significant data was judged to be meager. This was particularly true of hypnotizability scores in relation to the other variables available for analysis. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Neveu gives the name 'Induction' to his own development of the techniques of Bernheim, which he regards as a more comprehensive system than classic hypnosis and as primarily an interpersonal communication with ensuing mobilization of the patient's abilities to modify affective and other psychosomatic aspects of his condition. Neveu uses the method on hospitalized patients as treatment and

research, citing its advantages over psychoanalysis, narcoanalysis, and other therapies which have many limitations. (E.M.E.)

1953

Rosen, Harold (1953). Hypnodiagnostic and hypnotherapeutic fantasy---evocation and acting-out techniques. Journal of Clinical and Experimental Hypnosis, 1 (1), 54-66.

#### NOTES

Developed techniques to reach patients who have little motivation for psychotherapy, sometimes hypnotizing them without their knowledge or conscious consent. "By still other techniques, symptom-formation was then blocked and the inevitable, resultant anxiety reaction repressed, so that underlying fantasies could erupt into conscious awareness even to the point of being acted out" (p. 65). By these means he determined the neurotic or psychotic functions being served by the patient's physical symptoms. The hypnotic interpersonal relationship is "a fantasy-evoking one in which the patient, on the basis of his own experiential background and with more ready access to his pre-conscious, thinks, feels, experiences, reacts and even acts-out exactly as he believes the hypnotist wishes him to, projecting his own impulses, desires and fantasies to the therapist" (p. 66).

2002

GOW, MICHAEL (2002). Treating dental needle phobia using hypnosis. [Paper] Presented at IFDAS/SAAD 10th International Dental Congress on Modern Pain Control, Edinburgh, June 2003, also at BSMDH (Scot) meeting December 2003.

This case illustrates the effectiveness of short-term hypnosis treatment for a dental needle phobia. What is significant is the dental history of the patient and the longstanding effect of her dental phobias and how quickly hypnosis was able to remove this problem.

**Aim:** To manage dental needle phobia using hypnosis integrated into an anxiety management treatment plan."

**Case History:** Female, 48, had traumatic and painful experience at the dentist when 5, developed phobia of dental injections and treatment. Has had a dozen General Anaesthetics for dental treatment. Experiences psychosomatic pain prior to treatment.

**Methods:** Medical, dental and phobia history explored. Pre-treatment questionnaire assessed dental anxiety, reasons for anxiety, and ascertained management options. Post-treatment questionnaire assessed changes in dental anxiety and attitudes.

**Anxiety management techniques:** Needle Desensitisation, Relaxation, and Hypnosis (Regression, Progressive Muscular Relaxation, Glove Anaesthesia, Future Rehearsal etc.).

**Results:** Pre-treatment questionnaire revealed high level anxiety (26 out of high of 30 modified Corah score; and high anticipation of future pain during dental

treatment (10 out of high of 10 on a Visual Analogue Scale. Post-treatment questionnaire revealed low level anxiety (12/30) and low anticipation of future pain (4/10).

**Conclusion:** Hypnosis was an effective adjunct to anxiety management in this case, demonstrating how a non pharmacological approach can find long term solutions by addressing the causes of the anxiety. Previous pharmacological approach had only addressed the symptoms of the immediate anxiety. Successful completion of prescribed dental treatment plan and changes in patient?s attitudes highlight positive outcome.

This chapter reviews the main applications of emotional self-regulation therapy, which have received empirical support: smoking reduction, obesity, fear of flying, drug addictions, and premenstrual distress and dysmenorrhea. The logic of each treatment and main empirical results are summarized.

**1994**

Brown, Gail W.; Riddell, Rodney; Summers, David; Coffman, Brent (1994, August). Use of hypnosis by practitioners in the school setting. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

## **NOTES**

Hypnosis is a therapeutic procedure that is appropriate for some school-age clients. Through the use of hypnosis that utilizes metaphors and imagery, children can be empowered to find unique solutions to their problems. Children enjoy the feeling of power and mastery that they have when able to perform hypnotic phenomena. They like to play magic and can be told that a finger or other body part will become numb. Because a major goal of hypnotherapy is to teach a child to be an active participant in his or her own behalf, the focus is on creating solutions and mastering the situation rather than enduring the problems. Four case studies demonstrate the utility of hypnosis in the treatment of phantom pain and nausea, sleep terror disorder, school phobia, and spider phobia. In each case, treatment goals were realized. Because the solutions were self-generated, the behavioral changes maintained over time and situation.

Case #1: Hypnosis was used to help alleviate phantom limb pain and nausea during chemotherapy following amputation of the right leg at the knee due to cancer in a thirteen- year-old male. The client had indicated that he loved nature and enjoyed the mountains. The metaphor described a young tree that has just begun to grow small silvery leaves. The spring floods tear the limbs and branches from the stump. The deep roots and stump of the tree are all that remain. The tree is not the same as before the flood. Its roots are stronger, its base more sturdy compared to the branches and limbs. The young tree has withstood the catastrophe of the torrent of

waters and is even stronger than before. To counter the nausea and vomiting associated with chemotherapy a switch mechanism metaphor was used. The client was adroit with computers and had no difficulty picturing a switch located in his brain which could "turn off" the nausea from chemotherapy. A room contained all the unpleasant feelings that were being experienced. In this room is a light of a particular color that represents all the unpleasant sensations. Press the key on the computer that controls the switch to turn off the colored light in that room. Suggestions for healing were also given. Your body has known for years how to heal. Visualize the battle between good and bad cells and the victory of the good cells.

**Case #2:** Hypnosis was used to alleviate sleep terror disorder in a ten-year-old female. The onset of the subject's parasomnic symptomatology appeared to coincide with her starting kindergarten and her family's relocation shortly before. The initial treatment consisted of progressive relaxation, deep breathing, and the visual image of her "secret safe place." An induction utilizing a variety of images was presented. Hiking barefoot on a cool moss covered mountain trail, sitting in a an alpine meadow on a warm summer afternoon, and flying proved most effective in facilitating trance. The participant was told to "Visualize all your anxiety and tension as hard grey rocks. Pick up these rocks and place them in your pockets. Go to the front porch of your "secret safe place and on the porch is a "magic hefty bag." Place your hard grey rocks that contain all your anxiety and tension in the magic bag. Once in the bag, the rocks will no longer weight you down, you will be free of any feelings of stress or tension. Your bed is magic; it is covered with a special glue which will keep you in a reclining position until you are fully rested and ready to awaken."

**Case #3:** Hypnosis was used in the treatment of school phobia in a nine-year-old male. The student experienced intense anxiety whenever separation from the primary caretaker occurred. The teacher stated that this boy experienced frequent absences and crying spells that were only relieved by phone calls to his mother or the presence of his mother next to him in class. In preparation for the intervention, the student was asked to draw a picture of how he felt inside during a panic attack. He drew a fire. He also said that only his mother could put that fire out. This information was utilized in creating a metaphor that described a house in a small town. "The mother had left, and a young boy was left alone. While at home, the boy looked out the window and saw several boys trying to burn a neighbor's yard! Acting quickly, he called the fire department, grabbed the fire extinguisher and unraveled the garden hose. He was able to extinguish the fire. The neighbors and friends were very happy and praised the boy's performance. When his mother heard the good news, she quickly returned home and held a celebration in his honor." Following the metaphor, hypnotherapy continued with suggestions about fire extinguishers that the subject could use to put out emotional fires.

**Case #4:** Hypnosis was used in the treatment of spider phobia. Diagnosis of phobia was made in this eleven-year-old female when the fear or avoidance behavior was distressing. The child's strained facial expressions occurred even at the thought of seeing what she described as "a creepy, crawly creature with 8 legs." Preparatory to her first induction the participant was read the story of Charlotte's Web (White,

1980) to facilitate the imagery for future hypnotic work. In the following session systematic desensitization was accomplished using characters from the story of Charlotte's Web. During the third session the subject was age regressed to the first time she remembered seeing a spider. She recalled playing in the woods outside her family home on an island and seeing a large web stretched between two trees with a very large spider in the center of its web. She was then asked to remain at that place to look closely at that spider as it was most likely Charlotte or one of Charlotte's family. Upon closer investigation she saw not only Charlotte but "teeny-tiny babies." The event was reconstructed as a happy experience. The imagery provided by Charlotte's Web permitted the subject to fantasize her previous frightful experience and reframe spiders as cute little "teeny-tiny" babies with admirable human qualities.

Wormnes, Bjorn (1994, October). Hypnosis in integrated treatment of dental fear. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

Research reports from different countries estimate the proportion of adult dental phobic patients to be between 5% to 10%. It represents a large health problem. Helping patients to continue regular treatment by their local dentist and experience it as tolerable is the main treatment goal in our program. The main treatment method is a flexible and integrated exposure training. The psychotherapist works in cotherapy with the dentist. Using hypnosis in the dental chair is of great help, and patients are normally found to be very susceptible and easily hypnotized. Hypnosis helps the patient to experience increased tolerance of treatment and also to perform better than expected in the treatment situation.

1992

Kohen, Daniel P.; Mahowald, Mark W.; Rosen, Gerald M. (1992). Sleep terror disorder in children: The role of self hypnosis in management. American Journal of Clinical Hypnosis, 34, 233-244.

This paper describes four children, ages 8 to 12 years, with frequent, prolonged, or dangerous disorders of arousal. None had any significant psychological or behavioral problems. Each had a polysomnogram that showed sudden arousals out of slow-wave sleep associated with complex behavior. All responded to a short course of imipramine, 20 to 60 mg at bedtime, followed by and in conjunction with training in relaxation and mental imagery (self-hypnosis). Once the correct diagnosis was made, the treatment strategy was to (1) demystify the symptom complex through education, (2) establish prompt control of the symptoms with the use of imipramine, (3) train the children in self-regulation with self-hypnosis, and (4) discontinue the medication while maintaining control of the arousals. Over a 2-3 year follow-up all children remain asymptomatic. This is the first report of successful use of self-hypnosis for the treatment of polysomnogram- proven disorders of arousal in the pediatric population. Also reported are seven additional

children who were treated equally successfully with hypnosis without the use of medication.

1991

Kleinhauz, Moris; Eli, I. (1991). Hypnotic induction in dentistry: Coping with the fear of losing. International Journal of Clinical and Experimental Hypnosis, 39 (3), 125-128.

A common cause of stress among dental patients is the patient's fear of losing control in face of the "helplessness provoking" dental situation. Although hypno-relaxation and hypnosis serve as efficient tools to aid in the administration of dental treatment to such patients, some of them may view hypnosis as a further relinquishing of control to the hypnotist and thus resist hypnotic induction, despite their willingness to try to use hypnosis for therapeutic reasons. To avoid this resistance, a "self-control" induction method is suggested that enables the patient to remain in control throughout the process. This technique minimizes the threat of losing one's autonomy and thus enables treatment of these patients.

Reiss, Steven (1991). Expectancy model of fear, anxiety, and panic. Clinical Psychology Review, 11, 141-153.

The purposes of this article are to summarize the author's expectancy model of fear, review the recent studies evaluating this model, and suggest directions for future research. Reiss' expectancy model holds that there are three fundamental fears (called sensitivities): the fear of injury, the fear of anxiety, and the fear of negative evaluation. Thus far, research on this model has focused on the fear of anxiety (anxiety sensitivity). The major research findings are as follows: simple phobias sometimes are motivated by expectations of panic attacks; the Anxiety Sensitivity Index (ASI) is a valid and unique measure of individual differences in the fear of anxiety sensations; the ASI is superior to measures of trait anxiety in the assessment of panic disorder; anxiety sensitivity is associated with agoraphobia, simple phobia, panic disorder, and substance abuse; and anxiety sensitivity is strongly associated with fearfulness. There is some preliminary support for the hypothesis that anxiety sensitivity is a risk factor for panic disorder. It is suggested that future researchers evaluate the hypotheses that anxiety and fear are distinct phenomena; that panic attacks are intense states of fear (not intense states of anxiety); and that anxiety sensitivity is a risk factor for both fearfulness and panic disorder.

Russell, Christine; Davey, Graham C. (1991). The effects of false response feedback on human 'fear' conditioning. Behaviour Research and Therapy, 29 (2), 191-196.

Describes a human electrodermal conditioning experiment in which 28 students (aged 19-30 yrs) were given false skin conductance feedback during conditioned stimulus/stimuli (CS) presentation. In comparison with attentional control groups, Ss who believed they were exhibiting a strong conditioned response (CR) did actually emit a greater magnitude CR, while Ss who believed they were exhibiting a weak CR emitted a lower magnitude CR. When both self-report and behavioral measures of unconditioned stimulus/stimuli (UCS) evaluation were taken after

conditioning, response feedback (RFB) had not differentially affected Ss' evaluation of the aversiveness of the UCS. The response modulating effects of RFB may not be caused by RFB influencing evaluation of the UCS, but they are consistent with the hypothesis that beliefs about the nature of RFB influence the strength of the UCS representation itself.

Terr, Lenore C. (1991). Childhood traumas: An outline and overview. American Journal of Psychiatry, 148, 10-20.

Suggests 4 characteristics common to most cases of childhood trauma: visualized or otherwise repeatedly perceived memories of the traumatic event; repetitive behaviors; trauma-specific fears; and changed attitudes about people, life, and the future. Childhood trauma is divided into 2 basic types. Type I trauma includes full, detailed memories, "omens," and misperceptions while Type II trauma includes denial and numbing, self-hypnosis and dissociation, and rage. Characteristics of both types of childhood trauma can exist side by side. Such crossover Type I - Type II traumatic conditions of childhood are characterized by perceptual mourning and depression and childhood disfigurement, disability, and pain. Case examples are provided.

Zachariae, Robert; Bjerring, P.; Arendt-Nielsen, L.; Nielsen, T.; Gotliebsen, K. (1991). The effect of hypnotically induced emotional states on brain potentials by painful argon laser stimulation. Clinical Journal of Pain, 7, 130-138.

The relationship between pain perception and emotional states is well known. However, the nature of this relationship and how different emotional states affect sensory and cognitive dimensions of pain remains uncertain. Results from experimental investigations are often contradictory, which may be due to methodological difficulties in inducing pain and monitoring physiological responses. In addition, most studies have focused on a single emotion, and data on the relative effects of different emotional states are lacking. In the present study we attempted to eliminate some of these methodological problems. Laser evoked potentials were used as a quantitative correlate to pain perception and were measured in 12 highly hypnotically susceptible subjects during seven conditions: (a) a prehypnotic baseline condition; (b) a neutral hypnotic control condition; (c-e) hypnotically recalled anger, fear, and depression in randomized order; (f) a hypnotically recalled happy condition, and (g) a posthypnotic awake control condition. The pain evoked potentials were significantly decreased in the angry condition and significantly increased in the depressed condition compared with baseline. No differences could be detected for either the happy or the fear-related condition compared with the baseline or neutral hypnotic condition. A significant positive correlation between the subjective intensity of depression and the increase in evoked potentials was found, but none for the other three emotions. The results support earlier findings that clinical depression is related to increased pain perception, and findings that the expression of anger can inhibit the experience of pain. The lack of changes in pain-related potentials during the neutral and happy condition may indicate that effects

of psychological interventions such as hypnotic analgesia may be due to specific cognitive processes rather than a relaxed or pleasant state in itself.

## NOTES

Hypnosis was used as an experimental condition because the recall of emotion may be more intense and vivid than in nonhypnotized conditions. Pulse was measured as an indicator of arousal. Subjects (9 women, 3 men) scored at least 10 or 11 on the Danish version of the Harvard Group Scale of Hypnotic Susceptibility. Each S was interviewed to determine early life experiences associated with the emotions under study, and the Experimenter noted key words regarding the emotion-arousing situation (time, place, persons involved) to assist in evoking the emotional state.

Pain was evoked with laser stimulus (100 ms) in a 1 x 3 cm. target area, avoiding repeated stimulation at identical points within the area. Pain threshold (prehypnotic) was defined as 'a distinct sharp pin prick without any burning aftersensation.' During the baseline and experimental conditions, evoked potentials were elicited using a stimulus 1.5 times threshold.

Following a standardized 15 minute hypnotic induction, the four emotional states were induced (randomized across Subjects). Each emotion was the focus for 10 minutes, and evoked potentials were recorded during the last five minutes of each. Subjects were instructed to relax and clear their minds of images or emotions in between each emotion condition. No suggestions were given regarding pain or pain perception.

After the hypnosis conditions, Subjects were asked to rate the intensity of each emotion on an analogue scale, and to rate their experience of pain on an analogue scale. (As it turned out, most of the Subjects were not able to recall the intensity of pain during all four emotional states.)

The size of the evoked potentials to painful stimuli increased during depression 35.8% over prehypnosis baseline, but decreased during anger 46.8% below prehypnosis baseline. The difference between prehypnosis baseline and neutral hypnosis was not significant statistically. Also, the differences between the happy condition, the fearful condition, or the posthypnotic condition, and prehypnosis were not significantly different. Pulse increased 6.5% over baseline during anger, decreased 4.1% under baseline in depression, and evidenced no difference from baseline for the other two emotions.

"A significant ( $p < 0.05$ ) positive correlation ( $r = +.60$ ) was found between the subjective intensity of the depressed emotional state as measured on the visual analogue scale and the increase in power of the evoked potentials in the depressed condition compared to the prehypnotic baseline condition. There was a small ( $r = +0.35$ ) nonsignificant positive correlation between the subjective intensity of fear and the increase in power of the evoked potentials in this emotional state compared with baseline. No correlations between the increase in evoked potentials and the condition of happiness ( $r = +0.05$ ) and the condition of anger ( $r = -0.07$ ) could be detected. ... There was a positive correlation between the subjective intensity of happiness and anger ( $r = +0.70$ ,  $p < 0.02$ ). A positive correlation ( $r = +0.56$ ,  $p < 0.05$ ) between the intensity of happiness and the intensity of depression was found. No other correlations between intensity ratings reached significance level" (p. 134).

In their Discussion, the authors present the possibility that the differences in evoked potentials observed between different emotional states might be due to differences in attention/distraction, or differences in arousal/inhibition. They reject the attention/distraction hypothesis because evoked potentials increase more in the depression state than in the anger state, though anger was more intense than depression.

"There are, however, several findings that point toward support for a hypothesis that specific affects, and not attention in itself, may account for the opposite changes in evoked potentials. ... Subjects rated fear as even more intense (87.5%) than anger, but with no similar effects on evoked potentials. ... We also found a significant positive correlation between increase in evoked potentials and intensity of experienced depression; a finding opposite of what could be expected from an attention/distraction hypothesis.

"A simple attention/distraction hypothesis, therefore, cannot explain the opposite directions of evoked potentials in the two emotional states. ...

"The differences in pain evoked potentials therefore could be hypothesized to be more related to mechanisms of arousal and inhibition than attention in itself. ...

"Modulation of pain evoked potentials is most likely not due to the state of hypnosis in itself, but to the specific suggestions given under hypnosis, which may be the reason that previous studies of hypnotic modulation of event-related potentials have been inconsistent.... One must be careful not to assume a direct relationship between pain and evoked potentials. ...

"Based on earlier findings (6-10) one could have hypothesized that an increase in pain perception would be found during the condition of hypnotically induced fear. However our results did not show any significant difference in pain evoked potentials when the emotion of fear was induced. This may be due to the fact that the fear or anxiety did not relate to the painful stimulus in itself, but involved an earlier experienced anxiety or a phobic fear (i.e., of snakes or flying). ...

"Although the state of hypnosis itself does not seem to affect sensory pain perception, the hypnotic state might facilitate the effect of specific suggestions given under hypnosis by affecting cognitive processing. Chapman (44) has suggested that hypnotic analgesia is due to the control of the figure-ground transitions associated with the experience of pain. Likewise, different emotional states may affect figure-ground transitions differently. Whereas outwardly directed anger might prevent inner sensations of pain from emerging as figure, the emotion of depression and helplessness might force the surroundings in the background, letting inner sensations emerge as figure" (pp. 136- 137).

1989

Sansom, Deborah; Rachman, S. (1989). The effect of induced mood on fear reduction. British Journal of Clinical Psychology, 28 (3), 227-238.

I investigated the effect on fear reduction in a laboratory study of fearful people. A musical mood-induction technique was utilized to induce either a happy mood or a sad mood in 84 female undergraduates who were fearful of spiders or snakes. Following the mood induction, Ss' fears were reduced by participant modeling.

Measures of subjective fear and self-efficacy were taken before and after mood induction, after modeling, and 4 weeks later. Compared to the induced sad-mood condition, induced happiness was followed by a decrease in subjective fear and greater self-efficacy. No difference was found in the length of time taken to reduce fear for happy and sad Ss. Fear reduction during a sad mood was associated with greater return of fear than fear reduction during a happy mood.

Van den Bergh, Omer; Eelen, Paul; Baeyens, Frank (1989). Brief exposure to fear stimuli: Imagery ability as a condition of fear enhancement and fear decrease. Behavior Therapy, 20, 563-572.

Examined fear enhancement and fear decrease during brief exposure to fear stimuli. 140 good and poor imagery Subjects (aged 14-18 years) with medium fear levels toward spiders were exposed to a live spider, either by looking at it or by thinking of an invisible, but present spider during either 60, 180, or 360 sec. Control Subjects were given a distraction task. Subjective fear and behavioral approach were measured. Brief exposure hindered fear decrease compared to the control condition. Good imagers showed more fear decrease and were less affected by the mode of exposure. Fear enhancement occurred only in poor imagers at the longer exposure duration (360 sec) during thinking. In that condition, good imagers showed their greatest fear decrease.

1986

Belicki, Kathryn; Belicki, Denis (1986). Predisposition for nightmares: A study of hypnotic ability, vividness of imagery, and absorption. Journal of Clinical Psychology, 42 (5), 714-718.

The relationships of nightmare frequency to hypnotic ability, vividness of visual imagery, and the tendency to become absorbed in fantasy-like experiences were examined. Subjects were 841 undergraduate university students who participated in group tests of hypnotic ability, after which they estimated the number of nightmares that they had experienced in the prior year. In addition, 406 of the subjects completed Marks' Vividness of Visual Imagery Questionnaire, and Rotenberg and Bowers' Absorption scale. Of the subjects, 76% reported experiencing at least one nightmare in the prior year; 8.3% indicated one or more per month. Individuals with frequent nightmares scored higher on hypnotizability, vividness of visual imagery, and absorption.

Epstein, S. J.; Deyoub, P. L. (1981). Hypnotherapy for fear of choking: Treatment implications of a case report. International Journal of Clinical and Experimental Hypnosis, 29 (2), 117-127.

An eclectic hypnotherapeutic approach consistent with Sacerdote's treatment model was utilized for overcoming the swallowing difficulty of an adult male. Traumatic onset followed an active fellatio experience. Cognitive restructuring preceded

symptomatic improvement, and the client was nearly asymptomatic after 56 sessions. Further improvement was evidenced posttherapy on a 3-year follow-up study. The process of change is emphasized, highlighting the broader case management implications of this single case study. Clinical observations are supplemented with psychological test data, providing a richer framework for understanding client and therapy process.

**Wilson, John F. (1981). Behavioral preparation for surgery: Benefit or harm?. Journal of Behavioral Medicine, 4, 79-102.**

Elective surgery patients were prepared for surgery with training in muscle relaxation or with information about sensations they would experience. Relaxation reduced hospital stay, pain, and medication for pain and increased strength, energy, and postoperative epinephrine levels. Information reduced hospital stay. Personality variables (denial, fear, aggressiveness) were associated with recovery and influenced patients' responses to preparation. Less frightened patients benefitted more from relaxation than did very frightened patients. Nonaggressive patients reacted to information with decreased hospital stay along with increased pain, medication, and epinephrine. Aggressive patients responded to information with decreased hospital stay along with decreased pain, medication, and epinephrine. Patients using denial were not harmed by preparation. A catharsis/moderation model is proposed to explain how information benefits patients. An active coping model is proposed to explain the benefits of relaxation. This study suggests that behavioral preparation benefits even frightened, aggressive, or denying elective surgical patients.

**Weerts, Theodore C.; Lang, Peter J. (1978). Psychophysiology of fear imagery: Differences between focal phobia and social performance anxiety. Journal of Consulting and Clinical Psychology, 46 (5), 1157-1159.**

Spider phobics and speech anxious subjects imaged fear scenes with spider and public-speaking content and a series of standard scenes that were constructed to vary in degree of emotional arousal and movement. Heart rate, skin conductance, and ocular activity were recorded. Spider phobics rated all imagery contents as more vivid and reported more scene movement than speech anxious subjects. Both groups responded to their own fear scenes with higher ratings of emotion and a greater physiological response than to the other group's fear scenes. The arousal response of spider phobics to relevant fear scenes was greater than that of speech anxious subjects. The data suggest that the outcome of imagery-based therapies may be partly determined by type of fear.

**NOTES**

**Technical Memorandum 23-74 (October 1974), US Army Human Engineering**

Laboratory, Aberdeen Proving Ground, Maryland 21005, AMCMS Code 5910.21.68629, Contract No. DAAD05-73-C-0243, Dunlap and Associates, Inc. (now Stamford, CT), AD002557.

Sixty college men, divided into three equal groups, each attended two induced stress sessions in which their physiological, psychological and performance reactions were measured. Their responses were compared to determine if valid stress reactions could be induced through suggestion in an altered state (in this case, hypnosis), and also to determine the validity of such reactions if the subject had never before experienced that stress situation. It was demonstrated that valid stress reactions can be induced in an individual with the aid of suggestions, especially if the real stress situation has been experienced before. If no previous experience with that real situation exists, the subject still exhibits stressful reactions; however, the closest resemblance to real stress is found in the subjective or psychological measures, less similarity is found in the physiological measures, and the least similarity is found in the performance measures.

#### NOTES

Research and Development Technical Report ECOM-0161-F; AD-913 696L; Contract DAAB07-71-C-0161 with Signatron, Inc. (Lexington, MA). Distribution limited to U.S. Government agencies only; Other requests for this document must be referred to Commanding General, U.S. Army Electronics Command, ATTN: AMSEL-PP-CM-CR4, Fort Monmouth, NJ 07703. NOTES 2: This document reports on a U.S. Army research project using hypnosis to collect high fidelity samples of the voice under "combat stress" conditions in the laboratory. Using hypnotic regression, combat veterans "re-experienced" their own, actual high stress combat situations. Besides subjective reports of stress levels by subjects, physiological stress measures were obtained from polygraph recordings of heart, respiration and GSR activity. The voice samples were later analyzed by spectrographic techniques to determine which factors remain invariant to identify and authenticate the speaker in a military communications situation. Hypnotic techniques were shown to be useful in establishing controlled emotional states for laboratory research purposes. (Richard Bloom)

McReynolds, William T.; Barnes, Allan R.; Brooks, Samuel; Rehagen, Nicholas (1973). The role of attention-placebo influences in the efficacy of systematic desensitization. Journal of Consulting and Clinical Psychology, 41 (1), 86-92.

Systematic desensitization was compared with two attention- placebo control treatments - one taken from Paul and one currently devised as an elaborate, highly impressive "therapeutic" experience - and no treatment. It was hypothesized that (a) fear reductions following desensitization would be no greater than those

associated with an equally compelling placebo treatment and (b) fear and control measure changes following the previously used attention-placebo treatment would be less than those following desensitization and the present placebo control manipulations. Both hypotheses were supported, although support for the first was more consistent than for the second.

Davis, Daniel; McLemore, Clinton W.; London, Perry (1970). The role of visual imagery in desensitization. Behaviour Research and Therapy, 8 (1), 11-13.

## NOTES

**Summary:** a measure of visual imagery ability was obtained for 33 females who and participated in desensitization therapy for snake phobia. Visual imagery was positively related to pretherapy performance (closeness of approach to a live snake), but not to improvement. On the basis of these results and the results of two other studies, it was hypothesized that the fear of good imagers tends to be based on imagination while that of poor imagers tends to be based on sensory experience.

Most psychologists now recognize behavior therapy as effective in alleviating a wide variety of fears, but the nature of the processes underlying the various methods remains an open issue. Imagery has been of particular interest as a possible common denominator among various desensitization techniques. Lazarus (1961), for example, asserts that a "prerequisite for effective application of desensitization is the ability to conjure up reasonably vivid images," and Wolpe (1961) claims, "it is essential for visualizing to be at least moderately clear." London suggests that theoretically opposed treatments such as reciprocal inhibition (Wolpe, 1958) and implosion (Stampfl and Levis, 1967) may both be facilitated by repeated imagery which "produces a discrimination set such that the patient learns to distinguish between the imaginative, cognitive, affective aspects of experience, and the sensory and overt muscular aspects" (1964, p. 130). However, no systematic studies linking visual imagery to desensitization have been reported. This study examined the relationship between visual imagery and success in desensitization therapy.

1961

Cheek, David B. (1961). Value of ideomotor sex-determination technique of LeCron for uncovering subconscious fear in obstetric patients. International Journal of Clinical and Experimental Hypnosis, 9, 249-259.

(Author's Summary) "Unrecognized subconscious fears can be uncovered while using ideomotor questioning with a Chevreul pendulum or with finger signals. The technique described by LeCron for evaluating knowledge regarding the sex of an unborn child is a most helpful way of approaching subconscious fears. The frightened patient refuses to indicate knowledge of the sex of her unborn child. Uncovered fears can be resolved by appealing to conscious-level understanding with adroit questioning" (p. 258).

Spiegel, David; Frischholz, Edward J.; Maruffi, Brian; Spiegel, Herbert (1981). Hypnotic responsivity and the treatment of flying phobia. American Journal of Clinical Hypnosis, 23, 239-247.

Systematic follow-up data are reported for 178 consecutive flying phobia patients treated with a single 45-minute session involving hypnosis and a problem restructuring strategy. One hundred fifty-eight (89%) of the patients completed follow-up questionnaires between six months and ten and one half years after treatment. Results showed that hypnotizable patients were over two and one half times more likely to report some positive treatment impact than those who were found to be nonhypnotizable on the Hypnotic Induction Profile. In addition, the patients' previous experiences with psychotherapy were found to be significantly associated with treatment outcome. The clinical implications of these findings are discussed.

Maestri, D.; Perry, C.; Laurence, J.-R. (1996, August). Children's memory for a special event: Exploring the effects of repeated questioning on recall, suggestibility, and photo lineup identification. [Paper] Presented at the annual meeting of the American Psychological Association, Toronto, Canada.

Recollections of a visit at the Montreal Olympic Stadium from two groups of children (4.5- and 5.5-year-old) were elicited on four occasions with free recall, direct questions, and misleading questions. Recall was evaluated in terms of correct, incorrect, neutral, repeated, omitted, and attributional responses. To study the possibility of children choosing one type of suggestion more readily than the other, the misleading questions were further evaluated in terms of the type of suggestion implied. A photo lineup recognition task of familiar and unfamiliar faces present during the visit was also included. Children displayed high degrees of acquiescence to the misleading questions and a clear preference for the suggestion that did not involve their own person. In the photo lineup identification task, 21-37 percent

(across trials) of the children mistakenly judged familiar and unfamiliar faces as having been present at the event. Results were discussed in a legal context. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1996, Vol. 5, No. 3.)

#### NOTES

1:

8025, Ruehle & Zamansky, 1995 ABSTRACT: Neodissociation theory proposes that hypnotic suggestions are performed relatively automatically, whereas sociocognitive theories suggest that effortful cognitive strategies are necessary. To distinguish between the predictions derived from the two theories, we gave hypnotized subjects the suggestion to forget the number eight, and asked them to solve a series of addition problems using that number. It is a well-established finding in cognitive psychology research that subjective estimations of time depend on the amount of cognitive effort expended during that time. Increases in cognitive effort are associated with decreases in subjective time. Accordingly, if hypnotic subjects carry out a suggestion relatively automatically, they should perceive the time taken as longer than if they carry it out using effortful cognitive strategies. Highly hypnotizable subjects under hypnosis and low hypnotizable subjects instructed to simulate hypnosis were given the suggestion to forget the number eight and to replace it with nine. They were then given a page of addition problems, many of which included eights in the solutions, and were instructed to do the problems as quickly and accurately as possible. They were also informed that they would be asked to estimate the time spent completing the problems.

Subjects completed the addition problems and then gave their time estimates. As a control for changes in time estimation brought about simply by being hypnotized, all subjects also completed a series of addition problems without the amnesia suggestion, and again estimated the time. The order of the two conditions (i.e., with and without the amnesia suggestion) was counterbalanced across subjects.

Results showed that the simulators, who intentionally avoided the number eight in their solutions to the problems, perceived the time spent doing these problems as shorter than the time spent doing problems normally, without the suggestion to forget the number eight. The increase in cognitive effort therefore resulted in decreased subjective time, as expected. The hypnotized subjects, on the other hand, showed no difference in their time estimations under the two conditions. The two groups did not differ in their time estimates without the amnesia suggestion, but with the suggestion, the hypnotized group perceived the time as longer than did the simulators. The results, then, are consistent with neodissociation theory, since the hypnotized subjects appeared to expend relatively less cognitive effort in carrying out the amnesia suggestion.. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1995, Vol. 4, No. 3.)

#### 1995

Eisen, Mitchell L.; Henn-Haase, Clare (1995, November). Memory and suggestibility for events occurring in and out of hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

1:

Resistance to misinformation uses two paradigms: 1. Elizabeth Loftus - expose Subject to slides or videotape, give misinformation with leading or misleading questions 2. Martin Orne - pseudomemory, i.e. age regress people in hypnosis and suggest events occurred.

Each approach yields mixed results. Misinformation is accepted more readily in context of hypnosis; but there is no relationship to hypnotizability. Spanos found that highs were more responsive to social pressure. In general, in the absence of social pressure, when presented subtly and outside the context of hypnosis, the relationship diminishes. Other factors play a more prominent role: source of information, type of information, salience of information, etc.

They examined whether events occurring in context of hypnosis were more prone to distortion when assessed in biased fashion with use of misleading information, than outside hypnosis. Also, form of questions (dichotomous or with 'I don't remember' option).

They gave the Harvard and asked afterwards 3 misleading items (e.g. did you clench your fist, when they didn't do it). Also asked them to circle items if they had no memory of it. Tellegen Absorption Scale and Dissociation scale (DES) were administered a week later. Also a week later asked about events that occurred, including confederate items. Half of Ss had 2 choices, half had also 'I don't remember' as a third option.

In a previous study, resistance to misleading information was related to the strength of the initial memory and not to hypnotizability (article published in AJCH).

## RESULTS

When given 3 choices, the number of misleading items endorsed dropped from .7 to 0.4 which is the most robust finding in the study and affects the rest of the study. Many Ss who endorsed the items reported minutes later that they had no memory for the event (on the check list). While many Ss given only two choices wrote in the margin that the event had never occurred.

Offering an 'I don't know' third option decreased endorsement of the Harvard items also, from 6.4 to 5.2 which is significant. The relationship between hypnotizability and endorsement of misleading items became much weaker when accounting for this.

Scoring high on DES is significantly related to accepting misinformation. Tellegen Absorption Scale also related to accepting misleading information. Harvard Hypnotizability Scale was not related to accepting misinformation.

Total memory on the Harvard (before cue plus after cue) did not correlate with resistance to misleading information. History of abuse was related to hypnotizability. Have to evaluate whether it was traumatizing, multiple abuse, etc.

Eisen, Mitchell L.; Goodman, Gail S.; Qin, Jianjian (1995, November). Child witnesses: Dissociation and memory and suggestibility in abused children. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

1:

Our study looked at suggestibility and resistance to suggestion. During 5-day hospitalization for investigation of child abuse. The first day patient gets physical exam; 2nd day a genital exam, heart arousal, stress arousal; a later day had mental status, emotional functioning, cognitive functioning--and gross screen of IQ for age 5 and up and the digit span for 6 and up, plus rating of global functioning and provisional diagnosis. On Day 5 each child was given structured interview that included questions about the anal- genital exam, with some misleading questions included.

35 minutes after the psychological examination they were given questions about the exam, for brief memory. Next exam was forensic examination of memory for abuse. Gave memory for sentences, perceptual alterations scale (PAS), adolescent version of Dissociative Experiences Scale (A-DES); gave questionnaire to parents.

Hypotheses: suggestibility would be negatively related to age (more errors when younger). Sexually and physically abused children would show more dissociation or psychopathology. Dissociation or psychopathology should be inversely related to memory ability. IQ should be related to memory and resistance to misinformation. Wanted to reconcile two models of post traumatic stress disorder (PTSD): one says they have poorer memory, and the other says they are hypervigilant.

Over 100 children in the 200 received the questionnaire on Day 5. 39% were 3-5 years old, 41% 6-10 years old. 76% were African American. 22% had no documented abuse or neglect; 13% had experienced physical abuse; 30% sex abuse; 12% both types of abuse; 15% neglect; 8% parental addiction.

Measuring dissociation in kids is problematic. The concept is used to describe a huge range of phenomena. Scores on the DES are more highly correlated with the F Scale on the MMPI than with any other measure (Michael Nash's research). So the DES measures psychopathology. Also, children have healthy kinds of dissociation--daydreaming, etc. Josephine Hilgard noted that young kids are naturally involved in imagination. Early traumas may lead to this dissociative style. How do we sort out the healthy imaginal involvements of children from the psychopathology? There is not sufficient data at this time.

Available measures are not validated well. The CDC indicates behavior problems in children. The C-PAS conceptualizes dissociation as relating to eating disorders; the A-DES is a self report measure that related to psychopathology.

CDC scores increase, in 3-5 year olds, as the amount of abuse increases. This looks like general psychopathology, and it is a parental rating. The A-DES and C-PAS were not related to abuse or neglect. In the older groups the CDC related to poor performance on memory tests; but only for the 6-10 year olds. (Poorer memories in younger children could have masked the effect in them.)

The main finding for the study was clinician's estimate of Global Adaptive Functioning was significantly related to Resistance to Misleading Information. The effect did not show for the 3-5 yr old group, perhaps because their memory functioning is poor anyway. Also age was related to memory and suggestibility.

Frischholz, Edward J. (1995, November). A critical evaluation of the 1985 AMA Report on hypnosis and memory. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

1:

JAMA 1985 concluded that hypnotically refreshed memories are less reliable than nonhypnotic recall. There are two problems with their conclusion: 1. No consensually validated definition of 'hypnosis' is identified. They talk about administration of induction, and differences in hypnotic susceptibility. 2. Empirical criteria for discriminating the unique and/or moderating effects attributable to hypnosis are not specified.

For example Loftus showed that memory errors can be created without hypnosis. You should not just add hypnosis to that model.

The criticisms have not led to remedial practices. No research has been done to show how to minimize errors or how to facilitate accuracy.

'What is Hypnosis?' Something that is done vs. something that happens? A procedure or responsivity? Questions like this are relevant to research on whether hypnotically refreshed memories are less reliable than ordinary recall.

Hypnosis is not a 'valid therapeutic modality' (i.e., 'hypnotherapy' is a misnomer). Hypnosis can be used adjunctively with many different types of therapeutic modalities: --psychodynamic therapies --behavior modification treatments --cognitive restructuring strategies --systematic desensitization --flooding --direct suggestion

There is a specious communality: hypnosis is used in a different kind of way with each approach.

If hypnosis is defined in terms of whether an hypnotic induction procedure was administered to the subject, then hypnosis is a universal phenomenon (i.e., everyone can be administered an hypnotic induction procedure). This, in the AMA report, permitted the courts to define it this way, which leads to a number of ridiculous results.

We need to highlight 'What are the variables that are the source of the errors?' The sources are not hypnosis. We can minimize the sources by the way we ask questions, instruct the subjects, etc.

If hypnosis is defined in terms of the nature of the subjects' response to the procedures, then hypnosis is not a universal phenomenon (i.e., there are wide individual differences in hypnotic responsivity). I have shown that it is possible to alter memories, using the Loftus model, in people who are both low and high hypnotizable.

We need to take into account induction procedure, hypnotizability, type of memory, and the retrieval/influence procedure. The demand characteristics re forced responding, expectancies about memory (e.g. video recorder model), expectancies about hypnosis (e.g., everyone remembers) must be accounted for.

Dependent variables in this type of research include memory accuracy, memory errors, and subjective confidence.

Malinoski, Peter; Martin, Daniel F.; Aronoff, Jodi; Lynn, Steven Jay; Gedeon, Scott (1995, November). Hypnotizability, individual differences, and interpersonal pressure to report early childhood memories. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

1:

Infantile amnesia is attributed to developmental issues before 24 months. This study indicates non-hypnotic influences can shape early memories that cross the amnesia barrier.

227 Ss completed Harvard Scale and personality measures in Session 1. In Session 2 182 completed a suggestibility scale. In Session 3 they were selected, as if independent of earlier sessions - 143 [may have misheard number] Ss.

Interviewers told the selected Ss that they were experiencing something like psychotherapy, and they were asked to recall their earliest memory (independent of photos, what people had told them, etc.) Then Experimenters probed for earlier memories; that continued until Ss denied any more memories after 2 consecutive probes. Then Ss were asked to close their eyes and get in touch with more memories. Then they were told most Ss can remember more, including sometimes their second birthday party. After 1 minute, Ss were asked about memories of their second birthday. Then they were asked to focus on even earlier memories, implying it was expected and receiving complements for reporting earlier memories. Finally, Ss completed a post-study questionnaire.

Memory report was a verbal description of an event, person, or object. Initial memory mean age was 3.7; it correlated with Openness to Experience Scale and with Fantasy Proneness. Mean age of the last earliest memory report before the close eyes instruction was 3.2 years. After receiving visualization instructions, 59% reported a memory of their second birthday. Compliance correlated .33 with this. Subjective response, nonvoluntariness, and [missed words] also correlated.

Compliance scores correlated .28 with at least one memory at or before age 24 months. Yielding to leading questions correlated also with memory for an event at or before 24 months.

Clarity of memories decreased between conditions of initial memory, earliest query, birthday, and earliest memory. Mean confidence rating on 5 point scale for second birthday memory was 3.3; mean confidence rating for earliest memory was 3.6. Mean accuracy rating was 4.0, and 94% said their memory reports were accurate to at least a moderate degree.

The post study questionnaire, totally anonymous, indicated Ss did not feel much pressure to recall (2.9 on scale of 1-5). Only 9.8% indicated they felt a lot of pressure. Subjects also usually denied that they made up memories to satisfy the experimenter. On average, the reports of memory under visualization conditions occurred two years earlier than their first reported memories.

Spiegel, Herbert (1995, November). Hypnosis and memory: Point/counterpoint. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

1:

Humans need an interactive flow, a ribbon of concentration, that holds people together with self and environment; a healthy continuity of flow. If there are interruptions, that suggests pathology.

Bernheim said there must be some degree of involuntariness to have hypnosis. Many tests of hypnotizability (e.g. the Stanford scales) involve tests of behavioral compliance. The Hypnotic Induction Profile [HIP] incorporates a bio-psycho-social concept, not simply behavioral compliance, and actually measures the degree of involuntariness with arm levitation.

The eye roll item on the HIP relates to a capacity for dissociation.

Hypnosis involves Dissociation, Absorption, and Suggestibility; the degrees of which correspond with the three personality styles.\* [A presentation of the Spiegel and Spiegel theory of Dionysian, Odyssean, and Apollonian personality types followed here.]\*

Trance capacity is a constant. Depression can interfere with it, but when depression is relieved the person is responsive again. This is not so for schizophrenics, who do not improve in hypnosis when their symptoms are clinically contained. Cognitive fragility is always present.

The issue of memory is made interesting because of the phenomenon of intrinsic memory. (He gave an example of single case study of remembering how to do developmental drawing tests.)

Max Weber talked about balancing ethics of responsibility with ethics of conviction. In therapy the former is important; in forensics, the relevance of data for issues central to legal issue is important and external corroboration is essential.

Since we are getting around to believing that we don't need formal induction ceremonies to elicit hypnotic phenomena, we should apply that knowledge in the forensic setting. So isn't it relevant, in investigating a crime, to try to understand veridicality of a memory by understanding the hypnotizability of the subjects involved? Because if they are high hypnotizables and have a goal, there may be a twist in their memory; while lows may not have the same problem, and other things might affect the accuracy of recall for them).

Weitzenhoffer, Andre M. (1995, November). The incorporation of current events among true memories during age-regressions: Another way of creating pseudo-memories. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

1:

In 1947 while someone else was demonstrating hypnosis, the subject remembered a cat being squeezed and dying; a week later, in hypnosis, she said "That man with a cat is here again." So a pseudomemory became part of an earlier memory, which spontaneously appeared later during age regression.

This event reminds one of Milton Erickson's "February Man" [a case in which pseudomemories were created for purposes of treatment]. So I tried to repeat the 1949 experiment, in a demonstration with a classical somnambulist.

In the demonstration, the other experimenter offered to give the hypnotized Subject a cat; the subject asked him to intercede with her mother. This was during age regression to age 4. Later, regressed to age 5, she spontaneously said that she had a cat and had received it from the other experimenter the year before. The memory had been elaborated into another memory. When not age regressed, she told of a cat having been given to her by "a friend of the family."

We don't know whether, if we regressed these subjects to the same age again, they would still have this memory? I do not view these two experiments as actual replications of the February Man situation. What is in common with that case published by Erickson is the transformation of a current event into a memory in age regression. It is hard to dismiss the possibility of role playing. But these were very highly hypnotizable people.

1994

Ceci, Stephen J.; Loftus, Elizabeth F.; Leichtman, Michelle D.; Bruck, Maggie (1994). The possible role of source misattributions in creation of false beliefs among preschoolers. International Journal of Clinical and Experimental Hypnosis, 42 (4), 304-320.

In this article the authors examine one possible factor in the creation of false beliefs among preschool-aged children, namely, source misattributions. The authors present the results from an ongoing program of research which suggest that source misattributions could be a mechanism underlying children's false beliefs about having experienced fictitious events. Findings from this program of research indicate that, although all children are susceptible to making source misattributions, very young children may be disproportionately vulnerable to these kinds of errors. This vulnerability leads younger preschoolers, on occasion, to claim that they remember actually experiencing events that they only thought about or were suggested by others. These results are discussed in the context of the ongoing debate over the veracity and durability of delayed reports of early memories, repressed memories, dissociative states, and the validity risks posed by therapeutic techniques that entail repeated visually guided imagery inductions.

Frankel, Fred H. (1994, October). On patients remembering abuse when it in fact may not have occurred. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

NOTES

1:

The concept of hidden memories has supported the profession of psychotherapy for a century. This process can only occur if there is a mechanism to support it. Bowers says, if memory is not reliably accurate, it is not reliably inaccurate either.

"Ideas passing as descriptions lead us to equate the tentative with [the factual]" - Gould.

Three studies purporting to establish repression: 1. Briere & Comte sampled 450 adults who reported abuse. They asked, "Was there ever a time when you couldn't remember the forced experience?" How does respondent understand the question?

Clients were all in therapy. 2. Herman and Schatzow (1989) "verification of abuse" study. 53 Ss in a survivor's group. Reports percentages who had no or little recall. Authors don't acknowledge that the group discussion and the attitude of therapist may have shaped the response. It is also not clear how many Ss who claimed to have "verified" their accounts were among those who had severe amnesia for the event. They could be Ss who had never lost the memory in the first place. 3. Williams interviewed women who earlier were in Emergency Rooms because of abuse being suspected. 38% did not report childhood abuse when questioned, and author concluded it was due to repression. Significant numbers of adults cannot remember things even past the age of 5.

Problem with wording of questions. Some of the women interviewed might have preferred not to report the event. This was not investigated in the study.

Freyd, Jennifer J. (1994). Betrayal-trauma: Traumatic amnesia as an adaptive response to childhood abuse. Ethics and Behavior, 4.

Betrayal-trauma theory suggests that psychogenic amnesia is an adaptive response to childhood abuse. When a parent or other powerful figure violates a fundamental ethic of human relationships, victims may need to remain unaware of the trauma not to reduce suffering but rather to promote survival. Amnesia enables the child to maintain an attachment with a figure vital to survival, development, and thriving. Analysis of evolutionary pressures, mental modules, social cognitions, and developmental needs suggests that the degree to which the most fundamental human ethics are violated can influence the nature, form, processes, and responses to trauma.

#### NOTES

1:

A logical extension of this research direction, based on a strategy that has been very effective in cognitive neuroscience, would be to look for neuroanatomical underpinnings of the cognitive mechanisms implicated in dissociation. ... For instance, the ability to dissociate current experience may depend partly on representational structures that support spontaneous perceptual transformations of incoming events. One possible perceptual transformation that is amenable to scientific investigation, would be the creation of spatial representations in which the mental 'observer' is spatially distinct from the real body of that observer. Such a representation would fit patient descriptions of 'leaving their body' during a traumatic episode and viewing the scene as if from afar. Additionally one could investigate the role of mental recoding and restructuring during memory 'recovery' and psychotherapy" (pp. 19-20).

Kinnunen, Taru; Zamansky, Harold S.; Block, Martin L. (1994). Is the hypnotized subject lying?. Journal of Abnormal Psychology, 103, 184-191.

Do the verbal reports of deeply hypnotized Subjects truthfully reflect their subjective experiences of hypnotic suggestions? Exp 1 established that the electrodermal skin conductance response (SCR) provides an effective method for

detecting deception in the laboratory equally well in hypnotized and nonhypnotized Subjects. In Exp 2, deeply hypnotized and simulating Subjects were administered a number of hypnotic suggestions in a typical hypnotic session, without mention of deception, and were questioned about their experiences while SCR measures were recorded concurrently. Results indicate that 89% of the hypnotized Subjects' reports met the criterion for truthfulness, whereas only 35% of the simulators' reports met this criterion. Implications for the theory of hypnosis are discussed.

Lynn, Steven Jay; Nash, Michael R. (1994). Truth in memory: Ramifications for psychotherapy and hypnotherapy. American Journal of Clinical Hypnosis, 36, 194-208.

In this article we address a number of issues relevant to the practice of psychotherapy and hypnotherapy: How reliable is memory? How are therapists' and clients' beliefs and expectancies related to pseudomemory formation? Are certain clients particularly vulnerable to pseudomemory creation? Does hypnosis pose special hazards for pseudomemory reports? What are the variables or factors that mediate hypnotic pseudomemories? In addition to reviewing the literature on these topics, we intend to sensitize the clinician to the potential pitfalls of critical reliance on the patient's memories, as well as uncritically accepted clinical beliefs and practices.

#### NOTES

1:

We studied autobiographical memory in the college population, as manifested in the therapy situation, as a way of investigating an individual difference variable. Most people do not have recall before age 3 or 4 (and probably infantile amnesia begins before age 2).

Administered Autobiographical Memory Scale (AMS), and later in context of a hypnosis scale. 247 students were in phase 1, conducted as two separate experiments so that Ss wouldn't link the AMS to measures used in the second study.

First study was presented as a study of personal memories. Asked Ss to distinguish first five birthdays, circumstances around loss of first tooth, first day of high school. Also, they were asked about their earliest memory events, rated according to 3 scales (detail, vividness, accuracy of recall). Authors summed Ss' responses on these 3 ratings for the 8 item scale.

Part II. Administered various scales: Life Experiences, Fantasy Proneness, Wilson & Barber's scale, Imagery Control Scale, Global Psychopathology, 25 item scale of physical and sexual abuse, Brier's list of symptoms of abuse, and DES (Dissociative Experiences Scale). Imbedded were 12 items to test carelessness in responding (e.g. "I have never said Hello to anyone who wore eyeglasses.")

RESULTS. Phase 1. Two people indicated they had memories dating to before their first birthday; an additional 5% of Ss gave memories between 12-24 months. This

would probably be impossible. Another 14.4% described events between 24-36 months; 37.4% said their earliest memory was at age 3. Mean age for earliest memory was 3.4 years (which agrees with other surveys.) Only 1 subject stated his earliest memory was as late as the tenth year of life.

High intercorrelation was obtained, ranging .79 to .89, between ratings on any of the memory event ratings (as detailed, vivid, or accurate). There was a negative correlation of these ratings with age of recall. Ss who report more detail, vividness, and competence, were also likely to report earlier first memories.

Authors divided Ss into three groups based on age of first memory: 12 with first memory earlier than first year; those whose first memory was between 1-7 years; and those with a later first memory. The earlier memory group were more fantasy prone; and rated their memories as more reliable, vivid. This suggests there are persons who report memories that are covered by infantile amnesia, report them with greater detail, and are more fantasy prone than those who report memory events beginning later in life. This is consistent with Wilson & Barber's finding that fantasy prone people have vivid recall of early childhood events.

None of the memory reports correlated with psychopathology or dissociation. Dissociation (DES) was correlated with abuse indicators, however. Compared top and lowest 10% and middle range on DES on their memory scores and found no relationship. There was no support for the idea that report of early life events in dissociative people is compromised. Failure to recall early memories shouldn't suggest that people are dissociative (which some therapists tend to do).

All three memory measures were associated with Harvard Scale scores. The AMS was administered at the same time as the Harvard. Objective responding on the Harvard correlated with detail, vividness, and accuracy of recall. Also, involuntariness of response correlated with all 3 measures of the AMS. Finally, subjective involvement correlated with all three measures of AMS. At least when hypnosis is measured first, and explicit connection is suggested, there is a connection. Further research is needed to see if the relationship holds when measured in independent contexts. This may explain why High Hypnotizables are more prone to pseudo memories and leading questions. They may come to confuse them with historical reality.

The results suggest caution for early memory reports. They may be vulnerable to confusing fantasy and reality, as well as to biasing effects.

Martin, D.; Tomak, J.; Lynn, S. J. (1994, October). Detecting simulation with the hypnosis simulation index. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

1:

Orne described demand characteristics of the hypnotic situation, such that some Ss want to either deceive the hypnotist or to please the hypnotist or to help the experiment work. To separate essence of hypnosis he devised an experimental technique, which informs S to role-play, and tells them intelligent Ss will be able to do this. Sheehan & McConkey note that though the model specifies subjective experience, it lacks a way of determining if people are truthful.

We developed a scale assuming hypnotized Ss would be truthful and wouldn't say they had experiences they didn't, but that simulators would exaggerate. The scale included events plausibly reported by highs but not widely reported.

The scale has 31 items, and is titled the Hypnotic Experience Scale. It has 24 items for experiences during hypnosis, 5 for experiences after hypnosis, and 2 for how deeply hypnotized they felt and what kind of hypnotic subject they thought they were.

Ss participated in 2 sessions. They had the Harvard group scale in the first, and simulation instructions in second session. Simulation instructions were read to Low and Medium subjects. To encourage Ss to keep eyes closed, they were told it was essential to keep their eyes closed. We had scores on:

Hypnosis Simulation Index

SCL 90

DES

Tellegen Absorption Scale

Highs did not receive any simulation suggestions. Then the Stanford Scale was administered. Highs and Simulators had to pass at least 9 Harvard items.

Of the predictors, only the Hypnosis Simulation Index discriminated. It correctly classified 94% of the Ss. To eliminate non-useful items, a stepwise discriminate analysis was performed. 15 items remained. These 15 items were used in a series of analyses. They discriminated between the 2 groups from 100% to 70% of the time.

This study is the first to successfully discriminate hypnotized from dissimulating subjects. Simulators' performance indicate they tend to respond in stereotypic ways that exaggerate how hypnotized Ss respond. Hypnotized Ss who passed more than 10 items only rated themselves as average on hypnotizability.

This has potential applications in forensic situations.

Ofshe, Richard; Singer, Margaret T. (1994). Recovered memory and robust repression: Influence and pseudomemory. International Journal of Clinical and Experimental Hypnosis, 42, 391-410.

A subset of the psychotherapists practicing trauma-focused therapy predicate their treatment on the existence of a newly claimed, powerful form of repression that differs from repression as used in the psychoanalytic tradition and from amnesia in any of its recognized forms. Recovered-memory specialists assist patients to supposedly retrieve vast quantities of information (e.g., utterly new dramatic life histories) that were allegedly unavailable to consciousness for years or decades. We refer to the hypothesized mental mechanism as 'robust repression' and call attention to the absence of evidence documenting its validity and to the differences between it and other mental mechanisms and memory features. No recovered-memory practitioner has ever published a full specification of the attributes of this mechanism. That is, the properties it would have to have for the narratives developed during therapy to be historically accurate to any significant degree. This article reports a specification of the properties of the robust repression mechanism based on interviews with current and former patients, practitioners' writings, and reports to researchers and clinicians. The spread of reliance on the robust

repression mechanism over the past 20 years through portions of the clinical community is traced. While involved in therapy, patients of recovered-memory practitioners come to believe that they have either instantly repressed large numbers of discrete events or simultaneously repressed all information about abuse they may have endured for as long as a decade. Patients' therapy-derived accounts are thought by some social influence, memory, and clinical specialists to be inadvertently created iatrogenic effects: inaccurate pseudomemories and confabulations produced due to patient-therapist interaction, the use of leading, (sic) suggestions, hypnosis, and the mismanagement of the dependent relation of the patient on the therapist. Three cases are reported which illustrate how new life accounts predicated by robust repression can develop during therapy with a recovered- memory practitioner.

Schefflin, Alan W. (1994). Forensic hypnosis: Unanswered questions. Australian Journal of Clinical and Experimental Hypnosis, 22, 25-37.

Many courts have mistakenly identified hypnosis as more suggestive than eyewitness testimony or leading questions, and therefore these courts have applied unnecessarily restrictive rulings on hypnosis. The dangers of suggestion in eyewitness and interrogation cases pose reliability problems that are equally as great. In all situations, pre- trial evidentiary hearings on admissibility of 'suggestive' testimony is essential. Expert testimony should be available to assist the judge. The forensic rules to date have failed to clarify some hard cases. In resolving these cases, courts are encouraged to adopt a case- by-case analysis rather than a total prohibition on hypnotically refreshed recollection. Courts have assumed conclusions about hypnosis that the laboratory experiments suggest are incorrect - juries are not overly persuaded by hypnosis testimony, there is no inevitable concreting effect and witnesses do not become impervious to cross-examination. Thus, the restrictive per se disqualification rules for hypnotically refreshed recollection are too severe.

Spiegel, David (1994, October). On patients not remembering abuse when it in fact may have occurred. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

1:

False memories and false non-memories may be two sides of the same coin. What is the evidence for repression?

If people are abducted by extraterrestrials, why don't they just keep them? [Joke!] It seems counter-intuitive that people would forget important, arousing things that happen.

The three main components of hypnosis (suggestibility, absorption, and dissociation) are also aspects of memory: 1. Absorption relates to encoding (narrowing attention); also happens during traumatic events (Loftus' "gun memory" which is so clear, while they don't encode what gunman's face looks like). 2. Dissociation relates to memory storage (compartmentalization of information). Traumatized people have symptoms of dissociation, depersonalization. If you are in an unusual mental state,

you may watch the event; the memory is stored without the usual network of associations. 3. Suggestibility relates to retrieval. The way questions are asked influences one's response. But hypnosis is not an infinite influencer; the main damage to memory contributed by hypnosis is "confident errors" (McConkey).

We did research one week after the Loma Prieta earthquake, and found significant cognitive alterations, memory alterations, etc. In our sample, 1/4 of the people felt detached from their body or from the ground right after the earthquake.

Memory alterations were compared with data from other studies after other traumas. Difficulties with memory occurred in 29% of our sample.

The disorganization of memory can follow even just witnessing trauma (e.g. the recent slaying of 8 people in the law office in San Francisco) And people who witnessed the execution of Harris. They were in no danger themselves, yet the level of dissociative symptoms were as high in the former.

The Briere & Cone and Herman & Shatzow studies are based on self report of earlier trauma, and that is a problem in research. But Williams' study does have the age of people when they were abused as children; see her article in Journal of Consulting and Clinical Psychology.

#### COMMENTS FROM THE AUDIENCE

Dabney Ewin: Sex abuse trauma differs from earthquakes because the abuser says, "If you tell anybody I'll kill you." This is like a post hypnotic suggestion, which is carried out compulsively when given to the victim during fear.

Dale: How do we account for the vigor in the attempts of each side to convince the other. The people who have been real victims of sexual abuse need to be able to talk with the people who are victims of False Memory Syndrome. The impact on a family is just as traumatic as the sexual abuse itself.

Response by D. Spiegel: I wouldn't recommend that combination, but the point you make about damage to the falsely accused is relevant. Their lives are shattered but remember the damage done throughout life by sexual abuse.

Yapko, Michael D. (1994). Suggestions of abuse: True and false memories of childhood sexual trauma. New York, NY: Simon & Schuster.

#### NOTES

1:

From the section titled "A Note to Therapists:"

"I would encourage you not to (1) preclude open communication at all times among family members; (2) act as your client's 'hired gun'; (3) act as if corroboration of allegations of abuse were unnecessary; (4) jump quickly to the conclusion abuse occurred simply because it is plausible; (5) suggest a history of abuse to someone who is not your client; (6) refer a client out for hypnotic confirmation or disconfirmation on the false premise that hypnosis is some kind of lie detector; (7) ask leading or suggestive questions; (8) assume repression is in force when someone does not have much memory from childhood; (9) rely on your memory of the interaction. Tape your investigative sessions and review them later for any evidence of possible unintentional contamination of your client's recollections" (p. 217).

1993

Hawkins, Russell (1993). An analysis of hypnotherapist-client sexual intimacy. International Journal of Clinical and Experimental Hypnosis, 41, 272-286.

While sexual interaction between psychologists, physicians, and other health therapists of all kinds and their clients is typically condemned by professional bodies as unethical, the controversy regarding the potential for hypnosis to produce compliant behavior in unwilling or nonconsenting subjects suggests that hypnotherapist-client sex may warrant special attention. Because the experiments required to clarify the potential for hypnosis to potentiate nontrivial compliance are themselves unethical and/or inconclusive, experimental methods cannot be adequately used to clarify this issue. Instead, the matter can be addressed by reference to other forms of evidence, such as the responses of therapists and clients to anonymous surveys and the analysis of cases, that have reached the courts. Consideration of this qualitatively deficient evidence suggests that even if the use of hypnotic suggestion can lead to compliance to sexual demands, overt coercion is seldom used in practice. Social psychological and situational factors are particularly salient in understanding therapist-client sex. The question of whether there are special properties of the dynamics of the hypnotic experience, other than specific coercive suggestion and beyond those typically found in other forms of therapy, is considered. Comparisons are drawn with other examples of socially condemned sex, such as teacher-student sex, sexual harassment in the workplace, incest, and extramarital sex.

#### NOTES

1:

Disclaimer--The following information is not intended to substitute for professional legal advice and should not be used as such.

The following events led up to our current situation in California, regarding the use of hypnotically elicited information in court:

1968 - Harding vs. the State of Maryland. First case in which the state prosecution requested use of hypnosis. (Prior to this hypnotically refreshed memory was not used in court testimony because the memory was regarded as unreliable.) Police hypnotized a state's witness, and a man was convicted of rape. Hypnosis in this case was considered no different from other memory jogging techniques (Like showing a witness pictures.)

1978 - Reiser published "Hypnosis and it's use in law enforcement." In it he stated that 60% of witnesses hypnotized by police gave important information that helped the case. Reiser is a psychologist working in the Los Angeles Police Department.

1976 - Chowchilla kidnaping case, the driver of the bus was hypnotized, and remembered enough of a license plate to catch the kidnappers.

1980 - Reiser, Handbook of Investigative Hypnosis\_ N=384 cases were investigated using hypnosis. In 67% of these cases, hypnosis was thought to have led to valuable information. Where external corroboration was possible, 90% of the new pieces of

information were accurate. The Society for Investigative and Forensic Hypnosis was established by Reiser.

During this same period, courts were pulling back from permitting hypnotically refreshed memories to be given in court testimony.

1979 Martin Orne (in the International Journal of Clinical and Experimental Hypnosis) proposed safeguards for the use of hypnosis for forensic purposes. 1. Licensed psychologist or psychiatrist does the hypnosis. 2. Hypnotist is independent of prosecution, defense, and investigator. 3. Any information regarding a crime given to the hypnotist before hypnosis must be written down. 4. The hypnotist writes everything the witness says. 5. All interviews, including the pre-hypnosis interview, are recorded. 6. Only the hypnotist and witness are in the room, and 7. independent verification is very important.

Inasmuch as Reiser had been training detectives to do investigative hypnosis, he countered the Orne requirements by noting that: 1. Therapists are not trained investigators; detectives typically work with trauma victims. 2. Reports of adverse side effects following investigative hypnosis are exaggerated 3. Confabulation and fantasy are no more prevalent in hypnosis than in waking state.

Herbert Spiegel, in addressing the reliability of hypnotically refreshed memories, said hypnosis can make an "honest liar" out of a person. That is, they can be personally convinced that they have remembered something that in fact did not happen.

1980 - Bernard Diamond, M.D. (psychiatrist and law professor) wrote an article in the California Law Review, noting that: 1. Hypnotically refreshed testimony is full of fantasy and confabulation. 2. A hypnotist cannot tell if the subject is simulating. 3. A hypnotized subject cannot discriminate between fact and fantasy. 4. A hypnotized subject could become hardened against cross examination because with hypnosis he becomes more confident.

Courts began using the Frye Rule: in order for expert testimony to be admissible, it must be what is generally accepted to be true, in the scientific research literature.

1982 - The Shirley Decision (California Supreme Court) A woman who was raped was hypnotized before the trial. The accused, a man named Shirley, admitted having sex but said it was not forced. The Supreme Court used the Frye Rule to exclude any testimony from either side from anyone who had been hypnotized. (This rule applied to any hypnosis, including hypnotherapy.) Later the Court revised it to say that the defendant could be hypnotized (but not the plaintiff) because nothing should impede their defense.

1982 - Proposition 8 passed (Victim's Rights bill) and allowed hypnotically refreshed testimony to be used.

1986 - Three Justices, including Justice Rose Bird, were removed from the California Supreme Court (by election) and the legislature wrote Section 795 (which represented a middle ground). Hypnotically refreshed memory is allowed if the court testimony is limited to pre-hypnotic recall.

1992

Christianson, S-A (1992). Emotional stress and eyewitness memory: A critical review. Psychological Bulletin, 112, 284-309.

## NOTES

1:

Although not addressing hypnosis specifically, this is a comprehensive review of literature on memory for negative emotional events relevant to issues of hypnosis and memory. The final conclusion is that emotional events are indeed remembered differently than neutral or ordinary events and are well retained with respect to the event itself and concerning central, critical detail (not peripheral detail). Such memories seem less susceptible to forgetting. There is evidence for dissociation between memory for emotional information and memory for specific event information. There is also evidence of amnesia or memory impairment effects after high-arousal events, with memory increasing as more time passes after the event. The functional amnesia effects are probably due to an interaction between altered encoding operations and the specific retrieval circumstances aiding consciously and unconsciously controlled reconstructive processes. There is little evidence to support Loftus' contentions that emotional stress is bad for memory.

Faller, Kathleen Couborn (1992, Summer). Can therapy induce false allegations of sexual abuse?. The Advisor (Published by American Professional Society on the Abuse of Children), 5 (3), 3-6.

## NOTES

1:

Concern about the impact of therapy on children's accounts of sexual abuse should be understood in the context of two phenomena: (1) the adult need to deny that children are sexually abused, and (2) adult identification with the alleged abuser. These phenomena operate at both individual and societal levels" (p. 3).

"Research related to impact of stressful situations on children's ability to recall provides mixed results, some studies finding children are less accurate if the event is traumatic (Peters, 1991) and others finding they are not (Goodman, Reed, & Hepps, 1985).

"Research reveals that it is rare for children to falsely allege that they have been touched in their private parts. In one study, a substantial proportion of children who experienced genital and anal touch during a physical examination by a doctor did not volunteer this information when asked general questions about the examination. The majority of children in the study revealed genital and anal touch only when they were asked specific questions like, "Did the doctor touch you there?" (Saywitz, Goodman, Nicholas, & Moan, 1991)" (pp. 3-4).

"Clarke-Stewart and her colleagues (1989) have demonstrated that children's interpretation of ambiguous events can be manipulated and altered by an authority figure who insists upon a particular interpretation (see also Lindberg, 1991)" (p.4).

"In sum, the research suggests that older children are likely to provide more complete unassisted disclosure than younger children. Younger children may need more memory cues in the form of specific questions than older children. Therapists are much more likely to find false negatives than false positives. Finally, therapists should be aware of the possibility the child may identify the wrong person. ... Generally, however, the research indicates that concern about the contaminating

effects of therapy on children's recollections of sexual abuse is exaggerated" (pp. 4-5).

"Research indicates that the proportion of fabricated reports may be higher in the divorce scenario than in other contexts (Faller, 1990; Jones & Seig, 1988). Studies suggest most false reports are made by adults, not children (Jones & McGraw, 1987; Jones & Seig, 1988)" (p. 5).

"Clinical research (Sorenson & Snow, 1991) and experience (Faller, 1988) indicate that for most children, revealing sexual abuse is a process which occurs over time. A typical pattern is one in which children begin with the least overwhelming experience and gradually disclose more and more as their accounts are accepted and believed" (p. 5).

"[In conclusion]... therapists should be aware of the findings from research on children's memory and suggestibility. This research indicates that there are vulnerabilities which should be taken into account during therapy" (p. 6).

Gravitz, Melvin A. (1992, October). Historical and legal issues. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

1:

The 1976 Chowchilla kidnaping case in California stimulated interest in using hypnosis for forensic investigation; in the same year, it was used in a case of airline hijacking in the Mediterranean to Uganda. Hypnosis is used for obtaining "leads" and doesn't claim to develop "the truth."

Other uses include: lifting amnesia of witnesses and victims of trauma--including but not limited to crime; obtaining additional information in nonamnesic Ss; evaluation of a subject's mental condition (e.g. multiple personality disorder vs malingering, as in the Bianchi case). In each use, hypnosis is not infallible, is not complete. But no procedure is. Motivation, resistance, transference are all critical.

Historic questions: 1. whether coercion is entailed 2. impact of hypnosis on memory 3. possible harm to subject, physically and mentally

The coercion issue dates to Mesmer, whose procedures led to accusations of immoral suggestions. In the 1880s Charcot said no one could be forced to do anything while the Nancy school (Liebeault) said they could. Since then we have seen laboratory studies using student volunteers, fake "poison," rubber daggers, etc., as well as recent "real life" studies where Ss were induced to violate their morals (see Watkins). Review articles include those by Jacob Conn of Baltimore and the 1985 JAMA article written by a panel headed by Martin Orne.

For impact of hypnosis on memory, see the Orne report which did not fully support using hypnosis for memory enhancement.

Regarding possible harm to a hypnotic subject in the 19th century, a young man's death was attributed to nervousness and exhaustion and diabetes due to repeated hypnosis. Other studies of death (of chickens, of a frog) due to repeated hypnotization were published. Now the consensus is that hypnosis is not dangerous (but incompetence using hypnosis may be dangerous).

#### LEGAL PRECEDENTS.

In 1897 a California court refused to accept testimony of a Subject who had been hypnotized. *People vs Eubanks*.

The 1950's Cornell case established that a person can be hypnotized for their own defense.

In 1963 the California supreme court ruled that a lower court made a mistake in not admitting testimony from someone who had been hypnotized.

In *Harding* (a Maryland case), the trauma victim, amnesic, was hypnotized one month later. The testimony was accepted. A 1983 Maryland appeals court overturned it, influenced by the California *Shirley* case.

In 1983 *Hurd* case, a victim, hypnotized, identified her husband as attacker. Lower court didn't permit the testimony; then a higher court reversed it. The court issued what are known as the Hurd rules, governing testimony that is acceptable: 1. hypnotist is licensed psychologist or psychiatrist with training in hypnosis 2. hypnotist must be independent of both the prosecution and defense 3. all information given to the hypnotist about the case must be written 4. hypnotist must obtain a nonhypnotic account of the memory before hypnosis is used. 5. must have taped record of the hypnosis sessions (preferably videotaped) 6. only hypnotist and subject should be present in the room

Soon after, California had the *Shirley* case. The California court ruled hypnosis per se is unreliable because it produces confabulation. This decision had a chilling effect throughout the country for several years.

In 1987 we had *Rock vs Arkansas*, the first and only case involving hypnosis to come before the U. S. Supreme Court. Vicky Rock shot her husband. Under hypnosis, she remembered she did not have her finger on the trigger, and her husband grabbed her and shook her. Lower court wouldn't admit the testimony of the gun expert, who testified the trigger was sensitive to jarring. Supreme Court ruled defendants (not necessarily others) could use hypnosis in their own defense.

Murrey, Gregory J.; Cross, Herb J.; Whipple, Jim (1992). Hypnotically created pseudomemories: Further investigation into the 'memory distortion or response bias' question. *Journal of Abnormal Psychology*, 101 (1), 75-77.

In order to study whether pseudomemories represent actual memory distortions or are a result of response bias, 60 highly hypnotizable subjects and subjects from the general population were divided into 4 experimental groups and were tested for pseudomemory manifestation after receiving a false suggestion. Of the 4 groups of subjects, 3 were offered a monetary reward as a motivation to distinguish false suggestion from the actual occurrence. Pseudomemory manifestation was found to be significantly higher among subjects not offered a reward than among subjects who were offered such a reward. The implications of these findings are discussed.

NOTES

1:

NOTES: The article contains a review of the literature through 1989. The study tested the hypothesis that when it is important to distinguish fantasy from reality in a hypnosis experiment, subjects can do so--a position presented by Spanos and McLean (1986). They used a verifiable event to test for pseudomemory production,

as in research published by McCann and Sheehan (1988). Subjects were 30 high hypnotizable and 30 unselected students.

Subjects were shown a videotape of a mock robbery scene. The next week, Groups A, B, and C heard audiotapes "to enhance memory," but in addition to motivating statements about "trying to remember" certain details, the tapes included misleading information (e.g. "Remember the color of the hat the robber was wearing" when in fact there was no hat on the robber). Subjects in these groups were 'influenced.'

"Both highly hypnotizable subject groups (Groups A and B) listened to the audiotape after being administered a 10-min hypnotic induction procedure (modified from that of Barber, 1969). Subject Group C listened to the audiotape without hypnosis. The control group, Group D, did not listen to the audiotape and was, therefore, classified as 'uninfluenced.'"

A week later subjects responded to multiple-choice and yes-no or true-false questions about the robbery scene. The yes-no question about whether the robber was wearing a hat served as the dependent variable, a measure of pseudomemory. "To motivate subjects to report the truth rather than to follow any perceived expectations of the experimental or social context, we offered subjects in Groups B, C, and D a monetary reward if they achieved the most correct answers on the quiz (according to the videotape). The reward was offered just before administration of the quiz to ensure that no collusion between the subjects could occur. Group A was not offered any such reward" (p. 76).

"The number of subjects in Group A (hypnotized, influenced, no reward) who reported the false information at posttest (12) was significantly greater than that of Group B (hypnotized, influenced, offered reward.... However, the difference in incidence of pseudomemory between Group B and the control group, Group D (not hypnotized, uninfluenced, offered reward), was nonsignificant" (p. 76).

Table 1 Incidence of Pseudomemory Per Group -----

----- False suggestion Group A Group B Group C  
Group D  
result (n=15) (n=15) (n=15) (n=15) -----

Accepted 12 6 7 3

Rejected 3 9 8 12 -----

----- Note. Group A = hypnotized, influenced, not offered reward.

Group B = hypnotized, influenced, offered reward.

Group C = not hypnotized, influenced, offered reward.

Group D = not hypnotized, not influenced, offered reward.

In the Discussion, the authors wrote, "Because the only variable among these groups was the reward, a reasonable conclusion from the findings is that pseudomemories manifested by the subjects were (for the most part) not actual memory distortions. Presumably, the reward provided the subjects in Group B an incentive to 'report the truth' and a disincentive to give biased reports on the basis of the perceived expectations of the social or experimental context. Thus these data suggest that pseudomemory effects or the occurrence of the pseudomemory phenomenon among

highly hypnotizable subjects can be minimized by providing a motivation to subjects to give unbiased reports.

"A major implication of these findings is that researchers should control for response bias resulting from perceived social demands or from leading test designs when they conduct pseudomemory research. Of further concern is the fact that a number of researchers contend that hypnotic interrogation of eye-witnesses can greatly facilitate the creation of pseudomemories (Levitt, 1990; Loftus, 1979; Orne, 1979; Putnam, 1979), and therefore hypnosis either should not be allowed in the courtroom or should be strictly controlled. Yet in light of our findings, response bias may be a confound in pseudomemory research, and thus researchers need to be cautious when making inferences to specific situations from data obtained in an experimental setting.

"Despite the existence of a confound of (unmeasured) differences in hypnotizability between the two groups, there was no significant difference between Group B and the control group (Group D). This suggests that if response bias is controlled for, there may not be significant differences in manifestation of pseudomemories between highly hypnotizable subjects and subjects representative of the general population. However, further research is needed in order to address this question" (pp. 76-77).

Ofshe, Richard J. (1992). Inadvertent hypnosis during interrogation: False confession due to dissociative state; mis-identified multiple personality and the satanic cult hypothesis. International Journal of Clinical and Experimental Hypnosis, 40, 125-156.

Induction of a dissociative state followed by suggestion during interrogation caused a suspect to develop pseudo-memories of raping his daughters and of participation in a baby-murdering Satanic cult. The pseudo-memories coupled with influence from authority figures convinced him of his guilt for 6 months. During this time, the suspect, the witnesses, and all the evidence in the case were studied. No evidence supported an inference of guilt and substantial evidence supported the conclusion that no crime had been committed. An experiment demonstrated the suspect's extreme suggestibility. The conclusion reached was that the cult did not exist and the suspect's confessions were coerced- internalized confessions. During the investigation, 2 psychologists diagnosed the suspect as suffering from a dissociative disorder similar to multiple personality. Both psychologists were predisposed to find Satanic cult activity. Each concluded that the disorder was due to "programming" by the non-existent Satanic cult.

Perry, Nancy W. (1992, Summer). How children remember and why they forget. The Advisor (Published by American Professional Society on the Abuse of Children), 5 (3), 1-2; 13-16.

#### NOTES

1:  
My memory is the thing I forget with.' (a child's definition, cited in Grossberg, 1985, p. 60)" (p. 1).

"Unlike the simpler forms of memory retrieval, free recall is strongly age-related... the recall skills of preschool children develop gradually" (p. 2). "...in some cases, younger children can provide more accurate information than adults (Lindberg, 1991). For example, if an event is particularly salient (as sometimes happens in cases of trauma), recall may be exceptionally good (Brainerd & Ornstein, 1991; Lindberg, 1991)" (p. 13).

"Children have limited ability to use memory strategies. For this reason, children often know more than they can freely recall" (p. 13).

"The use of rehearsal as a memory strategy is almost automatic for adults. ... Ten-year-olds also commonly use rehearsal to aid memory. Young children, however, have not mastered rehearsal (Harris & Liebert, 1991).

"Another memory strategy is imagery, which involves (1) mentally picturing a person, place, or object, or (2) visually associating two or more things that are to be remembered. Children develop imagery much later than other memory strategies. Indeed, some people never learn this memory strategy (Flavell, 1977)" (p. 13).

"... stress alone may not impair memory processes. Indeed, stress can lead to arousal, heightened attention, and improved encoding (Deffenbacher, 1983). However, stress that results from intimidation may lead to either impairment in encoding or problems in recalling or reporting memories" (p. 14).

"Because the effect of suggestion on material that has been well encoded tends not to be significantly different across age groups (Cohen & Harnick, 1980), it may be that younger children's inferior performance on suggestive tasks results from inferior encoding" (p. 15).

Summit, Roland C. (1992, Summer). Opinion: Misplaced attention to delayed memory. The Advisor (Published by American Professional Society on the Abuse of Children), 5 (3), 21-25.

## NOTES

1:

I believe this is the time to cap a century of progress with a monumental achievement in awareness. We must cherish and develop the concept that what we don't know can hurt us. We can establish, for the first time, that our lives and even the nature of our society can be shaped by experiences so terrible that they are, in the words of Josef Breuer a century ago, 'forbidden to consciousness' (1895, p. 225). We may learn that huge chunks of oppositional thought, cruelty, perversity, helplessness, self-destruction and mental illness are derived from this hidden reservoir of suffering, and we could inspire unprecedented achievements in healing, prevention and enlightened peacemaking" (p. 21).

"We have been slow to consider the implications of dissociation for protective awareness of child sexual abuse" (p. 22).

"And we should respect the painful threat that enlightenment poses for our comforting faith in a just and fair society. We would have to consider that we may be capable as a people of hiding our most grotesque activities under the cover of dissociation, so that we don't know we're doing it, our victims can't say it's happening, and as an outer society we will insist that no such thing could possibly exist" (p. 22).

"While it is urgently important to know that dissociation is real, it is doubly important not to endorse as accurate, in fact, details or encounters that may be part of a still unknown process of distortion" (p. 22).

"The most distinguished clinicians, the people who occupy the platform of authority as scientists and educators, are joining with those who, until now, have been recognized mainly for their adversarial positions. Now those two poles are coming together in aroused opposition to the phenomenon of delayed memory, especially when acquired in therapy with young women in their 30's, especially when those therapists lack an M.D. or a Ph.D. diploma. We face, once again, an ageist, sexist, elitist professional standoff around an issue that deserves to be explored in harmony" (p. 24).

"In California and several other states the statute of limitations has been suspended for individuals who can demonstrate delayed discovery of childhood trauma" (p. 24).

"The rush to judgment is not confined to civil litigation. There is no statute of limitations on murder" (p. 24).

"How many kids have hidden the memory of unspeakable assaults which can be unearthed years later to plunge them into courtroom testimony? How many free citizens could be sued or imprisoned by such remote discoveries? What should we do as scientists in support of or in opposition to those delayed memories?" (P. 24).

"We know that skepticism can quash the emergence of dissociated memories. Can we prove that therapeutic zeal cannot enhance such memories? Survivors who gain a clear picture of sexual assault in the climactic period of discovery tend to fade out the sharp edges as they achieve resolution and healing. The most seasoned survivors may discount the intermediate memories which once provided the impetus for their recovery" (p. 25).

1991

Gibson, H. B. (1991). Can hypnosis compel people to commit harmful, immoral and criminal acts?: A review of the literature. Contemporary Hypnosis, 8, 129-140.

The literature relating to whether hypnosis can be used to compel people to perform acts that are dangerous, immoral or criminal is reviewed, some evidence over the past 200 years being discussed. Relevant real-life instances are cited as well as the laboratory studies of the twentieth century. Detailed criticisms of the latter are made, and it is shown that although no really conclusive findings have emerged, such research has strongly implied that hypnosis does not increase compliance. Four past criminal trials concerned with alleged rape and sexual assault are cited. It is concluded that whilst hypnosis may be one among a number of techniques used in sexual seduction, it is not reasonable to claim that rape has ever been effected by means of hypnosis alone.

NOTES

Review of literature that concludes that while hypnosis may be one among a number of techniques used in sexual seduction, it is not reasonable to claim that rape has ever been effected by means of hypnosis alone.

Grabowski, Karen L.; Roese, Neal J.; Thomas, Michael R. (1991). The role of expectancy in hypnotic hypermnnesia: A brief communication. International Journal of Clinical and Experimental Hypnosis, 39, 193-197.

Previous research has yielded equivocal evidence of hypnotic memory enhancement. This study assessed effects of expectancy and hypnotizability on recall for videotaped material under waking and hypnotic conditions. Ss (n = 138) were informed of hypnotic induction either before (expectancy condition) or after (no expectancy condition) watching a videotaped enactment of a crime and completing an initial waking recall test (R1). Both groups then underwent hypnotic induction, and completed the test again (R2). Ss' raw recall scores were significantly greater under hypnotic than waking conditions, but this hypermnnesia was not evident when scores were corrected for mere increase in rate of responding. Ss expecting later hypnosis scored significantly higher than Ss with no such expectations, but again, this different was not evident in corrected scores. Hypnotizability of Ss was, however, related to corrected recall, with high hypnotizability Ss displaying the greatest increase in rate of responding from R1 to R2. No evidence for the hypothesized "suppression effect" underlying hypnotic hypermnnesia was found.

**NOTES**

1:

NOTES: Thus Ss tended to answer more questions on R2 but most of this increase was error. Moreover, high hypnotizability Ss displayed this pattern to a far greater extent than other Ss, indicating that they were more likely than others to increase the no. of responses made between tests.

The finding of an interaction effect between hypnotizability and corrected recall suggests that hypnosis does play some role in the hypnotic hypermnnesia described in the literature, possibly refuting the findings of several recent studies (e.g., Nogrady, McConkey, & Perry, 1986; Register & Kihlstrom, 1987). High hypnotizability Ss increased the number of responses made from R1 to R2 to a greater extent than other Ss. The lack of an interaction between hypnotizability and expectancy, however, fails to support the suggestion by Salzberg and DePiano (1980) that people of differing hypnotizabilities differ also in their susceptibility to demand biases.

As both Klazky and Erdelyi (1985) and Whitehouse et al. (1988) have noted, however, the use of hypnosis with witnesses of crimes may be useful if it can stimulate individuals to share uncertain recollections, perhaps providing otherwise unconsidered clues. The present data suggest that such guessing may also be increased by mere expectation of hypnosis. The value of forensic hypnosis may, therefore, be in part one similar to placebo: the simple notion of hypnosis placed in witnesses' minds may be sufficient to inspire useful leads.

Smith, William H. (1991). Antecedents of posttraumatic stress disorder: Wasn't being raped enough? A brief communication. International Journal of Clinical and Experimental Hypnosis, 39, 129-133.

Many rape victims, like those traumatized by war, accidents, and natural disasters, are able to recover from their ordeal with supportive, crisis-oriented treatment. For others, however, symptoms may persist and require more intensive treatment.

Hypnosis allows a modulated re-experiencing and abreaction of the traumatic event that can help to provide the victim with a relieving sense of mastery, and it fosters a receptive context for reassurance and interpretation regarding the irrational or exaggerated thoughts and feelings involved. 2 case examples are presented in which earlier conflicts appeared to play a role in perpetuating the patients' symptoms. Detecting and addressing these antecedents resulted in complete alleviation of long-standing problems through relatively brief treatment using hypnosis.

Spanos, Nicholas P.; DuBreuil, Susan C.; Gwynn, Maxwell I. (1991). The effects of expert testimony concerning rape on the verdicts and beliefs of mock jurors. Imagination, Cognition and Personality, 11, 37-51.

Mock jurors heard one of 4 versions of a 'date rape' case and deliberated in small groups, to a verdict. Exposure to the direct examination of an expert who testified about rape myths undermined belief in the defendant's testimony that sex with the complainant had been consensual, and increased the frequency of guilty votes. However, exposure to the expert's cross-examination reversed the effects of the direct examination on the frequency of guilty votes. Women jurors disbelieved the defendant and voted him guilty to a greater extent than male jurors, while in both sexes profeminist attitudes correlated with disbelief in the defendant's testimony but failed to correlate significantly with final verdicts. Implications are discussed.

Wagstaff, Graham F. (1991). Hypnosis and harmful and antisocial acts: Some theoretical and empirical issues. Contemporary Hypnosis, 8, 141-146.

## NOTES

1:

The author analyses paper in same issue of this journal: Gibson, H. B. (1991). Can hypnosis compel people to commit harmful, immoral and criminal acts?: A review of the literature. He presents a critique from the point of view of "state" theorists, and concludes: "Where does this leave us? The area seems to be a potential minefield for any unsuspecting dissociationist. Personally, I think that both parsimony, and what empirical evidence there is, point to a non-state approach to this issue. However, despite the inevitable uncertainties and differences of opinion, there is perhaps a very obvious and important lesson to be gained by all from studies in this area. It has been fashionable to write off experimental studies on this topic on the grounds that subjects in these studies generally perceive the situation as 'safe'; this is not only the case in hypnosis research but also in general social-psychological work on obedience (see, for example, Orne & Holland, 1968; Mixon, 1974). Some have questioned this assumption that subjects only obey the experimenter when they perceive the situation to be safe (see Barber, 1969; Milgram, 1974), but what often goes unnoticed is the significance of this assumption in itself. If labeling a situation as 'hypnosis', or even just an 'experiment', can make subjects think that any apparently harmful act they are requested to perform is safe, think of the implications; here, in itself, is a potentially powerful, even lethal, mechanism by which people in hypnotic contexts may be induced to perform harmful and antisocial acts. They perform them because, given the context, they

think it is safe to do so! In the study of Orne and Evans the venomous snake the subjects were instructed to grasp was placed behind an 'invisible' glass screen, and the acid they were instructed to throw at the experimenter had been, allegedly unknown to them, replaced by a harmless liquid; one wonders, however, if writers would be so dismissive if the liquid that Orne and Evans' subjects threw at the experimenter had actually burned him, or the snake that they picked up had actually killed them" (pp. 144-45).

Coe, William C. (1990). Are the Conclusions Valid? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 237-239.

NOTES

1:

The authors confounded variables, e.g. hypnotic susceptibility and monetary incentive (in Study IV), and Study IV was different from the other 3 studies, so that any differences/similarities between these studies can't be attributed to susceptibility level, degree of incentive, or interaction between them.

A simulator design would clarify why 50% of Ss in Study IV did not resist and lost \$100; also, postexperimental interviews focusing on Ss' reasons for resisting or not resisting would be helpful. Did nonresisters actually believe that they would receive \$100 for resisting?

The Subject population was not homogeneous in occupation, and students are financially poorer than others--which would affect incentive strength. Were those who resisted the ones who could use the money the most?

Small sample sizes obviating statistical tests is a problem. Coe nevertheless evaluates 4 variables in terms of the 'power' of their effects on hypnosis: 1. Susceptibility level. Studies I, II, and III all show correlations between hypnotizability and compliance with resistance, suggesting that high hypnotizables are not as susceptible to resistance manipulation; however across studies, highs in one study seem to comply at the same rate as lows in another study, and as many as 50% of high hypnotizables in the strong incentive (\$100) study were able to resist suggestions. 2. View of the Hypnotist. Coe states that one can't evaluate the question with the data given. One would need an experimental condition that would also create a negative view of the hypnotist, as all samples tended to view the hypnotist positively. 3. View of Resistance Instructor. Again, one would need a research design that separates the effects of hypnotic susceptibility from effects of Ss' views of the resistance instructor. "Nevertheless, Study IV suggests that for high susceptibles the view of the resistance instructor has little effect. Three resisters viewed him as positive, whereas the other three viewed him as negative; further, nearly all of the nonresisters viewed him as neutral" (p. 238). 4. Degree of Incentive. This too was confounded with susceptibility level, as "the higher value was only offered to the very high susceptibles in study IV. Half of them took it, half did not" (pp. 238-239). Coe also remarks that "the expectational effects on subjects of being in an experiment have not been addressed adequately. It is possible that the experimental paradigm as currently presented is incapable of providing an unambiguous answer

to the question of coercion. In naturalistic settings subjects may react quite differently than they do when they know they are participating in an experiment" (p. 239).

Gwynn, Maxwell I.; Quigley, Celia; Perlini, Arthur; Glatt, Richard; Spanos, Nicholas P. (1990, August). Eyewitness testimony: Effects of hypnotic interrogation and witness preparation. [Paper] Presented at the annual meeting of the American Psychological Association, Boston.

## NOTES

1:

There is notable absence of empirical research on the effects of witness preparation on subsequent testimony. The present study investigates the separate and combined effects of hypnotic recall procedures and witness preparation on subjects' confidence in, and maintenance during cross-examination, of mug-shot identifications.

Session 1: Subjects viewed a 65 second videotape of a mock crime involving a shooting. The offender in this video was a male approximately 40-50 years old, whose face was partially obscured by the brim of a baseball cap.

Subjects were then taken individually to another room, where a second experimenter presented them with a series of five photographic mug shots. Half of the series contained the mug shot; the other did not. Subjects indicate if any portrayed the offender and then to rate their confidence in their identification.

Subjects for Session 2 were randomly assigned to one of two conditions:

Hypnotic condition ... followed by "reliving" instructions modeled after Reiser's procedures used in training police detectives.

Nonhypnotic condition ... Each subject was then presented with the mug shot lineup and rated their confidence as in Session 1 with the same second experimenter.

Subjects who in Session 2 identified any mug shot as portraying the offender returned about one week after for a mock courtroom appearance. Subjects were randomly assigned to either a "prepared" condition, or a "nonprepared" condition, with the restriction of equal numbers of offender-present vs. offender-absent lineups and hypnotic vs. nonhypnotic subjects in each condition ... The subject-witness was questioned by the third same experimenter under direct examination and then cross-examined by a fourth experimenter in the role of defense attorney.

Subjects in the prepared condition were given pointers concerning their courtroom appearance. These pointers included counseling to answer all of the questions fully, to speak in complete sentences, and to present themselves confidently.

The videotapes of the subjects' testimonies were then shown to independent blind raters who rated the degree of confidence displayed by the subject-witness at two points, first after direct examination, and again after cross-examination.

To summarize the results: 1) As in a number of previous studies, eyewitness confidence was unrelated to mug shot identification accuracy. 2) The use of hypnotic techniques as practiced by many police investigators did not lead to an increase in the frequency or accuracy with which subjects identified a mug shot as portraying a previously viewed offender. 3) Again consistent with previous research, the use of hypnosis did lead to an increase in eyewitness confidence, without a corresponding

increase in accuracy, and this confidence increase was correlated with pretested levels of hypnotic susceptibility. 4) Contrary to the speculation of researchers such as Orne, Laurence & Perry, hypnotic procedures did not lead to the creation of unshakable witnesses who were impervious to cross-examination. And, 5) The usual practice of pre-trial preparation of witnesses did lead to a resistance of witnesses to be broken down under cross-examination.

In conclusion, the key factor found to affect eyewitness confidence and mug shot identification was not the use of hypnotic memory enhancement techniques, but rather the usual practice of pre-trial witness preparation.

Halleck, Seymore L. (1990). Dissociative phenomena and the question of responsibility. International Journal of Clinical and Experimental Hypnosis, 38, 298-314.

There are many controversies regarding the prevalence, causation, possible iatrogenicity, and treatment of multiple personality disorder. Those who view the disorder as much more prevalent than has previously been suspected believe it is caused by experiences of severe child abuse and have used rather unorthodox techniques to help the patient relate the experience of abuse to current problems of dissociation. Other clinicians believe the disorder is overdiagnosed and that it may be created or made worse by therapists who unwittingly reinforce symptoms of dissociation. Many of the controversies about these issues can be clarified by considering the manner in which clinicians attribute responsibility for undesirable conduct associated with the disorder. In dealing with multiple personality patients, clinicians regularly must decide whether their therapeutic approach will emphasize the patient's responsibility for undesirable conduct or will minimize it. Practical and theoretical arguments can be made for both approaches. There are important consequences to patients using either approach, and particularly harmful consequences with inconsistent approaches. Clinical experience and wisdom dictate that until we have more objective data about the results of various forms of treatment, the preferred method of treatment of multiple personality patients should continue to focus upon maximizing their responsibility for any type of undesirable conduct.

Hoencamp, Erik (1990). Sexual abuse and the abuse of hypnosis in the therapeutic relationship. International Journal of Clinical and Experimental Hypnosis, 38, 283-297.

In the Netherlands, individuals charged with rape may be prosecuted only in instances in which the suspect could have known that the victim was unconscious or in a state of powerlessness. Hypnosis might be looked upon as a method by which an unscrupulous person could sustain such a state of powerlessness in a victim. As an expert witness, the present author participated in a court case against a lay hypnotist who was accused of abusing 9 women. The methods and strategy used by the lay hypnotist are presented as well as are the diverse reactions of the women involved in the case. Feelings of nonvolition appear to have been a relevant factor in

the coercion, especially in women who demonstrated hypnotic phenomena such as arm levitation, catalepsy, etc. The basis for sexual coercion was established only after the interpersonal relationship had been redefined as a therapeutic relationship. Introduction within the pseudotherapeutic relationship of a sexual rationale for the presented complaints helped to provide a framework for actual sexual acts to occur. With certain individual patients, the introduction of hypnosis enhanced the subjective experience of nonvolition and with it the vulnerability for abuse. It may be hypothesized that patients with a tendency for external attribution and high hypnotizability are specifically at risk for this kind of abuse when hypnosis is used in the context of a therapeutic relationship.

Perry, Campbell (1990). Coercion by hypnosis? Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 242-243.

#### NOTES

1:

A postexperimental inquiry (following Orne, 1959) might have informed the reader of the degree to which operationalization of the coercion in terms of disobedience was successful. Without this additional step, it is difficult to determine whether what was found in the laboratory by these investigators applies to what has been reported in clinical and field settings for almost 200 years" (p. 242).

"In particular, elsewhere, the authors equate coercion with involuntariness and appear to view involition as a euphemism for coercion. While I agree that perceiving involition of one's own behavior may contribute to the commission of unconsenting acts in hypnosis, the two are easily distinguished at the conceptual level. Laboratory subjects ordinarily report much behavior in hypnosis that is experienced involuntarily, without the issue of it being coerced ever being broached" (p. 242).

Author describes cases in which patients claimed they participated in sex with hypnotist against their wills because they were hypnotized. "What may be happening in both of these reports is that the hypnotized subjects found themselves responding involuntarily; from this, they appear to have adduced that they could not resist the hypnotist's suggestion. That is, they were coerced not by hypnosis but by their belief, which was a direct function of the experience of involuntariness, that they could not resist" (p. 243). "In short, if a hypnotized person equates involuntary behavior with powerlessness, "coercion" may occur in this limited sense. Conceptually, this appears to be a far cry from equating involition with coercion" (p. 243).

Spiegel, David (1990). Theoretical and empirical resistance to hypnotic compliance. Invited discussion of Levitt, Baker, and Fish: Some conditions of compliance and resistance among hypnotic subjects. American Journal of Clinical Hypnosis, 32 (4), 243-245.

#### NOTES

1:

Does hypnosis bypass the will, facilitate coercion? The hardest thing for trauma victims to do is to admit helplessness. Furthermore, it is interesting that these same

dissociative phenomena seem to be elicited by traumatic experience, the stark imposition of involuntariness (Stutman & Bliss, 1985; Spiegel, Hunt, & Dondershine, 1988). What, then, are we to make of experiments that purport to show that hypnotizable and hypnotized individuals comply with hypnotic instructions irrationally? At some level this challenges our comfortable belief that we always act in our enlightened self-interest, unaffected by unwanted influence. If that can happen even once, our pride of self-ownership is reduced.

Taken as a whole, the studies show that high hypnotizables comply with hypnotic instructions, even in the face of resistance instructions, whereas low hypnotizables are less likely to, especially when conditions foster a relatively less negative view of the resistance instructor. As the authors note, subjects always viewed the hypnotist more positively than the resistance instructor, which in itself suggests the nonrational influence intrinsic to hypnosis. Free will is not abrogated, it is simply not exercised. The Ss are fundamentally choosing whether or not to comply. Half of the highs in Study IV resisted the hypnotic instruction. However, hypnotized individuals tend to narrow the focus of attention, thereby reducing their ability to consider alternatives such as the resistance instruction.

William James (1890) believed that all ideas were invitations to action. Why, then, do we not act on every idea we have, he pondered on a snowy morning while lying in bed. He observed that he would try to get himself to arise by picturing himself doing so. "Why, then, am I still in bed?" He realized that he was editing the primary idea, reflecting on how cold it was, how long it would take to light a fire, and how much time he had until his classes. In a state characterized by a narrowing of the focus of attention, we are less likely to edit the primary idea, and therefore more likely to act. In the experiments presented, the resistance instructor attempts to act as an external editor on the primary hypnotic instruction. Those capable of focusing attention sufficiently disattend to the editing and comply. These studies show that, thankfully, hypnosis is less than automatic submission to instruction but, interestingly, more than simple conscious response to new information.

1989

Gibson, H. B. (1989). The Home Office attitude to forensic hypnosis: A victory for scientific evidence or for medical conservatism?. [Comment/Discussion].

NOTES

1:  
The author is in agreement with the Home Office Circular (August 1988) that advises against the use of hypnosis in police investigations. However he disagrees with the Circular statement that "'There may be danger that, in some cases, the experience of hypnosis may cause longer term harm to the mental health of the subject...'" This is certainly not true if the proceedings are carried out by a competent health professional" (p. 26).

Lindsay, D. S.; Johnson, M. K. (1989). The eyewitness suggestibility effect and memory for source. Memory and Cognition, 17, 349-358.

Examined the possibility that eyewitness suggestibility reflects failures of the processes by which people normally discriminate between memories derived from

different sources. Misled and control subjects were tested either with a yes/no recognition test or with a "source-monitoring" test designed to orient Ss to attend to information about the sources of their memories. The results demonstrate that suggestibility effects obtained with a recognition test can be eliminated by orienting Ss toward thinking about the sources of their memories while taking the test. Findings indicate that although misled Ss are capable of identifying the source of their memories of misleading suggestions, they nonetheless sometimes misidentify them as memories derived from the original event. The extent to which such errors reflect genuine memory confusions (produced, for example by lay judgment criteria) or conscious misattributions (perhaps due to demand characteristics) remains to be specified.

1989

Pinizzotto, Anthony J. (1989). Memory and hypnosis: Implications for the use of forensic hypnosis. Professional Psychology: Research and Practice, 20 (5), 322-328.

NOTES

1:

The author reviews arguments regarding hypnosis in forensic investigations, offers procedures of a nonhypnotic nature to enhance memory recall, and suggests guidelines for hypnosis in criminal cases. The effects of hypnosis on memory, as well as the concomitant dangers regarding those effects, are discussed.

Sanders, Glenn S.; Gansler, David A.; Reisman, Stephen Jr. (1989). The effects of hypnosis on eyewitness testimony and reactions to cross-examination. American Journal of Forensic Psychology, 7, 33-60.

Investigative hypnosis has been a widely used and valuable police technique, but recent court rulings have expressed reservations about the admissibility of hypnotically related testimony. The proposed research is the first directly relevant evaluation of the most serious of the courts' reservations: the allegation that hypnosis produces excessive and unshakable levels of confidence in witnesses, thereby effectively denying opposing counsel the right of cross-examination. Volunteers from the community witnessed a simulated crime, and were then interviewed by a professional police investigator to obtain evidence and testimony. Two-thirds of these witnesses were randomly assigned to have their memory refreshed by one of two hypnotic induction techniques. All witnesses were subsequently examined and cross-examined by a pair of practicing criminal lawyers, and their videotaped testimony was evaluated by another volunteer sample of community residents serving as jurors. On both objective and subjective measures, hypnotized witnesses provided more complete and internally consistent testimony. However, neither form of hypnotic induction led to greater witness confidence, credibility, or resistance to cross-examination. Our results generally replicate previous findings in a more realistic investigative simulation. The discussion considers artifactual explanations of the confidence null effects, and explores theoretical and policy implications of the data.

## NOTES

People responding to a newspaper ad asking for volunteers who would be paid for participating in psychology research at the State University were later asked to undergo hypnosis. Of 45 who responded to the ad, six (13%) declined to have hypnosis. This rate of refusal has relevance to research on clinical hypnosis that requires paid volunteer participants.

Schuyler, Bradley A.; Coe, William C. (1989). More on volitional experiences and breaching posthypnotic amnesia. International Journal of Clinical and Experimental Hypnosis, 37, 320-331.

Highly responsive hypnotic subjects, who were classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia, were compared with each other on four physiological measures (heart rate, electrodermal response, respiration rate, muscle tension) during posthypnotic recall. Two contextual conditions were employed: One was meant to create pressure to breach posthypnotic amnesia (lie detector instructions); the other, a relax condition, served as a control. The recall data confirmed earlier findings of Howard and Coe and showed that voluntary subjects under the lie detector condition recalled more than the other three samples that did not differ from each other. However, using another measure of voluntariness showed that both voluntary and involuntary subjects breached under lie detector conditions. Electrodermal response supported the subjects' reports of control in this case. Physiological measures were otherwise insignificant. The results are discussed as they relate to (a) studies attempting to breach posthypnotic amnesia, (b) the voluntary/involuntary classification of subjects, and (c) theories of hypnosis.

## NOTES

The authors suggest that subjects observe themselves not remembering (i.e. not reporting memories) and conclude that they therefore could not remember. Such subjects, they say, are deceiving themselves in so far as they could remember if they were to direct their attention to salient cues.

Watkins, John G. (1989). Hypnotic hypermnesia and forensic hypnosis: A cross-examination. American Journal of Clinical Hypnosis, 32, 71-83.

Early enthusiasm for the hypnotic enhancement of memories of witnesses has faded since publication of a number of experimental studies which cast doubt on its efficacy and reported also that pseudo-memories could be confabulated under hypnosis. This has caused some investigators to assert that hypnosis should never be used to enhance the memories of eyewitnesses testifying in court. Many of these studies are themselves subject to errors in sampling, biases, and ignoring of the 'hypnotic relationship' effect. It is premature to recommend complete elimination of hypnotic hypermnesia in court situations, and several recent Supreme Court decisions seem to agree. Results of some previously unpublished studies are

reported, plus suggestions for improving research approaches to studies of hypnotic memory enhancement.

1988

Coons, P. M. (1988). Misuse of forensic hypnosis: A hypnotically elicited false confession with the apparent creation of a multiple personality. International Journal of Clinical and Experimental Hypnosis, 36 (1), 1-11.

A case is presented in which there was flagrant misuse of forensic hypnosis. The patient, a woman in her early 30s, was accused of shooting her 2 children. During a hypnotic interview, the police hypnotist used an extremely suggestive interrogative technique, and the suspect produced an apparent secondary personality who confessed to the shootings. Subsequently the prosecutor tried to enter the "hypnotic confession" as evidence against the defendant. The evidence was dis-allowed because of the manner in which it was obtained and because of the lack of verification from other sources. The literature regarding the use of forensic hypnosis is reviewed as is the literature regarding multiple personality and the experimental production of multiple personality-like phenomena.

Gudjonsson, Gisli (1988). Interrogative suggestibility: Its relationship with assertiveness, social-evaluative anxiety, state anxiety and method of coping. British Journal of Clinical Psychology, 27 (2), 159-166.

Investigated in 30 adults some of the theoretical components related to individual differences thought by the present author and R. Clark (1986) to mediate interrogative suggestibility as measured by a scale developed by the present author (1984). The variables studied were assertiveness, social-evaluative anxiety, state anxiety, and the coping methods generated and implemented during interrogation. Low assertiveness and high evaluative anxiety correlated moderately with suggestibility, but no significant correlations emerged for social avoidance and distress. State anxiety correlated significantly with suggestibility, particularly after negative feedback had been administered. Coping methods (active-cognitive/behavioral vs. avoidance) significantly predicted suggestibility scores. The findings give strong support to the present author's theoretical model.

McConkey, Kevin M.; Kinoshita, S. (1988). The influence of hypnosis on memory after one day and one week. Journal of Abnormal Psychology, 97, 48-53.

#### NOTES

1:

High- and low-hypnotizable subjects were given repeated tests in either hypnotic or awake conditions to recall pictures they had seen either one day or one week earlier. Hypnotic procedures were associated with increased memory performance by subjects; specifically, hypnotic subjects reported more correct material. Also, hypnotic procedures were associated with increased confidence in memory reports; in particular, high- hypnotizable Ss tested in the hypnotic condition displayed the most confident errors. The pattern of findings for subjects tested after one day

differed from that of subjects tested after one week, and this difference was related to the subjects' hypnotizability. Findings are discussed in terms of memory performance and the confidence associated with that performance.

Perry, Campbell (1988, November). An interactionist position on hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Asheville, NC.

Success in pain reduction is much greater in clinic (Crasilneck; Melzack et al; Cedercrentz - skull injury) than in lab (Hilgard's studies of highs and lows).

Central to the disagreement about special state/socio-behavioral theories is the question, "What are the origins of beliefs about hypnosis?" The beliefs can be modified by experience, which is mediated by individual differences.

Author suggests trying to predict which individual will respond to which hypnosis item. Since there are at least 3 factors in hypnotizability scales, one needs a number of variables to do this type of research. Nadon et al (Journal of Personality and Social Psychology 1987) predicted hypnotizability with PICS (an imagery control test) and Absorption scale plus Evans' Sleep Questionnaire subscale plus Belief in [paranormal events] subscale: predictions were 63% correct. PICS (as compared with other imagery tests) reflects imagery as a preferred mode of thinking. Now, can we predict who will make highly confident errors when asked to remember details of a crime? Who is more vulnerable when told a pseudomemory is veridical? In a test of this question, mimicking a field setting, the authors weren't able to predict the people who would make errors, who functioned at the same level following neutral instructions ("We don't know what we'll find") and Reiser-type instructions ("You can use a zoom lens to see the scene up close") in hypnosis. Also, the effect of an increase in confident errors was greater for highs than for lows. People with high hypnotizability and low PICS made the most errors. N.B. Since lows also increased in errors, one should be cautious in any case.

Creation of pseudomemory research: Using SHSS:C and PICS one can predict 81% of those who accepted and reported the implanted pseudomemory.

Sheehan, Peter W. (1988). Memory distortion in hypnosis. International Journal of Clinical and Experimental Hypnosis, 36, 296-311.

This paper presents data from a programmatic series of studies that varied the range of conditions affecting potential increase of recall, memory distortions, and distortions of confidence during and following hypnosis. All the studies used a paradigm that exposed Ss to misleading information some time before memory was tested and applied procedures in the hypnotic setting to analyze memory performance in both recognition and free recall. Results from the program failed to demonstrate any increment in accurate memory due to hypnosis, and the accuracy of memory reports in hypnosis was at times significantly reduced. Further, hypnotic recall was distinctively distorted when false information was introduced after, rather than before hypnosis. Results were discussed in relation to the role hypnotic as opposed to contextual variables may play in explaining Ss' memory test

performances, and some legal implications are drawn from the data.

#### NOTES

This article investigates 3 major questions: 1. whether hypnosis makes recollections more susceptible to error 2. whether hypnosis reliably enhances recall 3. whether hypnosis alters certitude of what is remembered, independent of accuracy

The author reviews earlier literature, noting that different methodologies lead to different, sometimes conflicting, results. He uses Loftus' methods, which "allows for systematic exposure to specific information that is erroneous and examines the after-effects of that exposure on subsequent attempts to remember" (p. 298). The Ss are tested initially for memory of an incident, with subtle introduction of false information; then retested in way that probes for correct recall/recognition by presenting the incorrect information as an alternative for response. (Loftus has presented the position that misinformation is incorporated into waking memory, and this examines whether the addition of hypnosis--especially with Ss who are highly hypnotizable--increases the effects.)

Sheehan reports six studies that varied type of memory test (free recall, recognition); type of instruction (hypnotic, waking, simulating); and level of hypnotizability (high, low). Each study dealt with the same incident that depicted an apparent robbery and three false pieces of information about the incident were presented to Ss in the misleading condition. The studies have been published elsewhere as: --Study 1 Sheehan & Tilden, 1983: High and low hypnotizable Ss tested under hypnosis & waking conditions. False information is given before hypnosis. --Study 2 Sheehan & Tilden, 1984: Real & simulating Ss presented with false information prior to hypnotic induction. --Study 3 Sheehan & Tilden, 1986: High hypnotizable and motivated low hypnotizable Ss presented with false information prior to hypnosis. --Study 4 Sheehan, Grigg, & McCann, 1984: Real & simulating Ss presented with false information after hypnotic induction. --Study 5 Sheehan & Grigg, 1985: High hypnotizable and motivated low hypnotizable Ss presented with false information after hypnotic induction --Study 6 (this article reports): High and low hypnotizable Ss tested under hypnosis and waking conditions. False information is given after hypnosis. Scene shown is described by hypnotist in a congruent (robbery) or incongruent (friendly encounter) way

Ss tended to give incorrect responses along the lines of the false cues, but this effect was not greater when hypnosis occurred after the leading information had been given. In two experiments (#4 and #5) the effect was associated with hypnosis. Thus, when Ss are hypnotized they are more likely to be misled by false information. Study 6 did not demonstrate the incorporation of false information into memory, possibly because there was a longer delay between presentation of the information and the memory test itself. This weakening effect of delay has also been shown by Loftus et al. (1978). High hypnotizable Ss in the hypnosis condition showed more distortion than lows not hypnotized in 4 of the 6 studies evidencing distortion.

The authors note that "confidence may be maintained in the hypnosis setting despite the presence of substantial inaccuracy. ... Simulating Ss performed just as confidently as real Ss ... raising the question that context may determine the results for confidence among real Ss. ... Where expectations were out of phase with stimulus

events [Study 6], confidence effects involving hypnosis did not emerge" (pp. 304-305).

"Overall, data indicated that hypnotic instruction may be more reliably associated with confidence than level of hypnotizability, though both variables are associated with confidence at one time or another. What is not clear, however, is whether hypnosis itself is at issue or the context of which hypnosis forms a part. That context, of course, may include the belief of Ss brought to the formal test situation that hypnosis increases memory. ... Simulating Ss reported higher confidence levels than real Ss when results were analyzed just for the hypnotic setting ..., for recognition testing in Study 4; simulating Ss were not distinct from hypnotic Ss under waking conditions of testing. It seems that the hypnotic setting itself, or expectations about it, obviously communicated that an expression of strong conviction was required. Collectively, results demonstrated that simulating Ss believed that a hypnotized person would be more confident, and they therefore reported greater confidence levels during their act of pretense" (pp. 305-306).

In their discussion, the authors note that there was more evidence for mis-reporting than for accuracy, but that hypnosis did not produce more error unless false information was given during hypnosis. High hypnotizable Ss produce many errors with a high level of confidence, but since simulators feign hypnosis by reporting high levels of confidence, it may be expectations about the ability of hypnosis to improve recall that influences these results. "Such expectations may influence hypnotic recall for all Ss, but this would not explain differential levels of confidence between high and low hypnotizable Ss when both are tested in exactly the same way-that is, when task demands are held constant" (p. 306).

"One major implication of the data is that future research should move away from focusing only on the truth validation or distorting influence of hypnosis to emphasize the role contextual features may play in accentuating memory distortion effects" (p. 307). "The one clear finding across all of the studies in the program was that hypnosis does not increase memory, and the findings provide no basis to justify the forensic application of hypnosis given that the point of forensic application is that hypnosis will help memory. Data also indicate that when leading questions are asked under hypnosis, they are likely to be more effective in distorting memory reports than when such questions are asked without hypnosis. Low resistance to misinformation was present among both hypnotic and waking Ss, but separated the two groups when the false information was given in hypnosis.

"One of the major inferences ... is that the most substantial risk to using hypnosis may lie not only with the tendency to mis-report itself, but with the tendency for hypnotic Ss to be convinced in their reporting no matter what the accuracy of their statements. This effect was pervasive enough that it may offer sufficient grounds for restricting how hypnosis should be used forensically" (p. 308).

Whitehouse, Wayne G.; Dinges, David F.; Orne, Emily C.; Orne, Martin T. (1988). Hypnotic hypermnesia: Enhanced memory accessibility or report bias?. Journal of Abnormal Psychology, 289-295.

Laboratory studies of hypnotic hypermnesia have yielded inconsistent evidence of memory enhancement, and the process responsible for the occasional positive findings have eluded identification. The present experiment assessed delay recall for filmed material under conditions in which subjects were required to answer all questions, by guessing if necessary. They also rated confidence in the accuracy of each response. After an initial wake-baseline forced-recall test, subjects were randomly assigned to hypnosis or waking conditions for a second forced-recall test. Both groups of subjects recalled additional correct details on the second test, but the magnitude of this hypermnesia was no greater for subjects exposed to the hypnosis treatment. Hypnotized subjects did, however, exhibit a significantly greater increase in confidence for responses designated as "guesses" on the prior waking test--a finding consistent with the view that hypnosis engenders a shift in the subjective criterion for what constitutes a "memory". Implications of these findings for the use of hypnosis in forensic situations are discussed.

Geiselman, R. Edward; Machlovitz, Helen (1987). Hypnosis memory recall: Implications for forensic use. American Journal of Forensic Psychology, 1, 37-47.

The Council finds that recollections obtained during hypnosis can involve confabulations and pseudomemories and not only fail to be more accurate, but actually appear to be less reliable than nonhypnotic recall. The use of hypnosis with witnesses and victims may have serious consequences for the legal process when testimony is based on material that is elicited from a witness who has been hypnotized for the purposes of refreshing recollection. NOTES 1: NOTES: The Council finds that recollections obtained during hypnosis can involve confabulations and pseudomemories and not only fail to be more accurate, but actually appear to be less reliable than nonhypnotic recall. The use of hypnosis with witnesses and victims may have serious consequences for the legal process when testimony is based on material that is elicited from a witness who has been hypnotized for the purposes of refreshing recollection.

APA Council of Representatives (1986, December). Resolution on hypnosis. Newsletter of Division 30, Psychological Hypnosis, of the American Psychological Association, 1.

NOTES

1:

The Council of Representatives adopted a motion that opposes the teaching of hypnosis to persons who are not fully trained in a health delivery profession. The motion presented by Dr. Gene Levitt, Division 30 representative to Council of Representatives, was passed by voice vote on August 24, 1986. It read as follows:

"Be it resolved that the American Psychological Association, in the interest of the public, opposes applications of hypnosis by persons who are not fully trained members or advanced students of a health delivery profession and who lack specific, in-depth training in hypnosis. Therefore, be it also resolved that APA opposes the teaching of hypnotic induction techniques or applications of hypnosis that involve

treatment or assessment with patients or clients to persons who are not fully trained members or advanced students of a health delivery profession. Be it resolved further that upon passage of this resolution, its text shall be conveyed to the APA Ethics Committee to consider its incorporation in the APA Code of Ethics. We note that the resolution is consistent with the preamble of Principle 1 of the code as well as the Standards for Providers of Psychological Services (Principles and Implications of Standards, 3)"

Dr. Levitt proposed that the motion be named the "Erik L. Wright Memorial Resolution" in honor of the Division 30 Council representative who introduced the first version of it in 1980.

**Laurence, Jean-Roch; Nadon, Robert; Nogrady, Heather; Perry, Campbell (1986). Duality, dissociation, and memory creation in highly hypnotizability subjects. International Journal of Clinical and Experimental Hypnosis, 34, 295-310.**

The present paper reports an initial attempt to create a pseudomemory in a group of highly hypnotizable individuals. It was found that for approximately 50% of Ss tested, recall of a specific event was modified when Ss integrated hypnotically suggested material which then posthypnotically was believed to be veridical. This modification in a previously reported memory was linked to a particular cognitive style found in high hypnotizable Ss, namely dual cognitive functioning. Ss reporting duality in hypnotic age regression, and, to a lesser extent, the hidden observer effect, were found to be the most prone to accept a suggested memory as real. These findings suggest the need to emphasize the importance of a cognitive-phenomenological approach to hypnosis and hypnotizability.

**Schacter, Daniel L. (1986). Amnesia and crime: How much do we really know?. American Psychologist, 41, 286-295.**

Claims of amnesia occur frequently after the commission of violent crimes and can have a significant bearing on the outcome of criminal trials. This article considers the relation between amnesia and crime within the broader context of research on memory and amnesia and provides a critical evaluation of current knowledge concerning the issue. Particular attention is paid to the problem of distinguishing between genuine and simulated claims of amnesia. It is suggested that reliable data concerning the nature of amnesic episodes that occur after the commission of a crime are sparse, and that there is as yet little evidence that genuine and simulated amnesia can be distinguished in criminal cases. The results of several laboratory studies are summarized that indicate that feeling-of-knowing ratings distinguished between genuine and simulated amnesia under conditions in which psychologists and psychiatrists did not.

**Sheehan, Peter W.; Tilden, Jan (1986). The consistency of occurrences of memory distortion following hypnotic induction. International Journal of Clinical and Experimental Hypnosis, 34, 122-137.**

The present study examined a range of circumstances for their effects on the vulnerability of hypnotic Ss to memory distortion. 26 high and 26 low hypnotizable Ss were tested individually in a design in which Ss received information that was either misleading or not misleading about a series of events depicting an apparent robbery. The information was presented prior to Ss being given hypnotic instructions, and low hypnotizability Ss were especially motivated for positive response in the session. Memory for the robbery was studied across a range of measures that included forced choice recognition, free recall, and response to leading questions. Results demonstrated predictably variable effects. The 2 groups performed appreciably differently in free recall, for example, while in recognition testing, data indicated that high and low hypnotizable Ss both incorporated misleading information into their memories to the same degree. Some implications of the data for the forensic context are discussed. NOTES 1: NOTES: 56 Ss were prescreened with Harvard Group Scale of Hypnotic Susceptibility, Form A, defining highs = 9-12, lows = 0-3. Used Loftus materials for testing memory (wallet snatching sequence, on a series of slides). Errors were classified as errors of fact, of inference, or conjectures. Highs had more intrusions that were errors of fact than lows did ( $p < .05$ ), confirming the earlier results published by Sheehan & Tilden, 1984. There was no significant association between hypnotizability level and intrusion of central detail (description of robber and victim), but 57% of highs and only 18% of lows intruded peripheral objects incorrectly into their own narrative reports (i.e. descriptions given of the surroundings),  $p < .01$ .

There were trends for high hypnotizable Ss to recall more objects correctly than low hypnotizable Ss during narrative reporting ( $p < .06$ ) and to recall more central objects ( $p < .06$ ), but not more peripheral objects. There may have been a loosening of criteria for memory among high hypnotizables, because they appeared to produce both greater accuracy and inaccuracy in recall of certain types of detail.

During the recognition testing, high hypnotizables exhibited significantly greater confidence in their responses than low hypnotizable Ss, but there was no group difference for accuracy. "Results for both tests of integration then (recognition and free recall) confirmed the prediction that hypnotic Ss incorporate false information into their memory, and the effect did not differentiate high from low hypnotizable Ss" (p. 131).

When a leading question implied that traffic lights were present in the scene, 34% responded in some way to that suggestion, and 20% said that they could see the lights in their minds eye; but 14% said that "although they could not see the lights, they nevertheless remembered they were there" (p. 132). Response to the leading question did not differ between high and low hypnotizable Ss.

In their discussion, the authors note that hypnosis did not enhance memory in this study. "Results overall suggest that hypnotic induction lowers the correspondence between confidence and accuracy. In the present study, hypnotic Ss were confident about their recall when the degree of accuracy of their reports suggested they should have been quite uncertain. Hypnotic instruction itself would appear, then, to

establish conditions that spuriously facilitate a high degree of confidence in the reports that Ss produce.

"A major point to be made about the present study is that both general distortion and confidence effects observed here cannot necessarily be attributed to hypnosis. There was no independent comparison condition, for example, to contrast results for hypnotic Ss with results for Ss receiving no induction procedures. Effects, then, could be attributed to the hypnotic context as much as to the effects of induction per se, and context rather than state may be responsible for the vulnerability of hypnotic Ss that has been observed. The influence of context is seen at least in the clear evidence for an interaction between situational factors and hypnotizability. In free recall, hypnotizable Ss were more prone to distortions than unhypnotizable Ss, while in recognition, hypnotizable and unhypnotizable Ss were equally prone. Mode of testing is, therefore, a major contextual variable that is related to the nature of the distortion and confidence effects that can be observed. Present data further indicate that the hypnotic context is associated with memory distortion even in Ss who have little capacity for being hypnotized, but who are instructed to believe that they can, in fact, experience much of what is being suggested" (pp. 133-134).

Forensic implications need to be tempered because of difference between laboratory and real life, but practitioners nevertheless should be cautious. "While it is not true that hypnotized persons, by virtue of their hypnotizability level, will always distort their reports more obviously than nonhypnotic Ss, so as to bring their recollections into line with what is implied or suspected, parameters do exist that clearly increase the risks of distortion that can occur after hypnotic instruction. This is evidenced, for example, by the distinctive distortion effects that have been demonstrated for high hypnotizable Ss when they are given induction instructions and later requested to tell their story in their own way. Overall, the present data imply that the law needs to closely evaluate the impact of the different settings in which hypnosis takes place and the different ways in which misleading information can be communicated to persons who are later asked to testify. The potential risks of hypnosis--as well as its utility--will depend critically on how that information has been conveyed, and the way in which Ss' memories are tested" (pp. 134- 135).

1985

Bliss, Eugene L.; Larson, Esther M. (1985). Sexual criminality and hypnotizability. Journal of Nervous and Mental Disease, 173, 522-526.

Investigated 33 17-35 yr old sexual offenders, 18 of whom had been convicted of rape, 9 of pedophilia, and 6 of incest. Ss completed a questionnaire containing a list of 15 factors that might have contributed to their crime, a self-report containing 305 items that are symptoms characteristic of 11 major psychiatric syndromes, and the Stanford Hypnotic Susceptibility Scale. Controls for the self-report were 48 individuals taken from a church group, nurses, technicians, and graduate students. Controls for the hypnotizability scale were cigarette smokers who smoked 1 1/2 pack/day and S data taken from the literature. Results show that two-thirds of the Ss had histories of spontaneous self-hypnotic experiences (dissociations); 7 of these were DSM-III multiples and 6 were probable multiples. This group had very high hypnotizability scores. The other one-third without histories of spontaneous self-

hypnosis had normal scores. It is concluded that spontaneous self-hypnosis contributed to the perpetration of the crimes in many of these cases, although other factors also directed the antisocial behaviors. (22 ref).

Coe, William C.; Yashinski, Edward (1985). Volitional experiences associated with breaching posthypnotic amnesia. Journal of Personality and Social Psychology, 48 (3), 716-722.

Highly responsive hypnotic subjects classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia were compared during posthypnotic recall. Subjects reported their voluntariness after the experiment. Two contextual conditions were employed (2 x 2 design): a lie detector condition meant to create pressure to breach amnesia and a relax control condition. In contrast to earlier findings, the recall data showed that both voluntary and involuntary subjects breached under the lie detector condition compared with their counterparts in the relax condition; however, the degree of breaching was not great in any condition. The results are discussed as they relate to studies attempting to breach posthypnotic amnesia and characteristics of the voluntary-involuntary dimension.

Geiselman, R. Edward; Fisher, Ronald P.; MacKinnon, David P.; Holland, Heidi L. (1985). Eyewitness memory enhancement in the police interview: Cognitive retrieval mnemonics versus hypnosis. Journal of Applied Psychology, 70, 401-412.

Compared effectiveness of three interview procedures for optimizing eyewitness memory performance: (a) the 'cognitive interview' based on memory-retrieval mnemonics from current memory theory, (b) the presently controversial hypnosis interview, and (c) the standard (control) police interview. Both the cognitive and hypnosis procedures elicited a significantly greater number of correct items of information from the Ss than did the standard interview. This result, which held even for the most critical facts from the films, was most pronounced for crime scenarios in which the density of events was high. The number of incorrect items of information generated did not differ across the three interview conditions. The observed memory enhancement was interpreted in terms of the memory-guidance techniques common to both the cognitive and hypnosis interviews. Neither differential questioning, time nor heightened subject or interviewer motivation could explain the results.

**Spanos, Nicholas P.; Weekes, John R.; Bertrand, Lorne D. (1985). Multiple personality: A social psychological perspective. Journal of Abnormal Psychology, 94, 362-376.**

The part of an accused murderer remanded for pretrial psychiatric evaluation was role played by 48 college students. Role players were assigned to interview treatments that varied in how extensively they cued for symptoms of multiple personality. The most explicit treatment (i.e., Bianchi treatment, n = 16) included a hypnotic interview that was used in diagnosing a suspect in the "Hillside strangler" rape- murder cases as suffering from multiple personality. A less explicit hypnotic treatment (n = 16) and a nonhypnotic treatment (n = 16) were administered to the remaining role players. Most subjects in the Bianchi treatment displayed the major signs of multiple personality (e.g., adoption of a different name, spontaneous posthypnotic amnesia). In a later session subjects who role played as multiple personalities performed very differently on psychological tests administered separately to each role-played identity. Those who failed to enact the multiple personality role performed similarly when tested twice. Findings are discussed in terms of a social psychological formulation that emphasizes the roles of active cognizing, contextual cueing, and social legitimization in the genesis of multiple personality.

**1984**

**Allison, R. B. (1984). Difficulties diagnosing the multiple personality syndrome in a death penalty case. International Journal of Clinical and Experimental Hypnosis, 32 (2), 102-117.**

The problems involved in diagnosing the multiple personality syndrome in a rape-murder suspect are illustrated by the case of Kenneth Bianchi and the Hillside Stranglings. Hypnotic investigations of his amnesia revealed "Steve," who admitted guilt for the rape-murders. "Billy" later emerged, claiming responsibility for thefts and forgeries. Attempts to evaluate Kenneth Bianchi with methods used in therapy yielded an original opinion that he was a multiple personality and legally insane. Later events showed the diagnosis to be in error. A new diagnosis was made of atypical dissociative disorder due to the effects of the examining methods themselves. Warning is given that it may be impossible to determine the correct diagnosis of a dissociating defendant in a death penalty case.

**Deyoub, P. L. (1984). Hypnotic stimulation of antisocial behavior: A case report. International Journal of Clinical and Experimental Hypnosis, 32 (3), 301-306.**

A case study is presented in which a 30-year-old man robbed a bank after being told

by a lay hypnotist that he could rob a bank if he wanted. The case is discussed in light of some of the literature on coercion and dangers in hypnosis.

#### NOTES

1:

This is a modified version of a policy brief prepared for the National Institute of Justice. The Conclusions read:

"The use of guidelines is designed to permit the subsequent evaluation of a hypnosis session by independent experts, in order to determine whether undue suggestiveness was present. Nonetheless, even when hypnosis has been used appropriately in a forensic situation and when the session has been monitored and conducted in a manner that is likely to minimize undetected biasing, inadvertent distortions of memory may still occur. Although the recommended guidelines for conducting the hypnosis session help determine what was done during the session, they do not prevent (nor is there any reliable way to prevent) subjects from confounding distorted hypnotic memories with prior and subsequent nonhypnotic recall or from placing undue confidence in these distorted recollections. Thus, the use of the results of hypnosis applied in forensic situations, as well as the use of the procedure itself, demands extreme caution.

"'Hypnotically refreshed' memories cannot be used to 'verify' facts for which no adequate evidence exists, especially when subsequent investigation has failed to produce any substantial independent corroboration and the individual did not recall the fact or was not confident of it prior to hypnosis. As long as the detail recalled is verified by independent physical evidence, the utility of hypnosis can be considerable and the risk attached to the procedure - if properly conducted - minimal. There is no way, however, by which anyone (including an expert with extensive experience in hypnosis) can for any particular piece of information obtained in hypnosis determine whether it is an actual memory or a confabulation. For these reasons, hypnotically induced testimony is not reliable and ought not be permitted to form the basis of testimony in court" (pp. 210-211).

1983

Smith, Marilyn C. (1983). Hypnotic memory enhancement of witnesses: Does it work?. Psychological Bulletin, 94 (3), 387-407.

Hypnosis is currently being used extensively by the police and other investigative agencies to "refresh" the memory of witnesses to a crime. The present author reviews the literature and discusses the issue of whether hypnosis can in fact enhance memory. In contrast to the myriad of anecdotal reports extolling the virtues of hypnosis for this purpose, controlled laboratory studies have consistently failed to demonstrate any hypnotic memory improvement. Although the relevancy of these laboratory studies may be questioned because they used verbal, frequently nonmeaningful stimuli in a low arousal environment, several recent studies that have used more forensically relevant, arousal-provoking stimuli persist in showing no hypnosis advantage. Since there is no clear documentation that hypnosis can improve memory, and since the courts have become increasingly reluctant to accept the testimony of witnesses who have undergone hypnosis because of the problem of suggestibility, several nonhypnotic procedures of memory enhancement are considered.

Schuyler, Bradley A. (1982). Further investigation of volitional and nonvolitional experience during posthypnotic amnesia (Dissertation, California School of Professional Psychology, Fresno). Dissertation Abstracts International, 44 (n6-B), 1977. (Order No. DA 8324472)

"Electrodermal responses were compared between highly responsive hypnotic Ss who were classified as having control over remembering (voluntaries) or not having control over remembering (involuntaries) during posthypnotic amnesia. Three contextual conditions were employed: Two were meant to create pressure to breach posthypnotic amnesia (lie detector instructions alone or with feedback that Ss had been detected as not having told all they could remember); the other provided feedback, in addition to the lie detector instructions, that Ss had told all they could remember. The recall data confirmed earlier findings of Coe and Yashinski and showed that voluntary and involuntary Ss did not differ in response to the contextual conditions. However, lie detector instructions alone did not create pressure to breach as in previous studies. In addition, electrodermal results were insignificant. The results are discussed as they relate to (a) amnesia, (b) the physiological detection of deception and physiological activation, (c) the voluntary/involuntary classification of Ss, and (d) theories of hypnosis" (p. 1977).

Author describes his involvement with the Los Angeles Police Department, using hypnosis for "enhancing the recall of key witnesses whose memories of the crime were poor" (p. 75). In 1975, the author and other experts in hypnosis trained 11 lieutenants and 2 captains to use hypnosis. The author describes the training program and a one-year demonstration project, during which volunteer witnesses and victims were interviewed by the hypnotist investigators. "In 77% of cases, important information was elicited that had not been available by routine interrogation. Approximately 16% of cases were solved with the aid of hypnosis" (p. 76). "Follow-up with the involved witnesses and victims has not revealed any instance of ill effects stemming from the hypnosis program, while 39.8% of the hypnosis subjects reported some relief or benefit resulting from the hypnosis session" (p. 77). Jean Holroyd

1979

Ault, R. L. Jr. (1979). FBI guidelines for use of hypnosis. International Journal of Clinical and Experimental Hypnosis, 27 (4), 449-451.

The Federal Bureau of Investigation uses hypnosis as a tool for investigative purposes in selected cases where further leads are needed and witnesses or victims are willing to participate in a hypnotic interview. All sessions are tape recorded, preferably by video. A hypnotic interview cannot necessarily provide accurate leads, and therefore careful investigative work is done to verify the accuracy of any information obtained in hypnosis. Psychiatrists, psychologists, or physicians specially trained in hypnotic techniques have been employed to add protection for the witnesses or victims being questioned under hypnosis.

Orne, Martin T. (1979). The use and misuse of hypnosis in court. International Journal of Clinical and Experimental Hypnosis, 27, 311-341.

The various forensic contexts in which hypnosis has been used are reviewed, emphasizing its advantages and pitfalls. The technique may be helpful in the context of criminal investigation and under circumstances involving functional memory loss. Hypnosis has no utility to assure the truthfulness of statements since, particularly in a forensic context, subjects may simulate hypnosis and are able to willfully lie even in deep hypnosis; most troublesome, actual memories cannot be distinguished from confabulations either by the subject or by the hypnotist without full and independent corroboration. While potentially useful to refresh witnesses' and victims' memories to facilitate eyewitness identification, the procedure is relatively safe and appropriate only when neither the subject, nor the authorities, nor the

hypnotist have any preconceptions about who the criminal might be. If such preconceptions do exist -- either based on information acquired before the hypnotic procedure or on information subtly communicated during the hypnotic procedure -- hypnosis may readily cause the subject to confabulate the person who is suspected into his "hypnotically enhanced memories." These pseudomemories, originally developed in hypnosis, may come to be accepted by the subject as his actual recall of the original events; they are then remembered with great subjective certainty and reported with conviction. Such circumstances can create convincing, apparently objective "eyewitnesses" rather than facilitating actual recall. A number of minimal safeguards are proposed to reduce the likelihood of such an eventuality and other serious potential abuses of hypnosis.

1978

Schafer, D. W.; Rubio, R. (1978). Hypnosis to aid the recall of witnesses. International Journal of Clinical and Experimental Hypnosis, 26, 81-91.

14 cases are presented of interrogation under hypnosis of witnesses and victims of crimes. Videotaping is considered essential for use of the court, if necessary. Interrogation of indicted people should be done only as an exception, if at all. The ideal case for hypnosis interrogation is with a witness or a victim where information is obtained which leads to evidence which itself will stand up in court without the need of the hypnosis interrogation to be presented as such. Guidelines for such interrogation are presented.

1954

Dittborn, Julio (1954). Dehypnotization and associated words. Journal of Clinical and Experimental Hypnosis, 2 (2), 136-138.

NOTES

1:

Author tested Freud's hypotheses about signs of emotional conflict gleaned from a word association test. A highly hypnotizable subject who had been accused of theft was tested with the word association test repeatedly. He had been given the suggestion, while in deep hypnosis, that any word provoking emotional conflict would automatically bring him out of hypnosis. That is, "dehypnotization was used as a new method to investigate the conflict-provoking quality of certain stimulus-words in an association word test" (p. 139). Freud's predictions were only partially supported.

Schneck, Jerome M. (1954). The divided personality: A case study aided by hypnosis. International Journal of Clinical and Experimental Hypnosis, 2 (3), 220-232.

NOTES

1:

Summary. Amnesia as a symptom assumes proportions more complex than would appear on the surface and the role of memory loss with specific reference to hypnotic recovery methods has been presented in several reports. Hypnotherapy

would appear to be a preferred technique for resolving the symptom and at times for more extensive investigation of the underlying problems. The case reported now involved an extensive memory loss for past life, including personal identity. This was followed after nearly a year by recall and concurrent amnesia for the intervening time period. The latter amnesia was dispelled by recall at first under hypnosis and then by post-hypnotic extension and elaboration of the nuclear material. The patient's history was outlined and several facts of apparent importance in relation to the memory loss were revealed. The purposive and motivational features were stressed. Therapy was conducted in a medico-disciplinary setting with limitations based on administrative requirements. Military-legal complications of the patient's personality disorder and functioning were outlined. The concept of the divided personality was introduced and related to multiple personality and to another type of behavior which is quite similar to the divided personality except that periods of amnesia are not involved. The divided personality involves major cleavages in the continuity of living with amnesia and the establishment of the individual in a setting where he undergoes extensive, significant operations relating to work, general activities, and even courtship and marriage. Unlike the generally accepted attributes of multiple personality involving considerable overt behavior, affect, and attitude alterations, the divided personality continues to function with his accustomed overt attitudes, interests, affect, and method of relating on an interpersonal level. Descriptively and overtly he is not too different if at all, but he seems to begin life anew in terms of setting and personal contacts. Cases of this type should be studied further with care, whenever possible, for further elicitation [sic] of psychodynamics. Hypnosis as a tool in treatment and investigation should prove helpful and is to be considered important.

1989

Van der Hart, O.; Friedman, B. (1989). A reader's guide to Pierre Janet on dissociation: A neglected intellectual heritage. Dissociation, 2 (1), 3-16.

A century ago there was a peak of interest in dissociation and dissociative disorders. Janet (1859-1947) was the most important scientific and clinical investigator of this period, whose work is reviewed in this article. The evolution of dissociation theory and its major principles are traced throughout his writings. His introduction of the term 'subconscious' and his concept of the existence of consciousness outside of personal awareness are explained. The validity and reliability of dissociation as the underlying phenomenon in a wide range of disorders is presented. It is proposed that Janet's theory and methodology of psychological analysis and dynamic psychotherapy are cogent and relevant for today.

1985

McConkey, Kevin M.; Perry, Campbell (1985). Benjamin Franklin and mesmerism. International Journal of Clinical and Experimental Hypnosis, 33 (2), 122-130.

This historiographical note reviews Benjamin Franklin's involvement with the practice and investigation of Mesmerism. A survey of material about Franklin's period in Paris (e.g., Lopez, 1966; Lopez & Herbert, 1975) indicates that he had a higher degree of personal involvement with, and a more detailed opinion of, Mesmerism than has been generally considered.

1980

Weitzenhoffer, Andre M. (1980). What did he (Bernheim) say? A postscript and an addendum. International Journal of Clinical and Experimental Hypnosis, 28 (3), 252-260.

When Bernheim (1917) made his pronouncement, "There is no hypnotism, there is only suggestibility" at a scientific congress in London in 1892, he shocked the scientific community, which turned against him for what amounted to heresy. Clearly, his colleagues understood him to deny existence to hypnosis as a state. That he only meant to shock them into viewing suggestion as being the primary agent and hypnosis as being one of its products rather than the other way around, as then held, was made fully clear by him in 1917 in one of his last writings. Recognizing there had been a misunderstanding, Bernheim made this very point and explained further that although hypnosis is sleep, it is only so in an incomplete form, one allowing the subject to be responsive and suggestibility to be elicited. From there he went on to develop the thesis that hypnotic behavior is the result of an integration of elicited automatisms (nonvoluntary acts) and conscious voluntary behavior, and not entirely a pure, non-conscious, nonvoluntary automatism. Bernheim also proposed in this later work that suggested behavior results from automatisms rendered possible by the "credivity," that is, the implicit belief of suggestible persons in the reality of whatever the suggestor states, a belief which is limited to the suggestor. (In contrast, the credulous person believes everyone.) Credivity is a particular outgrowth of the hypnotist-subject relationship. In his final writings, Bernheim thus called attention to the importance of interpersonal factors in hypnotism.

1965

Ellenberger, H. F. (1965). Charcot and the Salpetriere School. American Journal of Psychotherapy, 19, 253-267. (Abstracted in American Journal of Clinical Hypnosis, 1965, 8:2, 148)

Under the influence of Charles Richet, Charcot, in 1878, undertook a scientific study of hypnotism, using as subjects several female hysterical patients out of a hospital population of 5,000. As a result of the French Academy of Sciences' acceptance of his findings in 1882, hypnosis reached the dignity of a scientific modality. Other facets of Charcot's life, including esoteric disappointments and successes, are also mentioned by the author.

1962

Schneck, Jerome M. (1962). William Alanson White on Hippolyte Bernheim - a historical note. International Journal of Clinical and Experimental Hypnosis, 10, 115-117.

(Author's Abstract) At the turn of this century, William Alanson White visited Hippolyte Bernheim and his hospital at Nancy. He commented briefly on both in his autobiography. The latter is not widely known, so it seems appropriate and of interest to publish the account in a journal devoted to hypnosis. White achieved a position of stature as a psychiatrist and served as President of the American Psychiatric Association. Bernheim, a prominent psychotherapist of his day, was associated with Liebeault as a leader of the Nancy School in the Paris-Nancy hypnosis controversy. White's account of Bernheim is reminiscent of the better known description of Liebeault by J. Milne Bramwell in the latter's classic volume on hypnotism.

1957

Conn, Jacob H. (1957). Historical aspects of scientific hypnosis. Journal of Clinical and Experimental Hypnosis, 5 (1), 17-24.

The author relates the history of hypnosis beginning with pre-historic therapeutic suggestion, the trances of Persian Magi and Indian Yogi, and incubation or temple sleep in Egypt and Greece. Touching on practices among Egyptians, Romans, Greeks and the Middle Ages in Europe, he writes in more detail about Mesmer, John Elliotson, James Braid, Ambroise Auguste Liebault, Hyppolyte Marie Bernheim, and Jean Martin Charcot.

#### NOTES

Cites J. Herman, Mason, and Miller who accused Freud of retreating from trauma theory to save his theory. Feminists view the Oedipal theory as a coverup for the denial of child sexual abuse. This moral position fuels trauma theory and practice. It is the moral dimension of this debate that gives so many problems for the investigation of traumatic memory.

The intellectual origins of repressed trauma are examined here. Freud's early trauma theory, his later conflict theory.

Etiology of Hysteria (1896) presents Freud's argument, based on 18 patients: child is passive victim of experience imposed on them; memory is repressed and hysterical symptoms are derivatives of these repressed memories; when memories return as pictures the task of therapy is easier than if returning as thoughts. Bartlett's memory research showed visual image is followed by sense of confidence that surpasses what should be there.

The fact that patients had to be compelled to remember was offered by Freud as evidence against the idea that the memories were suggested. The patients initially would deny the reality of their memories, which Freud used in saying that we should not think that patients would falsely accuse themselves. In letter to Fleiss, he presented the conflict theory, which he presented in 1905 in Three Essays on Sexuality and later in My Views...on Etiology of Neurosis.

In 1905 Freud indicated he was unable to distinguish fantasy from true reports (and did not deny the existence of the latter). Freud often reconstructed the "memories" from dreams, transference, signs, symptoms, fantasies, etc. They were not produced as conscious memories, and it was Freud who inferred the sexual abuse. From signs of distress he took evidence of proof.

Freud presented his theory to his patients and then sought confirmation.

Freud asks us to abandon historical for narrative truth. The problems with Freud's first theory became worse with his second theory. In Introductory Lectures Freud states that opponents say his treatment talks patients into confirming his theories. He relies on the patient's inner reality confirming the theoretical ideas given to him. Success depends on overcoming internal resistance, however. The danger in leading a patient astray by suggestion has been exaggerated, because the analyst would have had to not allow the patient to "have his say." Freud denied strongly ever having done this.

Incorrect interpretations would not be accepted by the patients, and if believed would be suggestion. Brunbaum, another writer, said that this doesn't mean acceptance of a faulty idea won't occur. Both Milton Erickson and especially Pierre Janet reported cases in which suggestions were used to give benign memories to replace malignant ones.

Freud also viewed patient resistance to his interpretations as evidence that the interpretations were correct. Thus both resistance and acquiescence were thought to be validating. Popper's critiques using philosophy of science note that this makes his theory untestable.

Freud could not distinguish between the patient's reluctant acceptance of the truth and reluctant acceptance of a suggestion.

Contemporary theorists struggle less than Freud did with the problem of suggestion and suggestibility (and Freud did not have available the research on those areas!) Emotional upheaval that accompanies "insight" is readily taken to be validating. It may be true that bad memories are repressed, but that doesn't mean that all bad memories are true.

Treatment groups focus on recalling memories and sharing memories with others in the group, not on current relationships. Hermann states that the group provides

powerful stimulus for remembering. The group, of course, is reinforced by others remembering. Repeatedly considering the possibility of abuse can increase the sense of familiarity.

Current views expressed by some clinicians that certain symptoms and syndromes (eating disorders, etc.) indicate early sexual trauma are similar to Freud's theory of hysteria. In these proposals, the inability to recall abuse becomes evidence that it occurred; and it tallies with the patient not having a sense of remembering.

Because some believe it is necessary to bring memory to light for cure to occur, there is a tendency to believe the reports of early childhood abuse.

Recognizing that some "memories" may have been a product of a therapist's suggestion helps prevent untoward effects. Modern therapists recapitulate Freud's "slip" when they do not acknowledge the role of suggestion.

Endorsing repression does not commit us to a belief that recovered memories must be accurate in all particulars. A memory that is repressed does not escape the usual kinds of degradation of memory.

And just because the material comes from unconscious sources, or has emotional accompaniments, it doesn't mean it is true. (Bowers gave an example of his dream that Israel and Venezuela shared a common border, which was rectified by his waking awareness of the Atlantic Ocean and the Mediterranean. He noted that nothing like the Atlantic can be called upon if the dream is that one's parent molested oneself at the age of six.)

Ian Hacking, in *Rewriting the Soul*, labels a more fundamental indeterminacy (for the historical past itself). Bathing rituals in childhood can be redescribed as abuse, which determines the historical past rather than describing it. It is thus easier to justify abuse if the event is something that can be reinterpreted. For example, the conflicts of adolescents with their parents, may be reinterpreted later if personality problems continue. If in adulthood one concludes that abuse occurred, then bathing rituals can be reinterpreted as if it were earlier abuse, as if the abuse has continued for years.

Kunzendorf, Robert G.; Jesses, Michael; Dupille, Leonard; Butler, William (1990-91). Subliminal activation of intrapsychic conflicts: Subconscious realms of mind vs subconscious processes of mentation. Imagination, Cognition and Personality, 10, 117-128.

## NOTES

Cognitive-state monitoring theory asserts that people perceive subliminal stimulation without self-consciously monitoring its external innervation (as opposed to central innervation). Thus monitoring theory predicts that subconsciously perceived discord, in the absence of any 'external location' cues, should be misinterpreted as centrally generated discord and should disrupt self-generated behavior. Consistent with this prediction, mathematical problem-solving in the current experiment was disrupted after mathematically competitive males repeatedly heard the subliminal message IT'S WRONG TO CRUSH DADDY stereophonically localized in the middle of their heads--but not after they repeatedly

heard this subliminal 'Oedipal' message binaurally localized on one side of their heads. A subliminal message binaurally localized on one side of the self should not interfere with problem-solving behavior \_because, even though the message's external innervation is not self-consciously 'monitored,' its external location is inferable from subconscious cues.\_

Monitoring theory asserts that subliminal [perceptions] of 'unmonitored' messages are unaccompanied by any self-consciousness that one is perceiving them (rather than imaging them), and that subliminal or 'unmonitored' messages of distress are mistaken for self-generated distress.

Disruption by the 'internal' subliminal word WRONG seems to us consistent with the fact that disruption was limited to mathematically competent males.

Indeed, 'repression' itself is a mode of processing fearful information: a mode in which subjects suspend their self-awareness that they are perceiving fearful stimulation, as research by Kunzendorf and McLaughlin has demonstrated. This selective suspension of monitoring provides immediate relief from fearful stimuli, Freudian or otherwise, but it does so at the risk of turning self-conscious fear into subconscious anxiety (into consciously lingering fear without a self consciously perceived source). No subconscious realm full of lurking fears is implicated in this 'unmonitored' mode of self-protection. All that is implicated is an unconscious storehouse of potentially fearful memories--potentially fearful but sensationless memories, which can be 'suppressed' from conscious sensory representation or 'constructed' into conscious memory images or 'subconsciously represented' as unself-consciously imaged sensations.

1988

Nash, Michael R. (1988). Hypnosis as a window on regression. Bulletin of the Menninger : Clinic, 52, 383-403.

Examines the empirical evidence for temporal and topographic regression during hypnosis--which Freud explicitly defined as regressive. A review of more than 100 studies spanning 60 years of research found no convincing evidence that developmentally previous psychological structures are reinstated during hypnosis (temporal regression). In contrast, there is evidence that hypnosis enables subjects to elicit more imagistic, primary process, and affect-laden material (topographic regression). The author recommends a careful reexamination of two core assumptions underlying the concept of temporal regression: (1) that early structures in human development are imperishable, and (2) that regression necessarily involves reinstatement of infantile psychological structures.

1985

Nichols, Michael P.; Efran, Jay S. (1985). Catharsis in psychotherapy: A new perspective. Psychotherapy, 22 (1), 46-58.

Contemporary thinking about catharsis in psychotherapy is still dominated by Breuer and Freud's work with the cathartic method. Psychoanalysts take the fact that Freud abandoned catharsis as evidence of its ineffectiveness, while the emotive

therapies developed in the 1960s returned to Freud's earliest view that neurosis results from repressed affect and can be cured by cathartic uncovering. Emotional memories continue to be thought of as foreign bodies lodged in the human psyche and requiring purgation. Unfortunately, this view divorces people from responsibility for their conduct and encourages a fractionation of human experience into feeling, thought, and action. In the current presentation, emotion is construed instead as a class of blocked or partially blocked actions, and in terms of a two-stage adaptational process. Implications of this view for psychotherapeutic practice are proposed, emphasizing richer self-expression and fuller appreciation of the consequences of responsible vs. disclaimed actions.

Crabtree, Adam (1984, October/1986). Explanations of dissociation in the first half of the twentieth century. In Quen, Jacques M. (Ed.), Split minds/split brains (pp. 85-108). New York: New York University Press. (Based on symposium in Bear Mt., N.Y., by Section on the History of Psychiatry of Cornell University Medical Center)

#### NOTES

In 1907 Morton Prince, Editor of *Journal of Abnormal Psychology*, introduced a symposium by listing 6 meanings of subconscious: 1. that portion of our field of consciousness which is outside the focus of attention 2. (Janet's idea) - split off ideas which may be isolated sensations like the lost tactile sensation of anesthesia, or maybe aggregated into groups or systems. The author quotes Janet as stating that "they form a consciousness coexisting with the primary consciousness and thereby a doubling of consciousness results" (p. 87). The primary consciousness is usually dominant, but sometimes is reduced under exceptional conditions (e.g. automatic writing). 3. the subconscious self or hidden self -- a part of every human, not just seen in psychopathology; this is a personalized entity; every mind has a double, with the unconscious self having powerful effects on feelings, thoughts, and reactions of the conscious self 4. extends #3 to include not only ideas that remain active below surface but also those which are inactive -- forgotten or out of mind 5. Frederic Myers' concept of the 'subliminal self' which had 3 functions:

a) inferior - seen in processes of dissociation

b) superior - seen in works of genius, arising from 'subliminal rush' of information, feelings, and thoughts which lie below consciousness

c) mythopoeic - the unconscious tendency to create fantasies 6. physiological meaning, e.g. William Carpenter's 'unconscious cerebration' in which unconscious phenomena are interpreted in terms of pure neural processes unaccompanied by mental activity.

Prince suggested some redefinitions to clarify unconscious and subconscious. He would replace Janet's subconscious with co-conscious and reserve unconscious for physiological processes that lack the attributes of consciousness. Prince noted that co-conscious ideas have been called unconscious (e.g. by Freud) but said that is confusing and to be avoided.

"Coconscious ideas include states we are not aware of because they are not the focus of our attention, and also pathologically split-off and independently active ideas or

systems of ideas, such as occur in hysteria and reach their most striking form in co-conscious personalities and automatic writing.

"Prince prefers the term coconscious to Janet's subconscious for two reasons. First, because it expresses the simultaneous coactivity of a second consciousness. And second, because the coactive ideas or idea systems may not be outside the awareness of the personal consciousness at all. They may be recognized by the personal consciousness as a distinct consciousness existing alongside it.

"Thus, through his redefinition of terms, Prince makes simultaneous activity of two or more systems of consciousness in one individual the key element in dissociation. He thereby moves the issue of amnesia or lack of awareness by one system of another into the background, making it a secondary, nonessential element. Prince was one of the few to provide a theoretical framework for dissociation in which any combination of interawareness among the coconscious systems was possible" (p. 91). Two researchers at the turn of the century came to opposite conclusions about the nature of the Subconscious Self that every human has. Morris Sidis saw it as "a brutelike consciousness with a tendency toward personalization. Frederic Myers held that it included those functions and much more, being the source of all that is human, including the highest intuitive powers" p. 96.

Bernard Hart, in 1910, did an analysis of Janet and Freud. Janet's work is essentially descriptive: "he is always talking about a consciousness which manifests itself in a way we can \_perceive\_, whether by listening to it talk, reading its written communications, or watching its movements" (p. 97). However Janet's spatial model of dissociation cannot explain the presence of the same material (e.g. memories) in two or more dissociated systems. According to Hart, Freud offered the conceptualization that Janet lacked, in his idea of the Unconscious .

Freud's Unconscious is not in competition with Janet's subconscious. "Janet's subconscious is the arena of dissociated phenomena which manifest in observable form as elements coactive with the personal self. Freud's unconscious is a conceptual, nonobservable construction put forward to explain certain facts of human experience. In this way Hart equates the unconscious with the atomic theory in physics or the theory of heredity in biology" p. 99. But Hart also thought Freud's theory did not do justice to dissociative phenomena. Not only do psychoanalysts show little interest in double personality or multiple personality, they also neglected dissociation on the phenomenal level.

In 1915 Freud denied the existence of a second consciousness and wrote, "there is no choice for us but to assert that mental processes are in themselves unconscious, and to liken the perception of them by means of consciousness to the perception of the external world by means of the sense organs" (p. 101). Janet claimed that Freud had simply taken over his own system and given it a new terminology, and in 1924 Freud wrote an angry rebuttal. For him, "dissociated systems are simply separate groups of mental but unconscious elements. As our consciousness turns now to one group, now to another, as a searchlight shines now on one object and now on another, the dissociated groups manifest in conscious life. ... There exists no doubling of consciousness" p. 102.

Jung's ideas were closer to those of Janet, and like Janet he made dissociation a key concept in his theory. The \_complex\_ is unconscious, has an archetypal core clothed

in personal experience, is like a self-contained psyche within the big psyche, sometimes called a fragmentary personality dwelling inside us. Dissociation for him meant being cut off from the Ego, which is the center of an individual's field of consciousness. "Dissociated or autonomous complexes are those which have no direct association with the ego" (p. 103). If complexes are charged with enough energy they will become manifest--as a neurotic symptom, as projected into idea of a god or demon, or perhaps as an alternate personality. Therefore Jungian treatment aims at assimilating dissociated complexes into the ego.

Decker, Hannah S. (1984, October/1986). The lure of nonmaterialism in materialist Europe: Investigations of dissociative phenomena, 1880-1915. In Quen, Jacques M. (Ed.), Split minds/split brains (pp. 31-62). New York: New York University Press. (Based on symposium in Bear Mt., N.Y., by Section on the History of Psychiatry of Cornell University Medical Center)

## NOTES

Emphasizes spiritism, hypnotism, and the career of Pierre Janet.

Janet's career paralleled an increased interest in dissociation, because he had contact with scientists studying spiritism, used hypnosis, and insisted on a scientific approach. He coined the words "subconscious" and "dissociation." As his sphere of influence declined, so did scientific interest in dissociation--especially multiple personality disorder.

Scientific study of dissociation began with investigations into religious exorcism and spirit possession. For example, at the behest of Prince Max Joseph of Bavaria, Mesmer duplicated the exorcisms of Father Gassner (causing convulsions) using hypnosis. Following Mesmer, there were reports of multiple personalities (e.g. an "exchanged personality" in Germany, reported in 1791 by Eberhardt Gmelin).

"Partly because of this growth of knowledge of multiple personality, a new model of the mind developed during the early 19th century: the mind was dual; there were conscious and unconscious mental states. Later, it was said that there was a dominant conscious personality with a group of underlying subpersonalities. Eventually it was declared that split fragments of personality could act autonomously" p. 37.

The scientific study of these phenomena continued under the leadership of Frederic Myers of The Cambridge Society for Psychical Research. According to William James, Myers was the first to consider the phenomena of hallucination, hypnotism, automatism, double personality, and mediumship as connected parts of one whole subject. The Cambridge Society was involved in the transition from the use of automatic writing by mediums to its use for clinical purposes and experimental research in the 1880's and 1890's.

Increasing numbers of multiple personalities reported in the literature in late 19th century led to increased interest in hypnosis and to the concept of dissociation. The author details the contributions of Janet, and then explains how interest declined in dissociation and in hypnosis due to the following: 1. Experimental psychologists in Germany (e.g. Wundt) refused to deal with anything that resembled the "unconscious," and neglected the point of view of the experiencing person. 2. Those

few psychologists interested in the unconscious found projective tests (Rorschach, TAT) an easier avenue than hypnosis or automatic writing. 3. Many mediums were exposed as frauds, e.g. Flournoy's popular "From India to the Planet Mars". 4. Janet himself was very critical of parapsychology. 5. When Charcot died suddenly, it was discovered that some of his assistants had rehearsed the behavior of hypnotized patients. 6. Hypnotists' extravagant claims (e.g. past life age regression) led to a wave of reaction against them. 7. Questions were raised about the iatrogenic nature of multiple personality. 8. Conscientious hypnotists discovered drawbacks

- not everyone could become good hypnotists (e.g. Freud)
- not everyone could be hypnotized
- some patients faked hypnosis
- extreme sensitivity of hypnotized patients to the hypnotist's wishes led to biased results
- hypnotist sometimes was conditioned to things in certain way by his first patient

9. Janet didn't have the personality of a leader, and he argued with the psychoanalysts about who should get credit for certain ideas

**1980**

Watkins, Helen H. (1980). The silent abreaction. International Journal of Clinical and Experimental Hypnosis, 28 (2), 101-113.

The cathartic release of bound affect is a psychotherapeutic technique whose value has been proved over the years. Although Freud abandoned hypnotic abreactions, it was while working with this approach, in collaboration with Breuer, that he discovered unconscious processes (Breuer & Freud, 1895/1957). In spite of criticisms about the permanence of therapeutic results achieved through abreactions, the procedure continues to be employed in such differing approaches as hypnoanalysis, narcosynthesis, flooding, implosive therapy, primal scream, and gestalt therapy. A considerable limitation to the use of cathartic release lies in the fact that the violent release of powerful emotions is usually accompanied by screams, howling, cursing, or shrieks of fright. Practitioners who conduct their therapeutic sessions within most professional office buildings are often loath to initiate and work through such affective releases, even when therapeutically indicated, because of the sound disturbance to colleagues and other patients in the waiting room. The "silent abreaction" was developed as a procedure for releasing strong angers through perceptual and experiential, but not verbal, channels. It is a hypnotic visualization technique which can be adapted to the patient and to the circumstances in which the abreaction is to be conducted. While no data is yet available comparing its effectiveness with more vocal methods, the technique has been used successfully with a number of treatment cases. The silent abreaction offers an opportunity for the therapist to employ this valuable approach when the treatment setting would not normally accept a loud release of violent angers. The theory, specific techniques for its induction, and clinical case examples are presented.

**1977**

MacMillan, M. B. (1977). The cathartic method and the expectancies of Breuer and Anna O.. International Journal of Clinical and Experimental Hypnosis, 25, 106-118.

Expectancies about the consequences of the suppression of behavior and about the effects of expressing emotions are proposed as sources of the "talking cure" which developed during Breuer's treatment of Anna O. and which later became known as the cathartic method. Although the argument is similar to one proposed by Ellenberger (1970, 1972) it sets out a more rational alternative to his explanation that the method was partly a creation of the mytho-poetic unconscious. The analysis of the interaction between Breuer and Anna O. makes explicit the expectancies underlying each of the steps through which the cathartic method developed and traces these expectancies to the general beliefs and the specific theoretical interests shared by them.

#### NOTES

In summary, in the actual hypnotic relationship, the attitudes of the operator may influence his behavior markedly and are probably even more important than those of the subject in carrying through a successful relationship. It has been indicated in another paper that the subject's impulse handling is more important than his attitude toward hypnosis in actual hypnotizability. This view is a re-interpretation of that of Sarason and Rosenzweig (16) with regard to the same problem. The way the operator handles his own impulses seems in itself a most significant problem, and is expressed in his reactions to the induction and later the trance state of the subject. It is indicated that to some workers, the hypnotic response of the subject offers a rare feeling of power which may have psychosexual implications of a heterosexual or homosexual kind depending on the sex of the patient and the emotional needs of the operator. Child-parent relationship attitudes may also be elicited as well as conflicts about dominance-submission related to earlier experience of the worker.\*\* As suggested by Bruno-Bettelheim (1) for children who cannot participate in relations with others as a result of a fear of their own hostility, it appears that some persons might find the hypnotic situation difficult because of a similar factor. Thus some therapists or research workers might be impelled to reject the use of this measure or to fail in using it, because of a non-verbalized fear of their own impulses toward a 'helpless' subject in their power. This same situational response may be a problem that arises in the psychotherapeutic or even ordinary medical relationship. Its effect may be to limit full exploration and exploitation of therapeutic possibilities, and to hamper treatment of numerous disorders.

"It is perhaps appropriate to point out in conclusion that Freud left hypnosis, it would seem, because of some unresolved problems. Wolstein (23) says because he could not hypnotize all his patients and because of the magical connotations of hypnosis. The hypnosis in transference is still an open field. Are the two phenomena over-lapping or on a continuum? Are the problems of the therapist really the same in both areas? Is transference an aspect of hypnosis" (pp. 66-67).

\*\*\* Data on male-female differences in success as hypnotists with members of the opposite sex might be very illuminating" (p. 66).

Kline, Milton V. (1955). Freud and hypnosis: II. Further observations on resistance and acceptance. Journal of Clinical and Experimental Hypnosis, 3 (2), 124-129.

#### NOTES

Summary. Freud's rejection of hypnosis in the development of psychoanalytic psychology becomes upon closer examination a two fold process. It involves on the part of Freud the conventional recognition that suggestion plays a basic role in the primitive emotional energy that binds people together and influences the acting out of primary libidinal drives. From an ontogenetic (and presumably phylogenetic) point of view, Freud viewed suggestibility as a repressive element in the organization of behavior and one which in effect had to be dealt with indirectly. To deal with it directly was to create a state within which powerful emotions of an unpredictable nature could emerge. Hypnosis to Freud was a 'condition' which led to general heightened suggestibility and was identical with it. To make use of this condition was in essence an attempt to make use of an individual's energies in a dependent and essentially uninhibited manner. It seemed to Freud that having produced the hypnotic 'condition,' one actually had achieved a state of suspension or ablation of certain critical ego functions and this could lead to an intense and perhaps unmanageable interpersonal relationship. It was almost an 'ethical' rather than a scientific view as Freud discussed it in his thinking and theorizing about a general psychology.

"To a great extent the basic concepts of psychoanalysis were developed as the result of Freud's awareness of the existence of hypnotic phenomena and his need to circumvent and indirectly deal with the ego manifestations of this 'condition.' Thus Freud never really rejected hypnosis as a mechanism of human behavior. His comment of the psychosocial development of man (from which psychoanalytic psychology is influenced) was heavily weighted by his awareness of 'suggestibility' and the 'condition' descriptively called hypnosis.

"The simple equation of hypnosis with suggestibility is now scientifically outmoded and incorrect. The role of suggestion and its psychosomatic equations has taken on a drastically changed perspective in social psychology, particularly with regard to the early concepts of Le Bon, Freud and McDougall (5). For these reasons alone, Freud's circumvention of hypnosis becomes increasingly unsound scientifically and adherence to such a perception of hypnosis serves only to obscure theoretical research in psychology and to maintain a rigidity born essentially of emotional ties and ethics alien to the nature of scientific inquiry" (pp 128-129).

1954

Dittborn, Julio (1954). Dehypnotization and associated words. Journal of Clinical and Experimental Hypnosis, 2 (2), 136-138.

#### NOTES

Author tested Freud's hypotheses about signs of emotional conflict gleaned from a word association test. A highly hypnotizable subject who had been accused of theft was tested with the word association test repeatedly. He had been given the

suggestion, while in deep hypnosis, that any word provoking emotional conflict would automatically bring him out of hypnosis. That is, "dehypnotization was used as a new method to investigate the conflict-provoking quality of certain stimulus-words in an association word test" (p. 139). Freud's predictions were only partially supported.

### GALVIN SKIN RESPONSE

2002

Gravitz, Melvin (2002). Hypnosis as a counter-measure against the polygraph test of deception.. Polygraph Journal, 31, 293-297.

This article presents a bibliography of experimental and applied studies for reference by those interested in the use of hypnosis as a counter-measure in the "lie detector" test.

1999

De Pascalis, V.; Magurano, M. D.; Bellusci, A. (1999). Pain perception, somatosensory event-related potentials and skin conductance responses to painful stimuli in high, mid, and low hypnotizable subjects: Effects of differential pain reduction strategies. Pain, 83 (3), 499-508.

In this study, pain perception, somatosensory event-related potential (SERP) and skin conductance response (SCR) changes during hypnotic suggestions of Deep Relaxation, Dissociated Imagery, Focused Analgesia, and Placebo, compared with a Waking baseline condition, were investigated. SERPs were recorded from frontal, temporal, central, and parietal scalp sites. Ten high, 9 mid, and 10 low hypnotizable right-handed women participated in the experiment. The following measures were obtained: (1) pain and distress tolerance ratings; (2) sensory and pain thresholds to biphasic electrical stimulation delivered to the right wrist; (3) reaction time and number of omitted responses; (4) N2 (280+/-11 ms) and P3 (405+/-19 ms) peak amplitudes of SERPs to target stimuli delivered using an odd-ball paradigm; (5) number of evoked SCRs and SCR amplitudes as a function of stimulus repetition. Results showed, high, mid and low hypnotizables exhibited significant reductions of reported pain and distress ratings during conditions of Deep Relaxation/Suggestion of Analgesia, Dissociated Imagery and Focused Analgesia. High hypnotizable subjects displayed significant reductions in pain and distress levels compared to mid and low hypnotizables during Dissociated Imagery, Focused Analgesia and, to a lesser degree, during Deep Relaxation. Placebo condition did not display significant differences among hypnotizability groups. High hypnotizables, compared to mid and low hypnotizables, also showed significant increases in sensory and pain thresholds during Dissociated Imagery and Focused Analgesia. High, mid, and low groups showed significant reductions in P3 peak amplitudes across all hypnosis conditions and, to a lesser degree, during Placebo. The temporal cortical region was

the most sensitive in differentiating SERP responses among hypnotizability groups. On this recording area the subjects highly susceptible to hypnosis displayed significantly smaller P3 and greater N2 peaks during Focused Analgesia than did the other hypnotizable groups. In this condition highly susceptible subjects also reported the highest number of omitted responses and the shortest Reaction Times. These subjects also showed faster habituation of SCRs when compared with mid and low hypnotizables. During Dissociated Imagery and Focused Analgesia, highly hypnotizable subjects also disclosed a smaller total number of evoked SCRs than did mid and low hypnotizable subjects. The results are discussed considering possible common and different mechanisms to account for the effects of different hypnotic suggestions.

Abstract from National Library of Medicine, PubMed

1996

Lee, Lai H.; Olness, Karen N. (1996). Effects of self-induced mental imagery on automatic reactivity in children. Journal of Developmental and Behavioral Pediatrics, 17 (5), 323-327.

The purposes of this research study were: (1) to determine whether changes in cardiac rate, skin temperature, and/or electrodermal activity occur as children change mental imagery and (2) to determine whether such changes are related to age, sex, or other variables.

Children who were evaluated in this study had no previous experience with hypnosis or biofeedback training and were in good health with no learning disabilities. Thirty-eight boys and 38 girls ranging in age from 5 to 15 years were studied in a comfortable setting with a constant room temperature and biofeedback equipment. A Procomp 5DX computer software unit was used to measure autonomic reactivity during baseline and mental processing periods. After baseline monitoring indicated stabilization of autonomic measures, each child was asked to think about being in a quiet, pleasant place for 120 seconds. Pulse rate, skin temperature, and electrodermal activity were recorded. A resting period followed, and each child was then asked to think about an exciting activity, such as a preferred sports activity, for another 120 seconds. At the end of this monitoring, each child was asked to describe what had been his/her mental imagery during the two monitoring periods. Data analysis used paired t tests and repeated measures analysis of variance. For all children, the pulse rates showed significant decreases ( $p < .001$ ) during quiet and relaxing imagery and significant increases ( $p < .001$ ) during active imagery. Skin temperatures increased significantly ( $p < .001$ ) during quiet imagery and active imagery, whereas electrodermal activity decreased ( $p < .001$ ) during active imagery. Observed changes did not relate to age or sex.

The results confirm our clinical observations that deliberate changes of mental imagery by children results in immediate autonomic changes. Questions evolving from this study and similar studies done in adults are: (1) Do average-thinking processes impact on autonomic changes over long periods of time and (2) do these changes ultimately impact on health, such as cardiovascular status?

Wickramasekera, Ian; Pope, Alan T.; Kolm, Paul (1996). On the interaction of hypnotizability and negative affect in chronic pain: Implications for the somatization of trauma. Journal of Nervous and Mental Disease, 184 (10), 628-635.

The high risk model of threat perception predicts that high hypnotizability is a risk factor for trauma-related somatization. It is hypothesized that high hypnotizability can increase experimentally induced threat or negative affect, as measured by skin conductance level, in a linear or dose-response manner. This hypothesized interaction of hypnotic ability and negative affect was found in a consecutive series of 118 adult patients with chronic pain symptoms. Larger increases in skin conductance levels during cognitive threat were significantly related to higher levels of hypnotizability. In addition, individuals with high hypnotizability retained higher skin conductance levels than individuals with low hypnotizability after stress. The clinical implications of the interaction of hypnotizability and negative affect during threat perception and delayed recovery from threat perception are discussed in terms of cognitive mechanisms in the etiology and therapy of trauma-related dissociative disorders.

Olness, Karen N.; Lee, Lai (1995, November). Effects of self-induced mental imagery on autonomic reactivity in children. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

#### NOTES

One study that shows an IgA increase with hypnotic suggestion has been replicated and is in press.

The present study emerges from work using hypnosis with biofeedback. Morgan's work with athletes has suggested the relationship between imagery and physiological activation. This has been observed clinically but not heretofore documented.

We are not using formal hypnosis. Each child was asked to think about being in a quiet place, doing exciting activities, baseline, etc. The children exhibited no neurological disorders, cognitive dysfunction, nor were they on medications at time of the study.

We confirmed our clinical experience: there was an increase in pulse rate when imagery changed to activity. Skin temperature continued to go up during the period (despite imagery of being active like being on roller coaster). Skin conduction went down during baseline. EDA [electrodermal activities] was higher during active imagery.

How do average daily thinking processes impact on autonomic changes over long periods of time? Do these changes affect cardiovascular status?

Clinically we observed that some children are more labile in different modalities, and under stress they react more in that system.

Wickramasekera, Ian (1995, November). Hypnotic ability, skin conductance, and chronic pain. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

## NOTES

T. X. Barber's book in 1969 states that hypnotizability is unrelated to psychopathology. Hilgard's book states that hypnotic ability and negative reactivity are unrelated. However clinicians working with somatization-type symptoms (headache, irritable bowel disease) may observe a surplus of people very high or low in hypnotic ability. How do we account for the discrepancy between clinic and lab?

Is this a context effect, since I only see people who are sick? It turns out that the low hypnotizable patients present mainly in primary care, medicine and surgery. The highs present with psychophysiological problems.

The author posits that when hypnotic ability and negative affectivity coincide, they lead to physical disease. (He uses "negative affectivity" for what used to be called Neuroticism.) Negative affect is not simply verbal report; one must also consider autonomic physiology as part of it (cf.. Dan Weinberger's research).

Highs are at risk for illness because: 1. They can amplify or attenuate signals of threat. 2. They demonstrate surplus pattern recognition (see meaning in randomly distributed events). 3. They have surplus empathy (poor boundaries).

Lows are at risk because: 1. They deny or attenuate the role of cognitive and emotional events on somatic symptoms. 2. They demonstrate rigidity in information processing; they are locked into critical, sequential, analytical information processing.

Under low stress (mental math), Lows and Highs do not differ on Subjective Units of Distress (SUDS) for mental arithmetic; for high stress (more difficult math) there is a large difference between groups.

High, Medium, and Low hypnotizable Ss with chronic pain and no observable pathology (TMJ, back pain, etc.) were measured on skin conductance (EDR): there were no differences during baseline, but differences emerged during a stress condition. We did not find this kind of difference using muscle tension! Patients were not on medications. GSR is a purely sympathetic nervous system measure, unlike heart rate that also has parasympathetic input. There is almost a dose-response relationship between hypnotizability and reactivity with GSR under stress conditions.

High Hypnotizable and High Negative Emotion Subjects: EDR 12.5 SUDS 63.5 Lie Scale (Marlowe Crowne)

Moderate Hypnotizable and Low Negative Emotion Subjects: EDR 3.77 (p.<.01) SUDS 66.5 (n.s.) Lie Scale 20.7 (p.0001).

Thus, you could not see a difference in these two groups from their verbal report, their MMPI, or an interview. Their distress is out of mind [but not out of body].

We also studied Body Mass Index (weight related to height), which correlates highly with adiposity (Garrow, 1983). We used High Hypnotizable - High Neuroticism Subjects, compared to Medium Hypnotizable - Low Neuroticism Subjects. H-H BMI = 34.6 M-L BMI = 24.1 (significantly different, though preliminary results).

If you just use a correlation you won't see this result. You have to consider both hypnotizability and negative emotion together.

**COMMENTS FROM THE AUDIENCE:**

Question re Marlowe Crowne as a measure of defense.

Wickramasekera's answer: I believe it is orthogonal to hypnotizability and both are pathways to pathology. I look at both the Marlowe Crowne and Neuroticism.

Auke Tellegen: In Weinberger's research you need to see an interaction between test variables. I think you should view them independently, not assume an interaction.

Zamansky, Harold S.; Ruehle, Beth L. (1995). Making hypnosis happen: The involuntariness of the hypnotic experience. International Journal of Clinical and Experimental Hypnosis, 43 (4), 386-398.

The authors tested the hypothesis that hypnotized individuals do not truly experience their responses to suggestions as occurring involuntarily, but instead absorb themselves in imagery that is congruent with the suggestions while avoiding critical thoughts, or even simply comply with suggestions without genuinely experiencing their responses as nonvolitional. Participants were instructed to engage in thoughts and imagery that conflicted with the suggestions given, were urged to pay attention to their behavior, and were questioned regarding the perceived involuntariness of their responses. Simultaneously, electrodermal skin conductance responses provided a measure of the truthfulness of their reports. It was found that responses to all hypnotic suggestions were reported as being involuntary, in spite of the conflicting imagery and increased saliency, and that these reports were truthful. These findings provide disconfirming evidence for the sociocognitive theories of hypnosis.

1994

Kinnunen, Taru; Zamansky, Harold S.; Block, Martin L. (1994). Is the hypnotized subject lying?. Journal of Abnormal Psychology, 103, 184-191.

Do the verbal reports of deeply hypnotized Subjects truthfully reflect their subjective experiences of hypnotic suggestions? Exp 1 established that the electrodermal skin conductance response (SCR) provides an effective method for detecting deception in the laboratory equally well in hypnotized and nonhypnotized Subjects. In Exp 2, deeply hypnotized and simulating Subjects were administered a number of hypnotic suggestions in a typical hypnotic session, without mention of deception, and were questioned about their experiences while SCR measures were recorded concurrently. Results indicate that 89% of the hypnotized Subjects' reports met the criterion for truthfulness, whereas only 35% of the simulators' reports met this criterion. Implications for the theory of hypnosis are discussed.

Smith, Julien T. (1994). Hypnosis and distraction in the relief of medical pains in an ethnically diverse population of young children (Dissertation, Washington State

University, Pullman). Bulletin of Division 30, Psychological Hypnosis, APA, 4 (3), 11.

An ethnically diverse sample of children (N = 36) and their parents volunteered for the study and were trained, with the expectation of equal effects, to use both distraction and imaginative involvement to reduce pain and anxiety. Standardized measures of pain, anxiety and hypnotizability were obtained. Skin conductance response confirmed pain stimulation. Half the subjects used imaginative involvement first and the other half used distraction first. All procedures were video taped. Blind raters judged subjects' responses and subjects reported pain on a standardized scale. Data were collected at baseline, during two intervention sessions and at follow-up. Supporting Hilgard's neodissociation theory, hypnotizable subjects significantly reduced both subjective and objective pain and anxiety scores in response to hypnotic imagination involvement in contrast to low hypnotizable Ss. No significant effects were found for the distraction condition. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1995, Vol. 4, No. 3.)

#### NOTES

We did two studies on patients with chronic pain which was of severe or moderate intensity for 6 or more months, and was unresponsive to standard medical management.

#### STUDY 1.

We found that sorting patients into high, moderate, and low hypnotizable people, giving them cognitive stress (mental arithmetic), the groups differ. Highs, when not hypnotized, have a dose response relationship to the cognitive stress; they react stronger physiologically and take longer to return to baseline. We also found a relationship between hypnotizability and negative affect. Though their GSR is different, they don't perceive it (as measured by Subjective Units of Distress, or SUDS). We don't know what the relationship between these variables is like pre-morbidly however.

#### STUDY 1.

Predicting from High Risk Model. Predisposers [to illness], triggers (stress and hassles), and buffers interact.

There is evidence for a genetic component in hypnotizability, which is one of the predisposers. Male monozygotic twins  $r = .54$  Female monozygotic twins  $r = .49$  Male dizygotic twins  $r = .24$  Female dizygotic twins  $r = .08$  [May not have heard correct figure?]

Highs are at risk for illness because: 1. They can amplify or attenuate signals of threat. 2. They evidence surplus pattern recognition (see meaning in randomly distributed events). 3. They have surplus empathy (poor boundaries).

Lows are at risk for illness because: 1. They deny or attenuate the role of cognitive and emotional events on somatic symptoms. 2. They demonstrate rigidity in information processing.

Hypnotizability and electrodermal activity were studied in our first study. The highs are hypersensitive, like the princess and the pea. We obtained a statistically significant conditions effect (stress vs no stress) and hypnotizability x conditions effect.

#### STUDY 2.

We studied people high on both Hypnotizability and Negative Affectivity (a stable trait, with a genetic basis) or Neuroticism. This combination leads to problems. These people will amplify negative events. These two personality variables are orthogonal  $r = -.12$ . Tellegen et al, 1988, supports the genetic component. People high on Marlowe-Crowne have lower lifetime report of mental health symptoms. It too is orthogonally related to Hypnotizability.

We studied 138 chronic pain patients. We compared patients high on both hypnotizability and negative emotion to patients who had moderate hypnotizability and low negative affect. Electrodermal response (EDR) is 12.5 vs 3.7; SUDS is 63.5 vs 66.5 (indicating they had no perception of the electrodermal activity). The Lie score (Marlowe Crowne) is 17 vs 13. Patients high on both hypnotizability and negative emotion are more physiologically reactive than patients moderate on hypnotizability and low on neuroticism.

Out of mind (threat) is not out of body. If you give these people an MMPI or the Taylor Manifest Anxiety Scale you couldn't tell the difference between them.

The mechanisms we hypothesize can be used to block consciousness [by different means]: 1. High hypnotic ability (12-9) as in hypnotic analgesia 2. Low hypnotic ability (4-0) [Speaker didn't specify mechanism here.] 3. Repression (Negative emotion = 21 Lie = 67, a low Neuroticism score and high Marlowe Crowne suggest repression).

I focus on a group that is difficult to identify, the "somatacizer," because there is no identifying pathophysiology or psychopathology. To identify this type of patient we look at negative affect, coping skills, hypnotizability [missed notes on 3 other variables].

See recent paper in the journal \_Dissociation\_.

Wickramasekera, Ian (1994). Psychophysiological and clinical implications of the coincidence of high hypnotic ability and high neuroticism during threat perception in somatization disorders. American Journal of Clinical Hypnosis, 37, 22-33.

The electrodermal response to cognitive threat of un hypnotized female patients with somatic symptoms and high on both hypnotic ability and neuroticism (H-H) was found to be significantly higher ( $p < .01$ ) than that of a matched group of female patients moderate on hypnotic ability and low on neuroticism (M-L). On verbal report the H-H and the M-L groups did not differ, but they were significantly different on a measure of self-deception (L scale) or repression. The above findings are consistent with predictions from the High Risk Model of Threat Perception (HRMTP), which states that people in the H-H group are both chronically and

acutely more reactive to threat than the people in the M-L group. This finding may have important theoretical, clinical, and financial implications for the diagnosis, therapy, and prevention of somatization disorders seen in primary medical care.

Wickramasekera, Ian; Pope, Alan T.; Kolm, Paul (1994, August). Chronic pain, hypnotic ability and skin conductance level. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

The High Risk Model predicts that high hypnotic ability is a risk factor for the development of stress related psychophysiological disorders. It was hypothesized that greater threat perception as measured by skin conductance level (SCL) would be associated with higher levels of hypnotic ability. In a consecutive series of 118 adult patients with chronic pain symptoms, larger increases in SCL during cognitive stress were significantly related to higher levels of hypnotic ability. In addition, high hypnotic ability individuals retained higher SCL than low hypnotic ability individuals after stress. The clinical implications of high hypnotic ability for threat perception and recovery from threat perception are discussed in terms of cognitive mechanisms in the etiology and therapy of chronic stress related disorders. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall 1994, Vol. 3, No. 3.)

**Kinnunen, Taru; Zamansky, Harold S.; Block, Martin L. (1991, August). Is the hypnotized subject lying?. [Paper] Presented at the annual meeting of the American Psychological Association, San Francisco.**

To determine whether or not hypnotized subjects misrepresent or lie about their hypnotic experiences, electrodermal skin conductance responses were measured while groups of deeply hypnotized subjects and simulators responded to questions about their experiences to a series of suggestion. 89% of the responses of the hypnotic subjects met the criteria for truthfulness, while 65% of the responses of the simulators indicated deception. Differences between "reals" and simulators were highly significant. The relevance of the results for the nature and theory of hypnosis is discussed. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Provided by former Editor, James Council.) NOTES 1: This article is based on an Award Winning Paper presented at the American Psychological Convention in San Francisco, 1991.

**Russell, Christine; Davey, Graham C. (1991). The effects of false response feedback on human 'fear' conditioning. Behaviour Research and Therapy, 29 (2), 191-196.**

Describes a human electrodermal conditioning experiment in which 28 students (aged 19-30 yrs) were given false skin conductance feedback during conditioned stimulus/stimuli (CS) presentation. In comparison with attentional control groups, Ss who believed they were exhibiting a strong conditioned response (CR) did actually emit a greater magnitude CR, while Ss who believed they were exhibiting a weak CR emitted a lower magnitude CR. When both self-report and behavioral measures of unconditioned stimulus/stimuli (UCS) evaluation were taken after conditioning, response feedback (RFB) had not differentially affected Ss' evaluation of the aversiveness of the UCS. The response modulating effects of RFB may not be caused by RFB influencing evaluation of the UCS, but they are consistent with the hypothesis that beliefs about the nature of RFB influence the strength of the UCS representation itself.

**1990**

**Sturgis, Laura M.; Coe, William C. (1990). Physiological responsiveness during hypnosis. International Journal of Clinical and Experimental Hypnosis, 38, 196-207.**

Four physiological measures - electromyogram, respiration rate, heart rate, and skin conductance - were recorded for 11 high and 11 low hypnotizability Ss. It was hypothesized (a) that physiological responsiveness during hypnosis would vary depending on the nature of the task instructions, and (b) that high hypnotizability Ss would show more physiological responsiveness than low hypnotizability Ss. The first hypothesis was substantiated across all 4 measures. Only heart rate levels supported the second hypothesis. The results are discussed as they relate to the 1 hypotheses and to future research.

Wain, Harold J.; Amen, Daniel G.; Jabbari, Bahmann (1990). The effects of hypnosis on a Parkinsonian tremor: Case report with polygraph/EEG recordings. American Journal of Clinical Hypnosis, 33, 94-98.

Although Parkinsonian tremors typically disappear during sleep and are reduced during relaxation periods, the effects of hypnosis on this type of movement disorder have been generally ignored. We observed a patient's severe Parkinsonian tremor under hypnosis and monitored it with EEG and EMG studies. The patient was taught self-hypnosis and performed it three to four times daily in conjunction with taking medication. The results suggest that daily sessions of self-hypnosis can be a useful therapeutic adjunct in the treatment of Parkinsonian tremors. NOTES 1:

#### NOTES

The patient scored low on the Hypnotic Induction Profile scale of hypnotizability and was unable to experience any classical hypnotic phenomena, but was motivated to learn self-hypnosis. For self hypnosis he visualized a relaxing scene.

Griffiths, M. D.; Gillett, C. A.; Davies, P. (1989). Hypnotic suppression of conditioned electrodermal responses. Perceptual and Motor Skills, 69, 186.

#### NOTES

With 5 subjects who had previously been aversively conditioned to a stimulus, during hypnosis previously acquired electrodermal responses were found to be significantly lower than in 12 control Ss. Thus previously conditioned electrodermal responses were suppressed. This contradicts findings of Edmonston (1968) who found that neutral hypnosis does not influence conditioned electrodermal responses and the validity of Pavlov's (1927) conditioning (inhibition) theory of hypnosis.

#### 1988

Davies, Peter (1988). Some considerations of the physiological effects of hypnosis. In Heap, Michael (Ed.), Hypnosis: Current clinical, experimental and forensic practices (pp. 61-67). London: Croom Helm Ltd.

#### NOTES

This chapter reviews literature on physiological correlates of hypnosis, but these notes are limited to only one fact reported in the review. The author writes, 'A recently completed, and as yet unpublished study by C. Gillett and H. D. Griffiths at

Bradford University investigated the relation between hypnosis and classical conditioning of psychophysiological responses. In a complex design involving both normal conditioning and normal test trials and a repetition of both acquisition and test trials under hypnosis, they found not only suppression of the conditioned response but also suppression of skin conductance responses to the half-second bursts of a 115-dB tone used as the unconditioned stimulus. Not to produce a significant autonomic response to such an intrinsically aversive stimulus is a remarkable feat which is probably outside the repertoire of simulators. However, even such results are not conclusive as the design did not include simulator control groups nor even neutrally instructed non-hypnotized group' (pp. 64-65 ).

Gruzelier, John; Allison, James; Conway, Ashley (1988). A psychophysiological differentiation between hypnotic behaviour and simulation. International Journal of Psychophysiology, 6, 331-338.

Psychophysiological differentiation between conditions of hypnosis and simulation were examined with markers evolved from a series of experiments charting neuropsychophysiological accompaniments of hypnotic behaviour. Eighteen subjects participated in two sessions in which bilateral electrodermal activity was monitored to moderate intensity tones. Measurement in Session I, a Baseline-Control, of individual variation in rates of habituation of orienting responses, non-specific responses and tonic levels of skin conductance, enabled allocation of matched groups to Session II in which the same auditory stimuli were mixed with a taped hypnotic induction. Half the subjects were instructed to fake hypnosis and the others to comply. In session II the groups were differentiated as follows: (1) rate of habituation to the tones was retarded in the simulation condition and facilitated in the hypnosis condition compared with baseline; (2) the incidence of non-specific electrodermal responses was elevated in simulators after instructions to 'fake hypnosis'; (3) right-hand levels of skin conductance were elevated in simulators; (4) all but one subject in the hypnosis condition admitted to hearing the tones whereas all but one in the simulation condition claimed not to have heard them.

1987

Minichiello, William E. (1987). Treatment of hyperhidrosis of amputation site with hypnosis and suggestions involving classical conditioning. International Journal of Psychosomatics, 7-8.

Hyperhidrosis of an amputation site utilizing hypnosis and/or behavioral strategies has not been reported in the literature. This case report is on the successful use of hypnosis utilizing principles of classical conditioning in the treatment of a patient with hyperhidrosis of an amputated limb with two previous unsuccessful sympathectomies. The patient possessing moderate hypnotic ability as measured by the Stanford Hypnotic Clinical Scale (SHCS), reported a pre-treatment score of 10 on a 0-10 severity and intensity of sweating scale, and a post-treatment score of 0. All gains were maintained at the two-year follow-up.

NOTES

The patient was hypnotized while an electric fan was blowing on his stump and prosthesis. Direct suggestions were given according to procedures of thermal biofeedback. The suggestions were: 1. You will notice in days ahead that your stump feels increasingly cooler and drier. 2. You will feel throughout the day as if a cool breeze from a fan is blowing on your stump. 3. Whenever you pay attention to your leg during the day, particularly after the first few hours of the morning, you will associate that leg with a cool dry breeze from a fan blowing on it. 4. You will increasingly develop the power to cool and dry your stump.

The results were that 2 1/2 weeks later patient reported reduced frequency and intensity of sweating and significant healing of the stump ulcers; rating = 2. One month later, patient reported continued progress with almost normal skin color and stump condition; the patient discontinued disability, and returned to work. Patient returned one month later reporting, "It's cured and my physician can't believe it." Rating = 0.

Author concludes that hypnosis should be tried prior to more invasive traditional procedures. In this case two previous sympathectomies failed to correct the condition and a third sympathectomy was being contemplated.

Pereira, Robert Peter (1986, July). The role of organismic involvement in hypnotic emotional behavior (Dissertation, Wayne State University). Dissertation Abstracts International, 47 (1), 385-B. (Order No. DA8605027)

Two hundred college undergraduates were pretested via the Harvard Group Scale of Hypnotic Susceptibility: Form A. Fifty subjects scoring in the range 7-12 were designated as Reals, while 25 subjects scoring in the range 0-4 were designated as Simulators. Reals and Simulators were given differential instructions before the administration of a second hypnotic induction procedure, which was accompanied by a task in which subjects were asked to relive each of three emotional experiences, i.e., fear, anger, and happiness. Reals were given instructions encouraging cooperation, while Simulators were instructed to try to convince a group of experienced hypnotists that they were deeply hypnotized, when, in fact, they would not be. "Physiological, overt-behavioral, and cognitive measures taken either during or following the relived-emotions task served as indices of Sarbin's organismic involvement construct. A post-experimental measure of the realness of subjects' relived emotional experience was regressed on these organismic indices in order to test Sarbin's assumption of a positive linear relationship between organismic involvement and belief-in imaginings, using data from the Real group only. Results indicated that, across all three emotions, the linear composite of organismic indices shared statistically significant amounts of variance with the criterion of experiential realness. Obtained amounts of shared variance ranged from 22% (during anger) to 55% (during happiness). These findings were interpreted as offering clear and robust support for Sarbin's theory of hypnosis. Suggestions for further research were offered. "The question of Real-Simulator differences was explored through several multivariate analyses of variance and covariance, using the organismic indices as dependent variables. These analyses were performed on the original

sample of Reals and Simulators, and on two subsamples of Reals/Highs and Simulators/Lows which were created through the use of pre- and/or post-experimental exclusion criteria. Reals/Highs showed statistically higher levels of effort than did Simulators/Lows during all three emotions, as well as higher levels of skin conductance and finger temperature during anger. These findings were interpreted as being of theoretical and practical significance. Multiple replications of the physiological findings were recommended in order to assess the extent to which the skin conductance and finger temperature variables might be used in practical, i.e., forensic contexts" (p. 385-B).

1984

Holmes, David S. (1984). Meditation and somatic arousal evidence. American Psychologist, 39 (1), 1-10.

The conceptual and methodological issues associated with research on the effects of meditation are reviewed. A summary of the research in which the somatic arousal of meditating subjects was compared to the somatic arousal of resting subjects did not reveal any consistent differences between meditating and resting subjects on measures of heart rate, electrodermal activity, respiration rate, systolic blood pressure, diastolic blood pressure, skin temperature, oxygen consumption, EMG activity, blood flow, or various biochemical factors. Similarly, a review of the research on the effects of meditation in controlling arousal in threatening situations did not reveal any consistent differences between meditating and nonmeditating (no-treatment, antimediation, or relaxation) subjects. The implications of these findings for research and practice are discussed.

Venturino, Michael (1984, August). Perceptual monitoring and allocation of attention (Dissertation, University of Maine). Dissertation Abstracts International, 45 (2), 707-B.

The processing ability of perceptual monitoring was investigated using a dichotic listening and shadowing task. Individual differences in the effectiveness of perceptual monitoring were also investigated by using susceptibility to hypnosis as a grouping factor. Subjects' skin conductance response (SCR) was conditioned to specific words by an electric shock. These conditioned words, and words semantically and acoustically related to them were presented in the relevant and irrelevant messages of the dichotic listening and shadowing task. Probability and magnitude measures of SCRs and subjects' verbal shadowing accuracy were used to assess performance. SCRs to critical words were significantly greater than to control words in both the relevant and irrelevant messages. However, the SCRs to words in the irrelevant messages were not as great as those responses elicited to words in the relevant message. The pattern of responding to the semantically and acoustically related words was similar for both the relevant and irrelevant messages. Subjects low in hypnotic susceptibility responded to critical words with significantly greater probability and magnitude of response than did subjects high in hypnotic susceptibility. Analysis of the shadowing performance data showed that the

perceptual monitoring process was quite effective. The occurrence of the conditioned word in the irrelevant message caused a shift in attention to the irrelevant message, manifested by a shadowing error. Subjects shadowing the message in their left ear committed significantly more shadowing errors than subjects shadowing the message in their right ear. No differences in shadowing performance were obtained for the hypnosis factor. The results were interpreted in terms of the deployment of attention to the environment, and the relationship of this deployment to the perceptual monitoring process" (p. 707).

1983

Borgeat, Francois; Goulet, Jean (1983). Psychophysiological changes following auditory subliminal suggestions for activation and deactivation. Perceptual and Motor Skills, 56, 759-766.

This study was to measure eventual psychophysiological changes resulting from auditory subliminal activation or deactivation suggestions. 18 subjects were alternately exposed to a control situation and to 25-dB activating and deactivating suggestions masked by a 40-dB white noise. Physiological measures (EMG, heart rate, skin-conductance levels and responses, and skin temperature) were recorded while subjects listened passively to the suggestions, during a stressing task that followed and after that task. Multi-variate analysis of variance showed a significant effect of the activation subliminal suggestions during and following the stressing task. This result is discussed as indicating effects of consciously unrecognized perceptions on psycho- physiological responses.

1982

Barabasz, Arreed F. (1982). Restricted environmental stimulation and the enhancement of hypnotizability: Pain, EEG alpha, skin conductance and temperature responses. International Journal of Clinical and Experimental Hypnosis, 30, 147-166.

Restricted environmental stimulation procedures were used with 10 Ss. The Stanford Hypnotic Clinical Scale: Adult, modified to include a posthypnotic suggestion for an analgesic reaction, and pain threshold and tolerance tests were administered prior to restricted environmental stimulation technique (REST), immediately after REST, and 10-14 days later. Occipital EEG alpha, skin conductance, and peripheral, core, and chamber temperature data were collected prior to, during, and after REST. A control group of 10 Ss was used to assess the effects of repeated hypnosis upon susceptibility scores and demand characteristics of the experiment. Multivariate analysis of variance results showed SHCS and pain tolerance scores to be significantly enhanced for Ss exposed to REST immediately after and 10-14 days later. Orne's (1959) postexperimental inquiry technique did not reveal experimental demand characteristics which might account for the results. EEG alpha density increased significantly in REST, but the increase was not progressive during the REST period. The maintenance of hypnotizability and pain tolerance at follow-up failed to support Reyher's (1965) theory of brain function and

behavioral regulation. E. R. Hilgard's (1977) neodissociation interpretation combined with J. R. Hilgard's (1974, 1979) imaginative involvement findings is viewed as a possible explanation.

**Brende, Joel O. (1982). Electrodermal responses in post-traumatic syndromes: A pilot study of cerebral hemisphere functioning in Vietnam veterans. Journal of Nervous and Mental Disease, 170, 352-361.**

This paper summarizes the findings of a pilot study which found a relationship between the post-traumatic symptoms of a) psychic numbing, b) intrusive recollections of traumatic events, and c) hypervigilance and lateralization of electrodermal response (EDR) measurements in six victims of psychological trauma. Hypnotically induced imagery of past traumatic events was often associated with left-sided EDR increases, psychic numbing with left-sided EDR decreases or bilateral EDR unresponsiveness, and revivifications of hypervigilant states with right-sided EDR lateralization. In several cases control of the experience of fear was associated with left- sided or bilaterally decreased EDR. These pilot study findings support previously stated hypotheses: a) EDR obtained from an extremity reflects contralateral cerebral hemisphere functioning; b) left hemisphere functioning is associated with hypervigilance; and c) right hemisphere functioning is associated with emotions and imagery. In addition, the pilot study findings suggest additional hypotheses: a) Post- traumatic symptoms are associated with poorly controlled or integrated cerebral hemisphere functioning; b) psychic numbing and intrusive images, flashbacks, and nightmares are associated with abnormal activation, suppression, or integration of right hemisphere functioning in relationship to the left; c) aggressive behavior, hypervigilance, and character pathology are associated with abnormal activation, suppression, or integration of functioning of the left hemisphere function in relationship to the right; and d) "splitting" as a psychological defense in Vietnam veterans with Borderline Personality Disorders is associated with physiologically impaired interhemispheric integration.

#### **NOTES**

The authors report that previous research suggests that electrodermal asymmetry may be related to emotional factors. They further suggest that electrodermal responsiveness reflects contralateral cerebral hemispheric functioning, with lower GSR associated with higher activation of the opposite cerebral hemisphere (see Lacroix and Comper, 1979). They indicate that the right hemisphere, which is involved in experience of emotion, also is associated with depression (when there is abnormal inhibitory function of right hemisphere) and affective disorders. The left hemisphere is involved in vigilance (Dimond & Beaumont, 1974). "Based on these findings, the post-traumatic symptoms hypervigilance, anxiety, and behavior disorders appear to be associated with atypical left hemisphere activation, intrusive recollections of traumatic memories and disturbing emotional states with atypical right hemisphere activation, and psychic numbing or emotional unresponsiveness with diminished right hemisphere activation, or overactivation of the left hemisphere" (p. 354).

In this pilot study, the therapist, who used hypnosis in all but one case, interviewed the patient for 30-50 minutes, focusing on helping the S to recall experiences of a traumatic nature. The therapist was supportive when disturbing emotions were evoked, responding flexibly by monitoring S's anxiety and moving back and forth between uncovering and supportive techniques.

#### **SUMMARY**

There were observably variable changes and bilateral differences in EDR within each of the six subjects in relationship to varying verbal, emotional, and imagery content, postulated to reflect contralateral hemispheric functioning. These observed changes were considered conclusive evidence of such functioning in post-traumatic states" (p. 358). "1. Lateralization of EDR to the left is associated with unpleasant emotions and traumatic imagery. ... "2. Lateralization of EDR to the right is associated with hypervigilance and aggressive outbursts. ... "3. Psychic numbing is associated with inhibition of bilateral EDRs (for example, lack of bilateral EDR activation occurred in every case at times) or with suppression of the left EDR. ... "4. General physiological arousal, a normal response to fear, is associated with increased EDRs bilaterally. ... "5. Relaxation and the subjective experience of safety and well-being, which have been reported to foster interhemispheric integration in normal subjects ... were observed to be associated with bilaterally decreased EDR in case I, an example of a less severe post- traumatic condition, but not observed during attempts at relaxation in Vietnam veterans with more severe post-traumatic symptoms. "6. Voluntary efforts to cognitively control fear were related to left hemispheric functioning, as observed in case IV when the subject attempted to control intrusive thoughts with cognitive activity and in Case III following the revivification of a frightening event when he made a shift from the hypnotic trance state to waking cognitive activity. In both cases, such cognitive activity was associated with a decreased right-sided EDR" (p. 359).

**DISCUSSION:** "The results of this pilot study, which demonstrated frequent EDR differences between hands during subjects' recollections of or attempts to suppress recollections of prior traumatic experiences, alters the traditional belief that increased skin conductance is always a predictable physiological measurement when the electrode is placed on only one hand, as Lacroix and Comper (46) have pointed out.

"The finding of EDR lateralization is consistent with the findings of deBonis and Baque (10) who reported that the degree of anxiety determines the presence of lateralization of EDR responses, of Gruzelier and Venables (30, 32) and Myslobodsky and Horesh (53) who reported that the presence or absence of psychopathology determines the direction of the lateralized response, and of Lacroix and Comper (46) that activation of one hemisphere may suppress contralateral EDR" (p. 359)

Holroyd, Jean; Nuechterlein, Keith; Shapiro, David; Ward, Frederick (1982). Individual differences in hypnotizability and effectiveness of hypnosis or biofeedback. International Journal of Clinical and Experimental Hypnosis, 30 (4), 45-65.

8 high and 8 low hypnotizable Ss used biofeedback and hypnosis to lower blood pressure in one session and forehead EMG activity in another session. Results were analyzed by repeated measures analyses of covariance using baseline physiological level on the dependent variable as the covariate. Electromyographic level was reduced more immediately by biofeedback than by hypnosis. When the task was to lower blood pressure, blood pressure and skin conductance were more effectively reduced by hypnosis than by biofeedback, considering only the first half of each session to eliminate within-session transfer effects. Hypnotizability did not predict overall outcome. Factors which may have prevented demonstrating a clearer relationship between hypnotizability and success using biofeedback or hypnosis are discussed. State and trait anxiety, cognitive strategies used during the tasks, and self-reported hypnotic depth are examined for correlates of successful performance.

On the basis of alternative hypotheses in the literature, 9 invited Ss undergoing wintering-over isolation at Scott Base, Antarctica, were tested for EEG alpha and hypnotizability. 8-channels of EEG, bipolar skin conductance (SC) and hypnotizability data were collected at Scott Base prior to and following the wintering-over isolation. Significant increases in alpha density and hypnotizability were found in Ss following isolation. The previously reported relationship between simple eyes closed alpha density and hypnotizability was not found prior to isolation; however, this correlation approached significance following isolation. The possible influence of psychophysiological arousability on baseline EEG alpha records was considered. Correction of EEG records using SC indices of arousal resulted in a significant correlation between EEG alpha and hypnotizability following isolation. A tendency toward significance was evident in the pre-isolation, SC corrected, correlation. The significant influence of environment on EEG alpha and hypnotizability is discussed as is the use of SC arousal indices to enhance EEG alpha/hypnotizability correlations.

Parker, Jerry C.; Gilbert, Gary S.; Thoreson, Richard W. (1978). Reduction of autonomic arousal in alcoholics: A comparison of relaxation and meditation techniques. Journal of Consulting and Clinical Psychology, 46 (5), 879-886.

To investigate and compare the effects of progressive relaxation training and meditation training on autonomic arousal in alcoholics, 30 subjects were selected from a population of alcoholics in a Veterans Administration hospital substance-abuse program. The subjects were randomly assigned to one of the following three experimental conditions: (a) progressive relaxation training group, (b) meditation training group, or (c) quiet rest control group. All groups met for 3 weeks during which state anxiety, blood pressure, heart rate, and spontaneous galvanic skin responses were measured. The measures were designed to assess the treatment effects following the first training session and at the end of the total training period. The results indicate that both progressive relaxation training and meditation training are useful for reducing blood pressure in alcoholics. In addition, significant

differences between the groups in the effectiveness of the relaxation procedures were found. Meditation training induced blood pressure decreases at an earlier point in the 3-week training period and affected decreases in systolic blood pressure that progressive relaxation training did not. These results support the idea of considerable specificity of response to relaxation techniques.

Slutsky, Jeffrey; Allen, George J. (1978). Influence of contextual cues on the efficacy of desensitization and a credible placebo in alleviating public speaking anxiety. Journal of Consulting and Clinical Psychology, 46 (1), 119-125.

This investigation was designed to determine the extent to which contextual cues mediated the effectiveness of systematic desensitization and a plausible placebo in alleviating public speaking anxiety. After participating in a public speaking situation that allowed the collection of self-report, physiological, and behavioral manifestations of anxiety, 67 subjects were randomly assigned to receive five sessions of either desensitization, "T scope" therapy, or no treatment. Each of these conditions was conducted in a context that either stressed the clinical relevance of the procedure or presented the procedure as a laboratory investigation of fear without therapeutic implications. Analysis of changes both between groups and within individuals indicated that desensitization reduced public speaking anxiety in both contexts, whereas the placebo was effective only in the therapeutic setting. The superiority of desensitization was most pronounced on the physiological variables. The results are interpreted as indicating support for a counterconditioning, rather than an expectancy, interpretation of desensitization.

Weerts, Theodore C.; Lang, Peter J. (1978). Psychophysiology of fear imagery: Differences between focal phobia and social performance anxiety. Journal of Consulting and Clinical Psychology, 46 (5), 1157-1159.

Spider phobics and speech anxious subjects imaged fear scenes with spider and public-speaking content and a series of standard scenes that were constructed to vary in degree of emotional arousal and movement. Heart rate, skin conductance, and ocular activity were recorded. Spider phobics rated all imagery contents as more vivid and reported more scene movement than speech anxious subjects. Both groups responded to their own fear scenes with higher ratings of emotion and a greater physiological response than to the other group's fear scenes. The arousal response of spider phobics to relevant fear scenes was greater than that of speech anxious subjects. The data suggest that the outcome of imagery-based therapies may be partly determined by type of fear.

Lick, John R. (1975). Expectancy, false galvanic skin response feedback, and systematic desensitization in the modification of phobic behavior. Journal of Consulting and Clinical Psychology, 43 (4), 557-567.

**This study compared systematic desensitization and two pseudotherapy manipulations with and without false galvanic skin response feedback after every session suggesting improvement in the modification of intense snake and spider fear. The results indicated no consistent differences between the three treatment groups, although all treatments were significantly more effective than no treatment in modifying physiological, behavioral, and self-report measures of fear. A 4-month follow-up showed stability in fear reduction on self-report measures for the three treatment groups. Overall, the results of this experiment were interpreted as contradicting a traditional conditioning explanation of systematic desensitization. An alternate explanation for the operation of systematic desensitization emphasizing the motivational as opposed to conditioning aspects of the procedure is discussed.**

**1974**

**Bloom, Richard F. (1974). Validation of suggestion-induced stress.**

**Sixty college men, divided into three equal groups, each attended two induced stress sessions in which their physiological, psychological and performance reactions were measured. Their responses were compared to determine if valid stress reactions could be induced through suggestion in an altered state (in this case, hypnosis), and also to determine the validity of such reactions if the subject had never before experienced that stress situation. It was demonstrated that valid stress reactions can be induced in an individual with the aid of suggestions, especially if the real stress situation has been experienced before. If no previous experience with that real situation exists, the subject still exhibits stressful reactions; however, the closest resemblance to real stress is found in the subjective or psychological measures, less similarity is found in the physiological measures, and the least similarity is found in the performance measures.**

#### NOTES

Compared the effectiveness of relaxation, hypnosis, and a control condition in reducing in dental phobics the reaction to pressure-algometer stimulation and the injection of anesthesia. For subjects with high baseline skin-conductance levels, relaxation was most effective in reducing stress reactions. Hypnosis did not differ from the control condition. For subjects with a medium or low skin-conductance baseline, relaxation was not effective. The hypnosis group rated their treatment as most effective, and the controls rated their treatment as least effective. Five-month follow-up indicated that all subjects in the hypnosis group returned for dental treatment and that 5 of 10 in the control group and only 1 of the relaxation group returned for care.

Tart, Charles T. (1963). Hypnotic depth and basal skin resistance. International Journal of Clinical and Experimental Hypnosis, 11, 81-92.

This investigation studied the relationship between a self-report scale for measuring the depth of the hypnotic state and basal skin resistance (BSR). The self-report scale accurately predicted the occurrence of hypnotic dreaming and amnesia, traditional criteria for medium and deep hypnotic states. BSR showed a high, positive correlation with the self-report depth scale. The data suggest that both the self-report scale and BSR may be useful measures for detecting changes in hypnotic depth. Sutcliffe, J. P. (1960). 'Credulous' and 'sceptical' view of hypnotic phenomena. International Journal of Clinical and Experimental Hypnosis, 8 (1), 73-102.

The author distinguishes between 2 interpretations of hypnotic phenomena: the credulous (S does or does not experience what the hypnotist suggests) and the skeptical (S reports what is suggested regardless of the "reality" of his experience). 2 groups of Ss (distinguished with respect to the presence or not of genuine hypnotic behavior and posthypnotic amnesia) were placed in a 3 [control (not under hypnotic trance), hypnotic trance, nontrance acting (S asked to act as if conditions were as suggested)] by 2 (stimulus present or not) design involving paraesthesias, hallucinations, and delusional thinking. Evidence (such as GSR, interference in thinking due to feedback, test measures of delusion) suggests that S does not misperceive the real situation, but misreports it. #### Summary and Conclusions

"Six 'good' hypnotic Ss were given a ten-minute 'hypnotic induction' and a series of 'hypnotic tests.' Both basic skin conductance and momentary variations in skin conductance (GSR) were recorded during the experiment.

"The results were as follows:

1. There was no significant variation in skin conductance during the 'hypnotic induction procedure.'
2. Skin conductance generally increased throughout the remainder of the experiment, i.e., when the Ss were given suggestions of 'sensory hallucinations,' 'age-regression,' 'analgesia,' 'negative hallucinations,' and 'post'-hypnotic behavior.
3. The Ss usually showed a GSR when they were given 'hallucinatory' suggestions, i.e., when they were told that they were becoming 'itchy,' 'thirsty,' and 'very hot.'

4. The GSR to a pinprick was essentially the same before the experiment and during 'hypnotic analgesia.' Also, the GSR was essentially the same, during 'hypnotic analgesia,' (a) when three Ss were told they would receive a pinprick but did not receive the pinprick, (b) when they were told they would receive a pinprick and did receive the pinprick, and (c) when they received a pinprick without being told they would receive it.

5. Four Ss showed a GSR each time they were asked to look at a 'negatively hallucinated' object and person. Two Ss did not show a GSR when they were asked to look at the 'negatively hallucinated' object (or person). The four Ss who showed a GSR stated, during or after the experiment, that they were by no means convinced that the person or object was no longer in the room. The two Ss who did not show GSR stated, after the experiment, that they had been 'certain' that the object (or person) was not present in the room.

6. Although the Ss stated that they did not 'remember' the 'post'-hypnotic suggestion (or anything else about the experiment), they usually showed a GSR when the E made the preliminary movements to give the signal for the 'post'-hypnotic behavior. (They also showed a GSR when E gave the signal for the 'post'-hypnotic behavior.)

"Since skin conductance is an index of the S's level of 'activation,' 'arousal,' or 'excitation,' these results indicate the following:

1. Ss do not necessarily become more 'passive' or 'relaxed' during the 'hypnotic induction procedure.'

2. Ss often become more and more 'excited' and 'aroused' when they are given a series of 'active' suggestions such as 'sensory hallucinations,' 'age-regression,' etc.

3. Ss often show momentary 'excitement' when they are 'hallucinating.'

4. A pinprick can 'arouse' a S to the same extent during 'hypnotic analgesia' as it can during 'normal waking.' In addition, 'hypnotic analgesic' Ss are often just as much 'aroused' by the threat of a pinprick as they are by an actual pinprick.

5. Many Ss become momentarily 'excited' when they are asked to look directly at an object (or person) which they have been told they will not be able to see. However, some Ss do not show this momentary 'excitement.'

6. Although Ss may state that they do not 'remember' the 'post'-hypnotic suggestion, they often become momentarily 'excited' when the E makes preliminary motions to give the signal for the 'post'-hypnotic act" (pp. 90-92).

**Summary**

**"Blood and urine samples were obtained from 18 university students at the beginning and end of two experimental sessions, one with and one without hypnosis. Some of the subjects relaxed during the sessions; others imagined or hallucinated a traumatic experience.**

**"Of a variety of measurements made, urinary volumes and 17-ketosteroids, the eosinophil count and psychogalvanometer recordings appear to give useful information about any changes due to the hypnosis. The biochemical changes caused by the experimentally produced emotions seem to depend on the individual and his past experience rather than the hypnosis. The data suggest that if the experience hallucinated is known to the subject, the biochemical changes indicate a relaxed state during the hypnosis. The psycho-galvanometer recordings may indicate an agitated state while the biochemical indices suggest a relaxed state" (pp. 106-107).**

**Sears, Alden B.; Beatty, Jeanne M. (1956). A comparison of galvanic skin response in the hypnotic and waking state. Journal of Clinical and Experimental Hypnosis, 4 (2), 49-60.**

**Summary.**

**In this experiment an attempt was made to determine whether or not there was a difference in the galvanic skin response between waking and hypnotic questioning. The 24 subjects were randomly assigned to one of four groups, each group following a different sequence of experimental conditions. During the first session, each subject observed a table top setup for 30 seconds and then wrote out what he could remember in both the waking and hypnotic states. During the second session, which followed seven or eight days after the first, each subject was asked a series of 14 questions concerning the table top setup. Half of the subjects answered the questions first in the waking and then in the hypnotic state; for the remaining 12 subjects hypnotic questioning preceded waking questioning. The galvanic skin response was recorded for both the waking and hypnotic questioning of all subjects, and the**

amount of deviation was measured in millimeters. Because the subjects tended to respond more slowly during the hypnotic questioning than during the waking questioning, a direct comparison of the amount of deviation in the two states could not be made. Consequently, two indicators of amount of deviation were considered necessary: mean deviation per second (D/T) and the mean average deviation (D/ND). No significant differences were found between the waking and hypnotic questioning in a comparison of the mean deviation per second for the group and for the males alone. However, there was a difference between waking and hypnotic questioning in the mean deviation per second for females, significant at the .01 level of confidence. The difference between the waking and hypnotic measures of the mean average deviation were also not significant for either the total group or for the males. For females, this difference was significant at the .001 level of confidence. No attempt was made to explain this apparent sex difference in the behavior of the galvanic skin response. It was suggested that further research be done to confirm and account for these results. The differences between the results of male and female subjects in this experiment, where procedures were the same for both, may account for the conflicting reports found in the literature. In many of the reported experiments the sex of the subjects has not been noted" (pp. 57-58). The questions were factual in nature, e.g. "What object is in the lower right hand corner."

1952

West, Louis Jolyon; Niell, Karleen C.; Hardy, James D. (1952). Effects of hypnotic suggestion on pain perception and galvanic skin response. A. M. A. Archives of Neurology and Psychiatry, 68, 549-560.

A study is reported in which pain perception and galvanic skin responses of seven subjects were measured before and during hypnosis. The depths of hypnotic trance varied from light to deep. Stimuli of measured intensity were administered, and changes in pain threshold were measured. Quantitative estimates of pain intensity were made by the subjects. Alterations in ability to discriminate between pains of differing intensities were noted. Quantitative records of galvanic skin responses were utilized, permitting statistical analysis of data from matched pairs. Data were collected at 45 experimental sessions, during which a total of 478 painful stimuli were administered, the stimuli varying in intensity from threshold to blister-producing levels. At each session, the subject's sensations from and responses to stimuli during a control period were compared with sensations from and responses to identical stimuli administered after hypnotic suggestions of anesthesia. The following observations were made: 1. Hypnotic suggestions of anesthesia influence pain perception by causing elevation of pain threshold, hypalgesia, and analgesia. 2. When hypnotic suggestions of anesthesia caused hypalgesia and elevation of pain threshold, ability to discriminate among stimuli of different intensities was impaired. 3. There was a general correlation between the depth of hypnotic trance and the degree to which pain perception was altered by hypnotic suggestion. 4. The galvanic skin response to noxious stimulation was diminished, and it sometimes disappeared, as a result of hypnotic suggestions of anesthesia. The galvanic skin

response was affected even when there was no alteration in pain perception, according to subjective reports. NOTES 1:

NOTES: The authors review literature on the effects of analgesia suggestions on the galvanic skin response and other autonomic nervous system responses. The present study differs from previous studies in the following ways: "1. The subjects were studied in various stages of hypnosis. 2. Quantitatively determined noxious stimuli were used instead of pinching or pinprick. 3. Changes in pain threshold were measured. 4. Quantitative estimates of pain intensity were made by the subject in the hypnotized and the un hypnotized state. 5. Changes in ability to discriminate between pains of differing intensity were noted. 6. Quantitative records of galvanic skin responses in the control and in the hypnotized state were utilized" (p. 552).

Analgesia was defined as "that state in which none of the noxious stimuli administered were reported as painful;" hypalgesia was defined as "a state in which noxious stimuli were reported as less painful than would be expected on the basis of reports of the same subject regarding the same stimuli in control situations" (p. 554).

In their Discussion, the authors state, "As a result of hypnotic suggestions of anesthesia, the following effects on sensation were observed: (1) no alteration in reports of pain intensity; (2) hypalgesia for higher-intensity stimuli without elevation of the pain threshold; (3) definite elevation of pain threshold with hypalgesia; (4) analgesia; (5) disturbances in pain discrimination.

" The third effect was observed in the majority of trials. The threshold elevation in light trances may be similar to that which can be produced by suggestion in the un hypnotized subject, but in deeper trances the effectiveness of hypnotic suggestion is much greater. The progression of effects 1 through 4 appears to be directly related to the depth of trance. The fifth effect was variable and was seen only in conjunction with the third effect. It is described as a separate phenomenon because the disturbance of ability to discriminate relatively between stimuli of differing intensities was only clearly observed when we were remeasuring pain thresholds. In actuality, it may merely represent a facet of altered pain perception, and the variability of its appearance may be related to the variable psychological state of the subject. It must be kept in mind that the hypnotic trance is not a static state" (p. 558). For one Subject, analgesia decreased in successive hypnotic sessions, while for four Subjects analgesia increased; a sixth Subject exhibited overall variability in hypnotic depth and analgesia from session to session.

The authors indicate that their review of the literature found no evidence that hypnosis, absent suggestions for analgesia, affects the galvanic skin response. In the present study, diminishment of the GSR is related to, though not dependent on, the effectiveness of the suggestion of anesthesia. "Thus, in Subject 2, with only moderate hypalgesia, the GSR to noxious stimuli was diminished by 64%; in S 6, with analgesia on nearly all trials, only 57%. It is particularly interesting that S 1 had a reduction in GSR of 26% after hypnotic suggestions which apparently had no effect upon his pain perception, and which seemed even to make him anxious. S 5 showed a direct correlation between depth of trance and decrease of GSR while Subjects 6 and 7 showed no such correlation" (p. 559).

"It is important to realize that on some occasions hypnotic anesthesia apparently led to complete disappearance of the GSR to all stimuli during a given session, such stimuli evoking pain of 6 or 7 dols in the control period. This phenomenon was seen twice with Subject 3, twice with Subject 5, and once with Subject 6. In several trials there was only a very slight GSR to the higher stimuli during hypnosis. In all the control periods there was only one occasion on which a stimulus evoking pain of 6 or 7 dols failed to produce a GSR, while equally intense stimulation failed to produce a GSR on 14 occasions after hypnotic suggestions of anesthesia. This observation is stressed because it suggests a need for caution in the clinical use of the GSR to distinguish organic from hysterical anesthetics" (pp. 559-560).

## GASTROENTEROLOGY

1996

Spiegel, Sharon B. (1996). Uses of hypnosis in the treatment of uncontrollable belching: A case report. American Journal of Clinical Hypnosis, 38 (4), 263-270.

Uncontrollable belching is frequently benign in origin, but can be distressing in its psychosocial consequences. Physicians have little to offer in the way of medical treatment. This is a case report of a 71-year-old woman with incessant eructation of four months duration treated with brief psychotherapy utilizing hypnosis. The patient was symptom-free at termination, and this improvement was sustained at six month follow-up. This paper includes a detailed description of some of the hypnotic suggestions as well as a discussion of the factors that may have contributed to change.

1992

Chantler, Lisa J. (1992). The treatment of irritable bowel syndrome using hypnosis. Australian Journal of Clinical and Experimental Hypnosis, 20, 39-47.

A single case is reported of the hypnobeavioural treatment of a patient with chronic irritable bowel syndrome. The success of this treatment suggests that it has potential over and above relaxation and other behavioural techniques alone.

Whorwell, P. J.; Houghton, L. A.; Taylor, E. E.; Maxton, D. G. (1992). Physiological effects of emotion: Assessment via hypnosis. Lancet, 340, 69-72.

Studied the effects of distal colonic motility of three hypnotically induced emotions (excitement, anger, and happiness) in 18 patients, aged 20-48, with irritable bowel syndrome. Colonic motility index was reduced by hypnosis on its own ( $p < .05$ ), and this change was accompanied by decreases in both pulse and respiration rates ( $p < .001$  for both). Anger and excitement increased the colonic motility index ( $p < .01$  for both), pulse rate and respiration rate ( $p < .001$  for both). Happiness further reduced colonic motility although not significantly from that observed during hypnosis alone. Changes in motility were mainly due to alterations in rate in amplitude of contractions. The results indicate that hypnosis may help in the

investigation of the effects of emotions on physiological functions. The finding that neutral hypnosis strikingly reduces fasting colonic motility may partly explain the beneficial effects of hypnotherapy with functional bowel disorders.

**1991**

Schwarz, Shirley P.; Blanchard, Edward B. (1991). Evaluation of a psychological treatment for inflammatory bowel disease. Behaviour Research and Therapy, 29 (2), 167-177.

Compared the effectiveness of a multicomponent behavioral treatment package, which included inflammatory bowel disease (IBD) education, progressive muscle relaxation, thermal biofeedback, and training in use of cognitive coping strategies, with the effectiveness of symptom-monitoring as a control condition. The treatment group consisted of 11 IBD patients (aged 25-62 yrs); 8 of 10 persons (aged 25-71 yrs) in the control group completed treatment. At posttreatment, the treatment group showed fewer reductions in symptoms (5) than the symptom-monitoring controls (8). However, treated Ss perceived themselves as coping better with IBD and as feeling less IBD-related stress. It is hypothesized that the differences in treatment responses may be related to differences between Ss with ulcerative colitis and Ss with Crohn's disease.

Whorwell, P. J. (1991). Use of hypnotherapy in gastrointestinal disease. British Journal of Hospital Medicine, 45, 27-29.

Recent controlled studies in the field of gastroenterology have shown that hypnotherapy is unequivocally beneficial in conditions such as irritable bowel syndrome and peptic ulceration. There is also some evidence for influence on certain physiological functions. Further research should help to define more clearly the role of this controversial form of therapy. NOTES 1:

#### NOTES

This is a summary of work the authors are doing in gastroenterology. The authors are doing pilot work with inflammatory bowel disease and also ulcerative colitis. Patients are given an idea of the pathophysiology. "First subjects are asked to place a hand on their abdomen and feel warmth and then to relate this sensation to the relief of pain, spasm, bloating etc. Second they are asked to visualize a river and imagine that it is their gut. They are then told to modify the flow in order to achieve a more satisfactory bowel habit. For instance it would be suggested to a subject with loose bowels that a fast-flowing river with broken water is changed into a much more slow, smoothly flowing one. To the trainee therapist these suggestions sound very unconvincing but they do seem to work.

"Patients often take many weeks to respond and this can be very testing for the resolve of both patient and doctor alike. Some patients seem to adopt a very passive approach to treatment, expecting the therapy to work rather akin to taking a tablet-they attend once a week and wait for something to happen." (p. 29). [They have to be taught that they must make the treatment work for themselves.]

1990

Prior, A.; Colgan, S. M.; Whorwell, P. J. (1990). Changes in rectal sensitivity after hypnotherapy in patients with irritable bowel syndrome. Gut, 31, 896-898.

Fifteen patients with irritable bowel syndrome were studied to assess the effect of hypnotherapy on anorectal physiology. In comparison with a control group who received no hypnotherapy, significant changes in rectal sensitivity were found in patients with diarrhoea-predominant irritable bowel syndrome both after a course of hypnotherapy and during a session of hypnosis ( $p < .05$ ). Although patient numbers were small, a trend towards normalization of rectal sensitivity was also observed in patients with constipation-predominant syndrome. No changes in rectal compliance or distension-induced motor activity occurred in either subgroup nor were any changes in somatic pain thresholds observed. The results suggest that symptomatic improvement in irritable bowel syndrome after hypnotherapy may in part be due to changes in visceral sensitivity. NOTES 1:

#### NOTES

This research involved 15 patients diagnosed with irritable bowel syndrome (IBS), which was defined as abdominal pain with abdominal distension and 'an altered bowel habit'--10 had diarrhea mostly and 5 had constipation mostly. Patients with this disease usually have an exaggerated colon sensitivity to many different stimuli, as well as lower threshold to a balloon inflated in the bowel for diagnostic purposes. The patients were treated with ten sessions of hypnosis, 30 minutes each, over a three month period. Dependent variables included self ratings of abdominal pain, abdominal distention, and 'bowel habit disturbance.' Each of the three variables received a score of 0-10; the total score therefore could range from 0-30.

Other ratings were obtained using the inflation of a rectal balloon as stimulus. "After a basal period of at least 15 minutes the rectal balloon was serially inflated with air at intervals of 1 min in 20 ml increments up to 100 ml and then in 50 ml increments up to the sensation of discomfort. The study was repeated after a rest period of 15 minutes. After hypnotherapy the S was restudied first in the waking state and then, after 15 min, following induction of hypnosis" During this procedure they measured balloon volume, rectal compliance (a function of volume and pressure), and presence or absence of repetitive rectal contractions.

In order to learn whether the analgesia being experienced in the rectal or bowel area transferred to other areas, patients experienced cold water immersion induced pain on one hand, for a measure of time until discomfort was felt (pain threshold, essentially).

The control group of 15 patients diagnosed with IBS received the same measures of balloon volume, rectal compliance, and presence or absence of repetitive rectal contractions.

The total symptom score (which might have ranged 0-30) dropped from 23.5 to 9.6, and 13 of the 15 patients rated their symptoms as much improved. The two Ss who did not experience improvement also did not return for the assessment using the

balloon. Therefore, the physiological assessment included only 13 Subjects, the ones who rated themselves as 'improved.'

"In patients with diarrhoea-predominant irritable bowel syndrome a decreased rectal sensitivity occurred after hypnotherapy which was significant for the sensations of gas and urgency. This was most pronounced in patients who could initially tolerate only small rectal balloon volumes (Fig 1). During hypnosis the results for rectal sensitivity in the diarrhoea-predominant group were similar to those noted after the course of hypnotherapy but were of a greater magnitude, reaching significance for all sensations (Fig 2).

"In the constipation-predominant Subjects there was a tendency for rectal sensitivity to move towards normal values both after the course of hypnotherapy and during hypnosis. Patient numbers in this subgroup were small, however, and the changes were not significant (Figs 1 and 2). Rectal compliance and distension induced motor activity were unaffected by hypnotherapy in both the diarrhoea and constipation- predominant patients" (p. 897).

It was noted that of patients who had manifested depression and/or anxiety (8 of 13), most showed psychological improvement--3 of them to a great degree--but there was no correlation between psychological improvement and the degree that visceral sensitivity was diminished. Also, the ten sessions of hypnotherapy did not affect length of time subjects could tolerate hand immersion in cold water.

"In the control group of 15 patients with the irritable bowel syndrome who did not receive hypnotherapy no changes in rectal sensory or motor parameters occurred when manometry was repeated on the same day or on a second study day nine to 12 weeks later (Table II)" (p. 897).

In their Discussion, the authors remark that "hypnotherapy seemed to produce a trend towards normalization of visceral sensitivity (Figs 1 and 2). This was most pronounced in the patients with diarrhoea-predominant irritable bowel syndrome who initially had particularly low sensation thresholds" (p. 898).

They continue, "The pathophysiological abnormalities which lead to the symptoms of the irritable bowel syndrome remain unclear. The increased visceral sensitivity found in the large [7-9] and small intestine [18, 19] in some patients with the irritable bowel syndrome may contribute to their perception of pain. In addition, an increase in rectal sensitivity might also contribute to the symptoms of urgency and frequency of defecation seen in many patients with diarrhoea-predominant irritable bowel syndrome. ... Hypnotherapy also induces an improvement in well being by increasing coping capacities, and may therefore decrease perceived stress" (p. 898).

"The present study suggests therefore that hypnotherapy might operate by a variety of mechanisms in patients with the irritable bowel syndrome. In those with visceral hypersensitivity it seems to alter the perception of rectal sensation, although the mechanism by which this is achieved is unknown. Modification at a cortical level or more locally along afferent pathways are possibilities. This does not, however, explain the symptomatic improvement in all subjects and hypnotherapy is probably also acting in a non-specific psychotherapeutic sense" (p. 898).

Schwarz, Shirley P.; Taylor, Ann E.; Scharff, Lisa; Blanchard, Edward B. (1990). Behaviorally treated irritable bowel syndrome patients: A four-year follow-up. Behaviour Research and Therapy, 28 (4), 331-335.

A 4-yr longitudinal study evaluated 19 patients (aged 23-60 yrs) suffering from Irritable Bowel Syndrome (IBS) who had completed a multicomponent treatment involving progressive muscle relaxation, thermal biofeedback, cognitive therapy, and IBS education at baseline. 17 Ss rated themselves as more than 50% improved. Six of the 12 Ss who submitted symptom monitoring diaries met the criteria for clinical improvement, (i.e., achieving at least a 50% reduction in primary IBS symptom scores). The means on all measures at long-term follow-up were lower than those obtained prior to treatment. When follow-up symptom means were compared with pretreatment means, significant reductions were obtained on abdominal pain/tenderness, diarrhea, nausea, and flatulence.

1989

Harvey, R. F.; Hinton, R. A.; Gunary, R. M.; Barry, R. E. (1989). Individual and group hypnotherapy in treatment of refractory irritable bowel syndrome. Lancet, 1 (8635), 424-425.

Thirty-three patients with refractory irritable bowel syndrome were treated with four 40-minute sessions of hypnotherapy over 7 weeks. Twenty improved, 11 of whom lost almost all their symptoms. Short-term improvement was maintained for 3 months without further formal treatment. Hypnotherapy in groups of up to eight patients was as effective as individual therapy. NOTES 1: NOTES:

DISCUSSION: The mechanisms by which hypnotherapy improves symptoms of IBS remain unclear. A placebo effect alone is unlikely, because few patients who improved on hypnotherapy suffered a relapse after formal treatment ended at 7 weeks; many patients continued to improve after the end of formal treatment. There was no disproportionate improvement in the feeling of wellbeing of patients who improved, and most of the patients who became nearly symptom-free had no initial tension or anxiety, as judged by GHQ scores. This suggests that the treatment is not just producing a psychological effect.

The effects... were less striking than those reported by Whorwell and colleagues. Nevertheless, the results were encouraging because all 33 had been refractory to conventional medical treatment."

Klein, Kenneth B.; Spiegel, David (1989). Modulation of gastric acid secretion by hypnosis. Gastroenterology, 96, 1383-1387.

NOTES

"The ability of hypnosis to both stimulate and inhibit gastric acid secretion in highly hypnotizable healthy volunteers was examined in two studies. In the first, after basal acid secretion was measured, subjects were hypnotized and instructed to imagine all aspects of eating a series of delicious meals. Acid output rose from a

basal mean of 3.60 to 6.80 ... with hypnosis, an increase of 89% ( = .0007). In a second study, subjects underwent two sessions of gastric analysis in random order, once with no hypnosis and once under a hypnotic instruction to experience deep relaxation and remove their thoughts from hunger. When compared to the no-hypnosis session, with hypnosis there was a 39% reduction in basal acid output ... and an 11% reduction in pentagastrin-stimulated peak acid output ...  $p < .05$ . We have shown that different cognitive states induced by hypnosis can promote or inhibit gastric acid production, processes clearly controlled by the central nervous system. Hypnosis offers promise as a safe and simple method for studying the mechanisms of such central control."

Tosi, D. J.; Judah, S. M.; Murphy, M. A. (1989). The effects of a cognitive experiential therapy utilizing hypnosis, cognitive restructuring, and developmental staging in psychological factors associated with duodenal ulcer disease: A multivariate experimental study. Journal of Cognitive Psychotherapy, 3, 273-290.

This study evaluated the effects of a Cognitive Experiential Therapy (CET)--in the past referred to as Rational Stage Directed Hypnotherapy--Cognitive Restructuring (CR), Hypnosis Only (HO), and a no-treatment control condition on the duodenal ulcer syndrome. CET is a systematic, stage-directed therapy that employs hypnosis and the cognitive restructuring of self-defeating cognitive, emotional, physiological, and behavioral tendencies. Seven criterion variables were assessed using two standardized instruments and questionnaire data. The standardized instruments included the Millon Behavioral Health Inventory (MBHI) and the Common Beliefs Survey III (CBS). Twenty-five volunteer duodenal ulcer patients were subjects in a 4 x 3 factorial design with repeated measures consisting of the four treatments and pretest, posttest, and follow-up. There was a significant treatment effect, and effects were observed on personality coping styles, beliefs and locus of control scales, and on gastrointestinal disturbance. CET appeared to have an ameliorative effect on psychological factors associated with duodenal ulcer.

1988

Colgan, S. M.; Faragher, E. B.; Whorwell, P. J. (1988, June 11). Controlled trial of hypnotherapy in relapse prevention of duodenal ulceration. Lancet, 1299-1300.

30 patients with rapidly relapsing duodenal ulceration were studied to assess the possible benefit of hypnotherapy in relapse prevention. After the ulcer had healed on treatment with ranitidine, the drug was continued for a further 10 weeks during which time patients received either hypnotherapy or no hypnotherapy. The two randomly selected groups were comparable in terms of age, sex, smoking habits, and alcohol consumption. Follow-up of both groups of patients was continued for 12 months after the cessation of ranitidine. After 1 year, 8 (53%) of the hypnotherapy patients and 15 (100%) of the control subjects had relapsed. The results of this study suggest that hypnotherapy may be a useful therapeutic adjunct for some patients with chronic recurrent duodenal ulceration.

**NOTES:**

"The aetiology of duodenal ulceration is poorly understood but it is probably multifactorial. ... Stress, both psychological and physical, has since been shown to affect gastric emptying and the secretion of acid and pepsin, but attempts to causally link stress and peptic ulcer disease have produced conflicting results.

"Hypnotherapy can modify the response to betazole-stimulated gastric acid secretion, although the mechanism by which this is mediated remains unclear" (p. 1299).

"The active [treatment] group received 7 sessions of hypnotherapy and were given an audio tape for daily autohypnosis; the other group were seen as often, but did not receive any hypnotherapy. The ranitidine was then stopped and both groups were reviewed every 3 months for a further year, with the active group receiving hypnotherapy at their follow-up visits. All subjects had an endoscopy at the end of the study, or sooner if a symptomatic relapse occurred.

"Hypnosis was induced as previously described, with attention focused on the abdomen by the use of the patient's hand. They were asked to imagine warmth beneath the hand and to relate this to the control of gastric secretion. Reinforcement by visualization was used if the patient had this ability" (p. 1299).

At the end of a year, on follow up, the patient relapse rate was 53% and controls relapse was 100%, a difference significant at  $p = 0.01$ .

In their Discussion, the authors state, "This study shows that hypnotherapy is helpful in maintaining remission in those patients with duodenal ulceration who are particularly prone to relapse. ... In this model, hypnotherapy might operate at a variety of levels in the disease process: it could act in a nonspecific psychotherapeutic sense increasing 'coping' capacities and decreasing perceived stress. Alternatively, hypnotically induced relaxation may affect gastric acid secretion, and there is some experimental evidence for this.

"The early relapse rate in the hypnotherapy subjects was similar to that of controls, but subsequently the curves showed a much greater separation. This finding could indicate that there is a subgroup of subjects who are particularly responsive to therapy. However, a detailed review of psychological and clinical parameters did not reveal any specific feature that could be used to predict a response to this form of treatment" (pp. 1299-1300).

**NOTES**

**2:**

Current etiology of duodenal ulcers includes the presence of bacteria *Helicobacter pylori* which is important in relapse. In order to compare treatments we must know what is the status of each group regarding the presence of this bacteria. Current treatment of duodenal ulcer includes metronidazole, amoxicillin and tetracycline to kill it. [Editor's Note: This appears to be a critique of the research methodology rather than notes on the article itself.]

**1984**

Whorwell, P. J.; Prior, Alison; Faragher, E. B. (1984, December 1). Controlled trial of hypnotherapy in the treatment of severe refractory irritable-bowel syndrome. Lancet, 1232-1234.

30 patients with severe refractory irritable-bowel syndrome were randomly allocated to treatment with either hypnotherapy or psychotherapy and placebo. The psychotherapy patients showed a small but significant improvement in abdominal pain, abdominal distension, and general well-being but not in bowel habit. The hypnotherapy patients showed a dramatic improvement in all features, the difference between the two groups being highly significant. In the hypnotherapy group no relapses were recorded during the 3-month follow-up period, and no substitution symptoms were observed.

Schneck, Jerome M. (1977). Hypnotherapy for ptyalism. International Journal of Clinical and Experimental Hypnosis, 25, 1-3.

This paper furnishes a description of brief hypnotherapy with a comment on theory in the case of a 56-year-old man suffering from ptyalism (excessive salivation). He was able to obtain considerable, but not complete relief.

1966

Zane, M. D. (1966). The hypnotic situation and changes in ulcer pain. International Journal of Clinical and Experimental Hypnosis, 14 (4), 292-304.

This is a study of internal and external hypnotic conditions associated with changes in pain developed during 5 hypnosis sessions in a patient with an acute duodenal ulcer. The 12 increases and 8 decreases in pain studied were found to be related to the interaction of coexisting reactions directed toward shifting social and private goals. Pain was associated with conflict among these reactions; intensification of pain occurred as a train of self-propagating internal events increased the conflict; relief of pain accompanied a reduction in the conflict. Increasing bodily disorganization resulted as shifts in focus of attention among social and private goals resulted in the rapid growth of conflicting mental and physical processes. An external stimulus, in the form of a highly individualized hypnotic suggestion, was often required to stop the disorganizing processes.

Dorcus, Roy M.; Goodwin, Phillip (1955). The treatment of patients with the dumping syndrome by hypnosis. Journal of Clinical and Experimental Hypnosis, 3 (4), 200-202.

#### NOTES

Psychological tests (MMPI and Manifest Anxiety Scale) were administered to 20 duodenal ulcer patients with successful outcome following subtotal gastrectomy and 20 with an outcome characterized by "one or more of the following symptoms: lack of appetite, aversion to food, aversion to particular kinds of food, nausea, vomiting, dizziness, sweating, cardiac palpitation, weakness, and weight loss" (p. 200). Since the symptoms are supposedly due to food passing more rapidly through the digestive tract the syndrome is called "dumping."

In the unsuccessful outcome group, four patients with symptoms persisting 8-26 months, received hypnosis (2 to 9 sessions). "The suggestions were directed towards

reducing tension (production of relaxation), removal of fear of this condition, enhancing the olfactory qualities of food, and the feeling of comfort with food or liquid intake" (p. 201). All four patients responded with remission of symptoms.

**1954**

**Kline, Milton V. (1954). Stimulus transformation and learning theory in the production and treatment of an acute attack of benign paroxysmal peritonitis. Journal of Clinical and Experimental Hypnosis, 2 (1), 93-98.**

#### **Summary**

A case episode from the hypnoanalysis of a patient with benign paroxysmal peritonitis has been presented to illustrate the nature of stimulus transformation in symptom formation and maintenance. Perceptual distortion and the role of the perceptual system in facilitating stimulus transformation has been discussed. Hypnotherapeutic intervention was based upon the awareness of the role of perceptual alteration in facilitating differential response and was effective in terminating the attack in its original form and in experimental revivification.

The autonomous factor in learning has been discussed in relationship to the drive for activity and reinforcement and resistance to all possible forms of spontaneous or planned retroactive inhibition. Resistance in neurosis possesses the essentials of all well established learned responses -- strength against extinction. Psychotherapy as a new learning experience will be resisted on a Gestalt basis -- dynamically and neurally. The recognition of the role of involuntary neuropsychological mechanisms in the development and maintenance of neurotic learning is essential in the planning and study of those remedial efforts which we term psychotherapy" (pp. 97-98).

#### **NOTES**

Patient was 30 year old male who had experienced pain attacks since age 10, usually running a course of 3-4 days and requiring bed rest and sedation. With hypnoanalysis attacks were reduced to 3/year. In the therapy excerpt presented, in age regression it was established that an (unconsciously) significant event occurred at a different time than was consciously remembered, and accounted thereby for the onset of an attack.

**1953**

**Kroger, William S. (1953). Hypnotherapy in obstetrics and gynecology. Journal of Clinical and Experimental Hypnosis, 1 (2), 61-70.**

#### **Author's Summary**

"A high percentage of gynecologic complains [sic] are due to psychic factors. Therapeutic efforts, therefore, must be directed primarily toward the psychologic component. Until recently, the principal weapon of the dynamically oriented physician was orthodox psychoanalysis. However, the increased interest for a relatively rapid approach has demonstrated the diagnostic and therapeutic value of hypnoanalysis. This development has been concomitant with the psychoanalyst's [sic] interest in 'brief psychotherapy' and narcosynthesis.

"In many functional gynecologic disorders, hypnoanalysis has supplanted the parent therapy even though this form of treatment utilizes the concepts of dynamic psychiatry.

"The relevant literature on the use of hypnotherapy in functional obstetrical and gynecological disorders has been reviewed.

"Significant areas for research have been pointed out.

"This review emphasizes that hypnosis *per se* is only of value in obtaining symptomatic relief. On the other hand, hypnoanalysis elicits the responsible dynamics behind the symptom, and is effective in reaching all aspects of the personality.

"Hypnoanalysis will be more applicable in obstetrics and gynecology when there is a wider acceptance of its techniques" (p. 68).

## GENDER

2000

Lichtenberg, P.; Bachner-Melman, R.; Gritsenko, I.; Ebstein, R. P. (2000). Exploratory association study between catechol-O-methyltransferase (COMT) high/low enzyme activity polymorphism and hypnotizability. American Journal of Medical Genetics, 96, 771-774.

Only recently have studies of electrocortical activity, event-related potentials, and regional cerebral blood flow begun to shed light on the anatomical and neurobiological underpinnings of hypnosis. Since twin studies show a significant heritable component for hypnotizability, we were prompted to examine the role of a common, functional polymorphism in contributing to individual differences in hypnotizability. A group of 109 subjects (51 male, 58 female) were administered three psychological instruments and tested for the high/low enzyme activity COMT val/met polymorphism. We observed a significant correlation between hypnotizability measured by the Stanford Hypnotic Susceptibility Scale (SHSS:C), ability to partition attention (Differential Attentional Processes Inventory or DAPI), and absorptive capacities (Tellegen Absorption Scale or TAS). The effect of COMT on the various dependent variables was initially examined by multivariate analysis that corrects for multiple testing. The dependent variables were SHSS:C hypnotizability scores, four attentional subscales of the DAPI, and TAS total score grouped by the COMT genotype (val/val, val/met, met/met) as the independent variable. Hotelling's Trace statistic was significant when scores were grouped by the COMT genotype (Hotelling's  $T^2 = 1.88$ ,  $P = 0.04$ ). Post-hoc testing using the Bonferroni correction shows that the only significant difference is between the val/met vs. the val/val COMT genotypes on hypnotizability. This association was significant for men but not for women. As for all case-control studies, these results need to be interpreted cautiously and require replication.

1999

Daniel, Sheryll (1999). The healthy patient: Empowering women in their encounters with the health care system. American Journal of Clinical Hypnosis, 42 (2), 108-114.

Many women's expectancies when they assume the role of patient include the experiences of regression, helplessness, passivity and fear. This paper describes techniques for interrupting this negative set and for facilitating the development of a self-efficacious state in which the woman experiences herself as an active and informed participant in her encounters with medical personnel.

#### NOTES

We did a study that follows the line that volunteers may differ from nonvolunteers for hypnosis experiments (Authors cite 3 studies, including one with Hilgard as later author; Brodsky; Zamansky). Also, Ss who volunteer early in the quarter at the university are motivated for hypnosis; later volunteers want course credit. The former want to experience hypnosis.

Previously we did a study on authoritative vs permissive suggestions with Ss who volunteered early or late in the quarter; Ss were tested twice. For Ss who volunteered in first 2 weeks of the quarter, scores decreased across testing; for Ss volunteering late, scores remained stable across testing. This implies that if an experiment were conducted late in a quarter we would conclude that repeated testing has no effect; if done earlier, we would have concluded repeated testing decreases scores.

This result has been replicated. It is therefore important to run Ss across an entire quarter or year.

The present study differs from the foregoing study. It addresses the question: Do life events affect scores on the Harvard Scale? Do tension, uncertainty, etc. affect scores? Would they depress scores? Are scores reactive to environmental events?

On January 14 the U.S. issued an ultimative to Iraq; that very day we administered a tape recorded version of the Harvard Scale of Hypnotic Susceptibility, preceded by the Tellegen Absorption Scale. The hypnotizability tests were self-scored for involvement and involuntariness. Tension throughout the day escalated, culminating with bombing 2 hours before the hypnosis screening. The graduate student announced war had started and told Ss they could leave if they wanted. All 52 Ss stayed!

Control group was 58 Ss tested at same time of the quarter, one year before (10 days into the quarter).

Analysis was by a 3 x 2 ANOVA. There was no main effect for time of testing, sex, or interaction for any measures on hypnotizability, or subjective involvement.

The Tellegen Absorption scale showed a significant timing x sex interaction: males on outbreak of war scored lower than all other groups (15 vs 21 or more for all other groups). Tensions had no effect on subjective or objective scores of

hypnotizability. Thus the males were affected on the Absorption Scale by outbreak of war.

The fact the Tellegen Scale was more reactive suggests hypnotizability may be more stable than Absorption. Absorption might have been depressed because males were more upset by images of military services.

Little research has been conducted to examine the possible positive effects on hypnotizability of positive events in real life.

1991

Persinger, M. A.; Makarec, Katherine (1991-92). Interactions between temporal lobe signs, imaginings, beliefs and gender: Their effect upon logical inference. Imagination, Cognition and Personality, 11, 149-166.

Rotton's Paralogic Test, Wilson-Barber's Inventory of Childhood memories and Imaginings (ICMI) and the PPI (Personal Philosophy Inventory) were administered to 100 male and 100 female university students. Both sexes displayed moderately strong (0.50) correlations between content-selected and factor analyzed clusters of possible temporal lobe signs, exotic beliefs and the numbers of childhood imaginings. Although there were no sex differences between the accuracy of logical statements that contained paranormal or neutral content, males who displayed more temporal lobe signs were more accurate for logical items that contained paranormal content. Females who displayed more imaginings were more accurate for valid than for invalid items. Accuracy for items with paranormal content increased with exotic beliefs but not with conservative religious beliefs for both sexes. The relationship between exotic beliefs and accuracy for items with paranormal content was especially strong for females. These results suggest: 1) gender differences in the neurocognitive processes that contribute to logical problem solving and 2) accuracy may depend upon the degree to which the subject matter is commensurate with the person's history of enhanced temporal lobe signs, capacity for fantasy and imaginings and beliefs in exotic concepts. NOTES 1:

#### NOTES

Review of related literature indicates that Personal Philosophy Inventory (PPI) temporal lobe signs are correlated with temporal lobe EEG alpha but not occipital lobe alpha (Makarec & Persinger, 1990), with increased suggestibility (Persinger & DeSano, 1986; Ross & Persinger, 1987), with creativity and proneness towards fantasy (Persinger & DeSano, 1986; Ross & Persinger, 1987; Makarec & Persinger, 1987), and with reports of psi experiences and beliefs in such things as reincarnation and aliens in UFOs ('exotic themes') (Persinger & Makarec, 1987; Persinger & Makarec, 1990).

This experiment was designed to answer four questions: " 1) Do imagery and temporal lobe signs emerge from the same source of variance?; 2) Do males and females differ significantly in their incidence of imaginings and temporal lobe signs?; 3) Do males and females differ in their ability to solve logical problems?; and 4) Is the accuracy of problem solving affected by the subject matter of the problem and the problem solver's temporal lobe signs and capacity for imagery?" (p. 151).

The PPI consists of 140 true-false items that were selected with a goal of discerning temporal lobe signs within a normal population. One 30-item subscale has items that are similar to experiences reported by patients with verified electrical foci in the temporal lobes, albeit milder (the TLS or temporal lobe sign scale). Of these 30 items, 16 refer to ictal-like experiences (the CPES, or complex partial epileptic signs), and 14 refer to interictal-like behaviors (ILB). CPES items are items like "Sometimes an event will occur that has special significance for me only," and "While sitting quietly, I have had uplifting sensations as if I were driving over a rolling road." ILB items are items like "People tell me I blank out sometimes when people are talking," and "When I lose an argument I spend a lot of time thinking about what I should have said."

Wilson and Barber's Inventory of Childhood Memories and Imaginings (ICMI) has 52 true-false items that include reports of paranormal experiences (5 items), moderate imaginings (18 items) such as 'When I was a child I enjoyed fairytales,' and extreme imaginings (15 items) such as 'When I was a child or teenager, at times I was afraid my imagining would become so real to me that I would be unable to stop it.'

Rotton's Paralogic Test [unpublished, at Florida International University, Miami] has 16 syllogisms, each with major premise, minor premise, and conclusion. "The person must decide if the argument is valid ( $n = 8$ ) or invalid ( $n = 8$ ). Half of each of the valid and invalid arguments refer to mundane material while the other half of the arguments refer to paranormal-related material. An example of the former is 'If a president is a crook, he would be impeached; Congress did not impeach Nixon. Therefore Nixon is not a crook' and 'If flying saucers really existed, somebody would have photographed one. Nobody has ever photographed a flying saucer. Therefore, flying saucers do not exist'" (p. 153).

Correlations were computed separately for males and females. Both groups increased in accuracy for paranormal items as their belief in things like reincarnation and UFOs ('exotic concepts') increased. Males with a higher number of temporal lobe signs demonstrated more accuracy for logic test items with paranormal (psi) content than logic test items with mundane content.

"The single most important correlation was between exotic beliefs and the interaction term for the Rotton scale; the coefficient was unusually strong (0.54) and highly statistically significant ( $p < 0.001$ ) for females only. Because of the manner in which the interaction term was calculated, this correlation meant that females who reported more exotic beliefs were also more accurate for valid items that contained paranormal content only" (p. 159).

In their Discussion, the authors write, "The significant positive correlations between exotic beliefs and the clusters of CPES items and extreme Wilson-Barber imagining items are expected associations according to Bear's concept of sensory-limbic hyperconnectionism [Temporal Lobe Epilepsy: A Syndrome of Sensory-Limbic Hyperconnectionism, Cortex, 15, pp. 357-384. It would predict that concepts (or word trains) that are unusual, strange or infrequent would be charged with emotional significance and personal value. Ideas that generate substantial imagery, such as time- travel, reincarnation and alien intelligence, would be particularly prone to this affective infusion from limbic sources.

Induction of such unique or intensified affective states, especially during childhood, would facilitate the development of more frequent or more extreme periods of dissociation in the adult. We have collected (unpublished) clinical evidence to suggest that the emergence of this pattern is found in the propensity for creative thinkers, including writers, poets, musicians, artists and scientists, to have had developmental histories that could have promoted temporal lobe lability without overt seizure activity; clusters of such "promoters" include mild physical abuse, febrile episodes, minor head injuries and likely hypoxic periods during extreme physical exertion (competitive athletics)" (pp. 161-162).

Another conclusion of the study is that males and females do not differ in their accuracy in solving syllogisms, but "the neurocognitive processes, as inferred from inventories of temporal lobe signs or childhood imaginings, by which the two sexes arrive at solutions may be quite different" (p. 162).

Loewenstein, R. J.; Putnam, F. W. (1990). The clinical phenomenology of males with multiple personality disorder: A report of 21 cases. Dissociation, 3, 135-143.

#### NOTES

There are striking similarities between male and female MPD patients, but males tend to have more alcoholism and antisocial behavior and have more subtle clinical presentations.

Lombard, Lisa S.; Kahn, Stephen P.; Fromm, Erika (1990). The role of imagery in self-hypnosis: Its relationship to personality characteristics and gender. International Journal of Clinical and Experimental Hypnosis, 38 (1), 25-38.

30 volunteer Ss practiced self-hypnosis for approximately 4 weeks and wrote a record of their experiences in a diary following each session. Imagery produced during self-hypnosis was coded in 2 ways: the imagery was either reality oriented or it was fantastic and had primary process qualities. Levels of imagery production remained virtually the same over a 4-week period. Self-hypnotic imagery was significantly greater for the female Ss than for the male Ss, particularly primary process imagery. Verbal expressivity (measured as the average number of words per page of each S diary) was calculated to control for the effects of verbal production on Ss' imagery scores. When imagery scores were standardized based on verbal expressivity, female Ss still produced significantly more primary process imagery than male Ss. Personality characteristics (assessed by standardized personality inventories) were examined in relation to self-hypnotic imagery. "Impulse Expression" was positively related to primary process imagery for the female Ss. "Outgoingness" was positively related to primary process imagery for the entire sample, but especially for the female Ss.

Weekes, John R.; Lynn, Steven Jay (1990). Hypnotic suggestion type, and subjective experience - the order-effects hypothesis revisited: A brief communication. International Journal of Clinical and Experimental Hypnosis, 38, 95-100.

In a replication and extension of Field, Evans, and Orne's (1965) research, no support was found for the hypothesis that suggestion order is related to hypnotic responding. Confirming earlier findings, subjects were no more responsive to suggestions ordered from easy-to-difficult than they were to suggestions ordered from difficult-to- easy. Measures of subjective involvement in suggestions, involuntariness, and archaic involvement with the hypnotist were no more sensitive to order effects, nor were order effects more apparent with subjects who received direct versus indirect suggestions. Confirming earlier research, direct suggestions did facilitate suggestion-related involuntariness and response to the hypnotic amnesia item after cancellation, whereas indirect suggestions enhanced fears of negative appraisal by the hypnotist. Thus, authoritative suggestions enhance responding to a cognitive-delusional item relative to more permissive suggestions. Finally, female subjects were more involved in suggestions than were males, particularly in response to more difficult tests items.

1988

Barrett, D. (1988). Trance-related pseudocyesis in a male. International Journal of Clinical and Experimental Hypnosis, 36 (4), 256-261.

Pseudocyesis has been linked in previous literature to trance phenomena. The present paper presents a case in which pseudocyesis was accidentally induced by hypnotic suggestion, continued by an autohypnotic process, and reversed by informal suggestion. This case has important implications for the role autohypnosis may play in maintaining the phenomenon and for the usefulness of hypnotic techniques in reversing the symptoms.

Spinhoven, Philip; Baak, Diana; Van Dyck, Richard; Vermeulen, Peter (1988). The effectiveness of an authoritative versus permissive style of hypnotic communication. International Journal of Clinical and Experimental Hypnosis, 36, 182-191.

The differential effectiveness of an authoritative versus permissive style of hypnotic communication was investigated, with locus of control as a moderator variable. 44 Ss received in counterbalanced order both the more authoritatively worded Harvard Group Scale of Hypnotic Susceptibility, Form A and the Wexler-Alman Indirect Hypnotic Susceptibility Scale (WAIHS), which is a more permissive scale with the same item content as HGSHS:A. Permissively worded suggestions did not enhance the level of hypnotic responsiveness. Locus of control did not predict the response level on one of the scales. Unexpectedly, significantly more female Ss preferred the WAIHS, and more male Ss preferred HGSHS:A. It is concluded that Ss' characteristics (i.e., hypnotizability) are more important for hypnotic responsiveness than variations in style of hypnotic communication or scale preference."

1986

Zilbergeld, Bernie; Edelstien, M. Gerald; Araoz, Daniel L. (1986). Hypnosis - Questions & Answers. New York NY: Penguin Books.

The editors requested experts in hypnosis to answer common questions that resulted from questionnaires given to over 600 health professionals who had taken a course in hypnosis during the previous three years, as well as a few questions suggested by colleagues. "We do not view this book as providing right answers, but instead as something clinicians can turn to when they have questions or want to learn how a recognized authority handles a particular issue. There are, in fact, no right answers, no one-and-only best way" (p. xviii).

1987

De Sano, Christine F.; Persinger, M. A. (1987). Geophysical variables and behavior: XXXIX. Alterations in imaginings and suggestibility during brief magnetic field exposures. Perceptual and Motor Skills, 64, 968-970.

12 male and 12 female volunteers were evaluated for their suggestibility before and after an approximately 15-min. exposure to either sham, 1-Hz or 4-Hz magnetic fields that were applied across their mid-superior temporal lobes. During the field application subjects were instructed to view a green light that was pulsating at the same frequency as the field and to imagine countering an alien situation. Results were commensurate with the hypothesis that weak brain-frequency fields may influence certain aspects of imaginings and alter suggestibility. NOTES 1: NOTES: "Subjects who had been exposed to the 4-Hz fields showed a significant decrease ... in heart rate compared to those who had been exposed to either the 1 Hz or sham-field conditions. A significant ... interaction of sex by field ... was noted for the change in HIP [Hypnotic Induction Profile] scales. Whereas both men and women in the sham-field condition tended to show less induction (~ 1 unit) on the second occasion ... women showed much greater (8.4 + 1.1) induction (= 3 units) if they had been exposed to the 1-Hz field while men showed much greater (8.0 + 1.5) induction (= 3 units) if they had been exposed to the 4-Hz fields. On the protocols, women reported significantly more fear responses than men. In addition, subjects who were exposed during the imaginings to the 4-Hz field showed more imaginings ... and more references to vestibular experiences (e.g., self or entity rising or floating) ... than those exposed to the other conditions" (p. 969).

"Dissociation scores on the HIP were correlated significantly ... with vestibular (0.44), imagery (0.43), and fear (-0.45) scores from the transcripts. Floating responses on the HIP were correlated with the amount of imagery. (0.46). There was a significant positive Pearson correlation between the compliance measure and the amount of arm levitation during the second induction only. These results suggest that hypnotic susceptibility may be increased following magnetic-field exposure but that the effective frequency is not the same for each sex. In addition, the amount of the imagery (particular vestibular experiences) increased if the person observed a light that was flashing at the same frequency as a 4-Hz applied magnetic field" (p. 969).

Lynn, Steven Jay; Neufeld, Victor; Matyi, Cindy L. (1987). Inductions versus suggestions: Effects of direct and indirect wording on hypnotic responding and experience. Journal of Abnormal Psychology, 96 (1), 76-79.

This study examined the effects of direct wording (authoritative language, specific responses) versus indirect wording (permissive language, choice of responses) of hypnotic inductions and suggestions in measures of behavioral and subjective responding. Subjects experienced suggestion-related involuntariness and suggested effects to a greater degree in response to direct-word suggestions (Harvard Group Scale of Hypnotic Susceptibility; Form A; Shor & Orne, 1962) than in response to indirect-worded suggestions (Alman-Wexler Indirect Hypnotic Susceptibility Scale; Pratt, Wood, & Alman, 1984). No difference in behavioral responding was observed. Furthermore, induction wording did not have an effect on these measures, nor did the wording of the induction and the wording of the suggestion types interact with each other. Female subjects attributed less of their responsiveness to their own efforts when they received direct suggestions, and male subjects were less likely to attribute their responsivity to the hypnotist's ability when they received indirect suggestions. Rapport with the hypnotist did not vary as a function of induction or suggestion wording.

Monteiro, Kenneth P.; Zimbardo, Philip G. (1987). The path from classroom seating to hypnotizability--a dead end: A brief communication. International Journal of Clinical and Experimental Hypnosis, 35, 83-86.

It has been proposed that classroom seating behavior predicts brain functioning involved in hypnotizability and in other cognitive processes. The present authors attempted to test this hypothesis and to replicate some earlier findings. The relationships between classroom seating preference, actual seating location, and hypnotizability in male and female students were investigated. No relationship was found between any of the seating measures and hypnotizability. These findings lend no support for the hypothesis that classroom seating predicts hypnotizability. This failure to replicate is discussed in relationship to the lack of theoretical grounding for the seating-hypnosis connection. NOTES 1:

#### NOTES

The authors review the literature, then present and test specific hypotheses that right-side seating preferences would be correlated with hypnotizability for males, while actual seating on the right side of the class would be associated with higher hypnotizability scores for females. This pattern should be more robust for right-handed than for left-handed students. They found no support for these hypotheses. They suggest that other measures of cognitive processing may correlate with a social behavior such as classroom seating. Monteiro & Zimbardo (unpublished ms.) found that the variables of field independence and field sensitivity predicted actual seating behavior in males and seating preference in females.

1985

Bliss, Eugene L.; Larson, Esther M. (1985). Sexual criminality and hypnotizability. Journal of Nervous and Mental Disease, 173, 522-526.

Investigated 33 17-35 yr old sexual offenders, 18 of whom had been convicted of rape, 9 of pedophilia, and 6 of incest. Ss completed a questionnaire containing a list of 15 factors that might have contributed to their crime, a self-report containing 305 items that are symptoms characteristic of 11 major psychiatric syndromes, and the Stanford Hypnotic Susceptibility Scale. Controls for the self-report were 48 individuals taken from a church group, nurses, technicians, and graduate students. Controls for the hypnotizability scale were cigarette smokers who smoked 1 1/2 pack/day and S data taken from the literature. Results show that two-thirds of the Ss had histories of spontaneous self-hypnotic experiences (dissociations); 7 of these were DSM-III multiples and 6 were probable multiples. This group had very high hypnotizability scores. The other one-third without histories of spontaneous self-hypnosis had normal scores. It is concluded that spontaneous self-hypnosis contributed to the perpetration of the crimes in many of these cases, although other factors also directed the antisocial behaviors. (22 ref).

1983

Johnson, Lynn S.; Dawson, Steven L.; Clark, Janet Lee; Sikorsky, Catherine (1983). Self-hypnosis versus hetero-hypnosis: Order effects and sex differences in behavioral and experiential impact. International Journal of Clinical and Experimental Hypnosis, 31, 139-154.

Recent studies (Fromm, Brown, Hurt, Oberlander, Boxer, & Pfeifer, 1981; Johnson, 1979, 1981; Johnson & Weight, 1976; Ruch, 1975) of self-hypnosis versus hetero-hypnosis are compared. A study is reported addressing unresolved questions about interactions between order of presentation and sex with the 2 types of hypnosis. 90 male and 149 female volunteer college students were proportionally assigned to 1 of 4 groups, each of which received 1 of the following hypnosis-order combinations on successive days: self hypnosis, then hetero-hypnosis; hetero-hypnosis, then self-hypnosis; self-hypnosis, then another self-hypnosis; or hetero-hypnosis, then another hetero-hypnosis. Half of each group of Ss had a male hypnotist; half had a female hypnotist. Analysis of variance of total scores for behavioral and experiential impact showed: (a) a general order effect, a decrease from first to second experience; (b) initial self-hypnosis to facilitate either subsequent experience, mitigating the general decrement; (c) switching modes to also reduce the decrement; (d) a clarification of certain order and sex interactions from earlier studies; (e) self-hypnosis to be behaviorally superior to hetero-hypnosis on later presentations; and (f) crossed-sex training to be experientially facilitory. Conclusions are drawn about unresolved issues in self hypnosis research, including the limits of comparability of self-hypnosis versus hetero-hypnosis, which depend on definitional assumptions of the self-hypnosis state and the allowance for order effects in the design. NOTES 1:

NOTES

In their Discussion, the authors note that self hypnosis and heterohypnosis yield similar results, and that although clinical hypnosis effects may increase with practice, such would probably not be true for hypnosis in the experimental setting. They speculate that "self-hypnosis triggers an 'active involvement' which provides more continuity in responsiveness across experiences, while hetero- hypnosis encourages a more passive mode which is more susceptible to external events (like order effects)" (p. 150).

**1981**

**Yanchar, R. J.; Johnson, H. J. (1981). Absorption and attitude toward hypnosis: A moderator analysis. International Journal of Clinical and Experimental Hypnosis, 29 (4), 375-382.**

2 factors which have been found to correlate to a small degree with susceptibility are (a) an individual's attitude toward being hypnotized and (b) an individual's capacity for subjective involvement in an experience (absorption). The present study was an attempt to replicate previous findings by Spanos and McPeake (1975) and to extend these findings to determine if there was a significant interaction between these 2 factors in their relationship to susceptibility. 99 Ss (65 females and 34 males) completed the absorption questionnaire of Tellegen (1979) and the attitude questionnaire of Barber and Calverley (1966). Their hypnotic susceptibility was assessed with the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962). Attitude and absorption were found to have small positive correlations with susceptibility, results which corroborate previous research. The multiple regression analyses indicated that there were no significant interactions between the factors of attitude, absorption, and sex.

**1978**

**Nichols, Michael P.; Bierenbaum, Howard (1978). Success of cathartic therapy as a function of patient variables. Journal of Clinical Psychology, 34 (3), 726-8.**

Treated sample of 42 patients with cathartic psychotherapy and evaluated differential effectiveness on types of patients. Patients without mental disorders experienced more emotional catharsis than all others, and those with obsessive compulsive personality disorders improved more than all others as a result of emotive treatment. Contrary to popular notions, neither women nor hysterics experienced more catharsis or improved more in cathartic therapy. Although women and hysterics may cry more easily in daily life, obsessives are apparently more able to maintain focus on unhappy experiences and are therefore able to express more emotion in cathartic therapy. Furthermore, it seems that cathartic treatment is beneficial by disrupting long-standing defenses against emotional experience, rather than by releasing stored-up affects.

**1976**

Coe, William C. (1976). Effects of hypnotist susceptibility and sex on the administration of standard hypnotic susceptibility scales. International Journal of Clinical and Experimental Hypnosis, 24, 281-286.

Hypnotists' susceptibility and sex were examined for their effects on the administration of the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & Hilgard, 1962). Neither resulted in different hypnotic responsiveness from Ss. Comparatively inexperienced hypnotists obtained data similar to the normative sample for the Stanford scale. The results suggest that inexperienced hypnotists are capable of administering standardized scales validly, and that characteristics of the hypnotist are relatively ineffective in distorting Ss' responses to these scales.

1975

Aletky, Patricia J.; Carlin, Albert S. (1975). Sex differences and placebo effects: Motivation as an intervening variable. Journal of Consulting and Clinical Psychology, 43 (2), 278.

NOTES

The present findings would suggest that future studies of placebo effects should take into account the nature of the dependent variable and the pertinent differential sex-role expectations" (p. 278). The performance measure was a dynamometer pull task. The placebo was a jelly applied to the forearm "and alleged to relieve muscular fatigue" (p. 278). The motivational instructions were telling Subjects that "individuals in good health and with normal muscle tonus would be expected to show improved performance on the posttreatment trial" (p. 278).

1970

Fromm, Erika; Oberlander, Mark I.; Gruenewald, Doris (1970). Perceptual and cognitive processes in different states of consciousness: The waking state and hypnosis. Journal of Projective Techniques and Personality Assessment, 34, 375-387.

Hypnosis was assumed to influence perceptual and cognitive functioning in the direction of increased primary process ideation and adaptive regression. The Rorschach test was administered to 32 Ss in the waking state and under hypnosis in counterbalanced order. Hypnosis was induced by a standardized procedure. Ss received identical instructions for the Rorschach in both conditions. Protocols were scored according to Holt's system for manifestations and control of primary process. Hypnotic Rorschachs showed an increase in primary process manifestations, but no changes in defensive and coping functioning, and no overall changes in the Adaptive Regression Score. However, the nature of the data was found to be influenced by Ss' sex and level of adjustment. NOTES 1:  
NOTES: The authors used High hypnotizables (SHSS>9) in this investigation.

1966

Cooper, Leslie M.; London, Perry (1966). Sex and hypnotic susceptibility in children. International Journal of Clinical and Experimental Hypnosis, 14, 55-60.

Sex differences in hypnotic susceptibility were investigated in a sample of 240 children. The Children's Hypnotic Susceptibility Scale was administered to 10 boys and 10 girls at each age level for 5-16 yr. There were no differences between the means of the boys and girls at any age for the 3 scores yielded by the measure. The percentage passing each item at each age for each sex was also computed. Of the resulting 264 comparisons only 1 (Item 10, Eye Catalepsy) was found to be significantly different at 1 age level (7 yr. of age) and was attributed to chance. It was concluded that there were no sex differences for the various items at the ages tested. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1965

Beigel, Hugo G. (1965). Three transvestites under hypnosis. International Journal of Clinical and Experimental Hypnosis, 13 (2), 71-82.

The literature on transvestism is reviewed. Most authorities agree that it is rarely, if ever, treated successfully. A therapeutic approach is outlined which combines conventional analytically-oriented psychotherapy with appropriate hypnotherapeutic techniques. 3 illustrative cases are presented. Clinical study in the manner described has been proved effective in less than 50 sessions in 10 of the 24 cases seen. It has helped to clarify the etiology of this condition. The widely accepted belief that transvestism cannot be treated successfully appears unwarranted in the light of the findings presented. (18 ref.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1964

Melei, Janet P.; Hilgard, Ernest R. (1964). Attitudes toward hypnosis, self-predictions, and hypnotic susceptibility. International Journal of Clinical and Experimental Hypnosis, 12, 99-108.

Correlation of questionnaire results from a sample of 1326 students with hypnotic susceptibility scores of 340 of these later hypnotized showed (a) that those volunteering for hypnosis were more favorable in attitude than those who did not volunteer; (b) attitudes toward hypnosis were predictive of susceptibility for females, not for males; and (c) self-predictions yielded significant low positive correlations with actual susceptibility for both sexes. Other findings concern differences between those having prior experience with hypnosis and those without such experience. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Rosenhan, D. L.; Tomkins, S. S. (1964). On preference for hypnosis and hypnotizability. International Journal of Clinical and Experimental Hypnosis, 109-114.

44 male and 44 female coerced volunteers, who either preferred or did not prefer to participate in hypnosis experiments, were compared with regard to (a) scores on the

EPPS, (b) birth order, and (c) performance on the Harvard Group Scale of Hypnotic Susceptibility. Sex-specific personality differences were obtained between Ss who preferred and did not prefer hypnosis, but these personality differences were not apparently relevant to hypnotizability. However, for females, preference for hypnosis correlated .41 with hypnotizability; for males no relationship was obtained. Some theoretical and methodological implications of these data are discussed. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1963

Deckert, G. H.; West, L. J. (1963). The problem of hypnotizability: A review. International Journal of Clinical and Experimental Hypnosis, 11, 205-235.

This paper summarizes the relatively unsuccessful effort to relate hypnotizability to sex, age, psychiatric diagnoses, suggestibility, and various personality traits. The problems of measurement, subject selection, controls, and experimenter bias are reviewed. Comparison of data is difficult and replication of studies infrequent. This might be attributed to incomplete reporting of methodology, defects in experimental design, and various conceptual problems. Concepts which view hypnotizability as "something" universal, "something" unique, or "nothing" are briefly appraised. Finally, hypnotizability is seen as a "term" describing a relationship between a "route" and a "state"--each identifiable by measurable criteria. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Levitt, Eugene E.; Hershman, Seymour (1963). The clinical practice of hypnosis in the United States: A preliminary survey. International Journal of Clinical and Experimental Hypnosis, 11 (1), 55-65.

A preliminary survey of 301 clinical practitioners of hypnosis who responded to a questionnaire suggests that reported success in inducing hypnosis is unrelated to claimed experience with hypnosis. Children and adolescents are reported to be more susceptible than adults, but there is no sex difference reported. Type of training is generally unrelated to reported success as a hypnotist. Reported percentages of patients who attain various levels of hypnotic depth are generally in keeping with earlier reports. Unexpected reactions to being hypnotized were reported by one out of four respondents.

Levitt, Eugene E.; Lubin, B. (1963). TAT card '12MF' and hypnosis themes in females. International Journal of Clinical and Experimental Hypnosis, 11, 241-244.

Modification of TAT Card 12M, so that the supine figure was a female, did not increase the frequency of hypnosis themes among sophomore student nurses. The hypothesis that difficulty in identifying with a male figure accounted for the card's inability to predict attitudes towards hypnosis in females was, therefore, not supported. The modified card did elicit significantly more identifications of the standing figure as a professional person. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Levitt, Eugene E.; Lubin, Bernard; Brady, J. P. (1962). On the use of TAT Card 12M as an indicator of attitude toward hypnosis. International Journal of Clinical and Experimental Hypnosis, 10 (3), 145-150. (Abstracted in Psychological Abstracts, 63: 5233)

This investigation indicates that responses to TAT Card 12M do not predict attitude toward hypnosis in female Ss, though such predictiveness has been reported for male respondents. The basis for this differential predictiveness may be that the latter give a significantly greater proportion of themes involving hypnosis. An explanatory hypothesis, based on perceptual theory and the stimulus properties of the card, is advanced. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

McCartney, James L. (1961). A half century of personal experience with hypnosis. International Journal of Clinical and Experimental Hypnosis, 9, 23-33.

#### NOTES

(Author's Summary and Conclusions). "After fifty years of experience with hypnosis, it is evident that it is not a superficial and careless technic but should be utilized only by capable, trained physicians, as are the other complex and difficult medical technics. ... In order to induce hypnosis, the patient must be perfectly willing to be hypnotized, he must have confidence in the practitioner, and he must concentrate on doing exactly as he is told. In selected cases, drugs or electrical impulses may be used for the initial induction of hypnotic sleep, but if hypnotherapy is to be continued, the physician must keep in contact with the patient by repeated suggestions. The technic used should fit the individual patient, but in most cases, verbal suggestions are all that is necessary to bring about dissociation. Hypnosis may be used to facilitate the beginning of mental catharsis, the establishment of transference, and may be easily instituted following narcosynthesis, electroshock therapy, minimum stimulus, or Sedac. Suggested activity under hypnosis may be carried out at a designated time, place, and manner after awakening. This is a result of autosuggestion and may be mistaken for psychopathic behavior. Such suggestions may be instituted by television, movies, radio, telephone, or recorded or written instruction. Hypnosis may be used to plant suggestions; if misused, it may create an obsessive-compulsive neurosis, while when properly used, it may overcome many functional symptoms and may be used to supplement other forms of psychotherapy" (p. 32).

1961

London, Perry (1961). Subject characteristics in hypnosis research: Part I. A survey of experience, interest, and opinion. International Journal of Clinical and Experimental Hypnosis, 151-161.

Questionnaire measuring (a) direct and observational experience with hypnosis, and (b) stereotyped attitudes towards hypnosis was administered to 645 undergraduate students of psychology. Results indicate hypnosis considered in generally favorable light. Girls were less willing than boys to be hypnotic Ss. Items regarding the nature of hypnosis reflected a rather sophisticated attitude. From Psyc Abstracts 36:01:3II51L. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1956

Sears, Alden B.; Beatty, Jeanne M. (1956). A comparison of galvanic skin response in the hypnotic and waking state. Journal of Clinical and Experimental Hypnosis, 4 (2), 49-60.

#### NOTES

"Summary. In this experiment an attempt was made to determine whether or not there was a difference in the galvanic skin response between waking and hypnotic questioning. The 24 subjects were randomly assigned to one of four groups, each group following a different sequence of experimental conditions. During the first session, each subject observed a table top setup for 30 seconds and then wrote out what he could remember in both the waking and hypnotic states. During the second session, which followed seven or eight days after the first, each subject was asked a series of 14 questions concerning the table top setup. Half of the subjects answered the questions first in the waking and then in the hypnotic state; for the remaining 12 subjects hypnotic questioning preceded waking questioning. The galvanic skin response was recorded for both the waking and hypnotic questioning of all subjects, and the amount of deviation was measured in millimeters. Because the subjects tended to respond more slowly during the hypnotic questioning than during the waking questioning, a direct comparison of the amount of deviation in the two states could not be made. Consequently, two indicators of amount of deviation were considered necessary: mean deviation per second (D/T) and the mean average deviation (D/ND). No significant differences were found between the waking and hypnotic questioning in a comparison of the mean deviation per second for the group and for the males alone. However, there was a difference between waking and hypnotic questioning in the mean deviation per second for females, significant at the .01 level of confidence. The difference between the waking and hypnotic measures of the mean average deviation were also not significant for either the total group or for the males. For females, this difference was significant at the .001 level of confidence. No attempt was made to explain this apparent sex difference in the behavior of the galvanic skin response. It was suggested that further research be done to confirm and account for these results. The differences between the results of male and female subjects in this experiment, where procedures were the same for both, may account for the conflicting reports found in the literature. In many of the reported experiments the sex of the subjects has not been noted" (pp. 57-58).

The questions were factual in nature, e.g. "What object is in the lower right hand corner."

GENERALIZED REALITY ORIENTATION.

Sheehan, Peter W. (1991). Hypnosis, context, and commitment. In Lynn, S. J.; Rhue, J. W. (Ed.), Theories of hypnosis: Current models and perspectives (pp. 520-541). New York: Guilford Press.

NOTES

1:

"There are several different ways to classify the model that is expounded in this chapter. One may view it ... as an individual-differences model of hypnosis, because it emphasizes the significance of intragroup differences in the pattern of hypnotic performance. Alternatively, one may view it as a phenomenologically based model... Invariably, however, single categories fail to do justice to the nature of theories, and hence it is perhaps wisest to view this theory as a means of exploring particular hypotheses about hypnotic phenomena that focus primarily on the meaning of suggestion as perceived by susceptible subjects. This model focuses, in a way that most other theories do not, on the motivational implications of the cognitive involvement of the susceptible subject in the events of the hypnotic setting. It offers a variant of contextual theories of psychological functioning, but is experiential in its emphasis rather than simply behavioral" (p. 537).

1989

Bryant, Richard A.; McConkey, Kevin M. (1989). Visual conversion disorder: A case analysis of the influence of visual information. Journal of Abnormal Psychology, 98, 326-329.

NOTES

1:

"examined the influence of visual information on a decision task that was administered to an individual with monocular visual conversion disorder. Findings indicated that his performance was influenced by the visual information and by motivation instructions. The findings are discussed in terms of a model of hysterical blindness that recognizes the interplay of cognitive and motivational processes" (p. 326).

Gabel, Stewart (1989). Dreams as a possible reflection of a dissociated self-monitoring system. Journal of Nervous and Mental Disease, 177 (9), 560-568.

Argues that dreams may be thought of as dissociative phenomena of a particular type that reflect a monitoring of and reaction to internal and external conditions within the dreamer. Under conditions of sleep, memories, emotions, information processing, and judgments about internal and external events may occur independently of the usual waking conscious system's information processing. Experimental and/or clinical work, related to hypnosis, REM phenomena, dreams, and hemispheric specialization are discussed to support this view. Dreams are described within the context of dissociation-based theories of personality organization.

1988

**Kumar, V. K.; Pekala, Ronald J. (1988). Hypnotizability, absorption, and individual differences in phenomenological experience. International Journal of Clinical and Experimental Hypnosis, 36, 80-88.**

The phenomenological effects associated with a baseline condition of eyes- closed and a hypnotic induction condition were compared across individuals of differing absorption capacity and hypnotizability. The results indicated that individuals of differing absorption capacity and hypnotizability reported different intensities of phenomenological experience during the baseline eyes-closed condition. The induction further augmented intensity differences for low, medium, and high absorption and hypnotizable Ss, but more so for high (and medium) than low hypnotizable Ss. The results support both a trait and state interpretation of hypnotizability, and highlight the importance of the interaction between these factors on the resulting hypnotic experience of S. NOTES 1:

**NOTES:**

Based on a review of relevant literature, the authors predicted that (1) during hypnosis and a baseline condition (eyes-closed), high absorption and high hypnotizable Ss will report the phenomenological effects at greater intensity relative to low absorption and low hypnotizable Ss, respectively; (2) hypnotic induction will be associated with increased absorption; greater alterations in awareness and experience; and decreased volitional control, rationality, and memory; (3) phenomenological intensity differences (hypnosis compared to eyes-closed) will be significantly greater for high than for low hypnotizable Ss.

They used the Phenomenology of Consciousness Inventory (PCI) developed by Pekala (1982), which is a 53 item self-report instrument that is completed retrospectively in reference to a preceding stimulus condition. The PCI measures the following dimensions and subdimensions: internal dialogue; self-awareness; state of awareness; imagery (amount, vividness); positive affect (joy, sexual excitement, love); negative affect (anger, fear, sadness); altered experience (time sense, body image, perception, unusual meanings); attention (absorption, direction); memory; rationality; volitional control; and arousal.

The 217 Ss were administered the Tellegen Absorption Scale, then sat quietly with eyes closed for four minutes, then completed the PCI, Form 1, relative to that 4-minute period. They were administered a slightly shortened version of the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A); before the posthypnotic suggestion and amnesia suggestion they experienced another 4-minute silent period during which they were told to 'continue to experience the state you are in right now.' After the HGSHS:A they completed PCI, Form 2, in reference to the silent period during the HGSHS:A, before they completed the 11-point questionnaire on the HGSHS:A.

Subjects who did not have reliable PCI response forms were removed from the sample, leaving 173 Ss who were divided into high, medium, and low Absorption groups, and high, medium, and low hypnotizability groups. The statistical analysis employed MANOVA on intensity scores for first the major PCI dimensions and then the 14 subdimensions using Conditions (eyes closed, hypnosis) and Groups.

There were significant main and interaction effects. Subsequent ANOVAs for each (sub)dimension, Conditions by Hypnotizability Groups (2 x 3) were then performed. Hypnosis "was associated with significantly less positive affect (joy, sexual excitement, love); negative affect (anger, sadness); visual imagery (amount, vividness); self-awareness, internal dialogue, rationality, volitional control, and memory; and significantly more altered experience (time sense, perception) and altered state of awareness.

"Significant main effects for Hypnotizability Groups were found for positive affect (joy, love); altered experience (body image, time sense, perception, meaning); attention (direction, absorption); self-awareness; altered state of awareness; rationality; volitional control; and memory.

"Post-hoc comparisons for the eyes-closed condition revealed that high relative to low, hypnotizables reported significantly greater alterations in body image, time sense, meaning, and altered state of awareness. Medium hypnotizable Ss, compared to low hypnotizables, reported significantly increased alterations in body image and state of awareness.

"Post-hoc comparisons for the hypnotic induction condition revealed that high, viz-a-viz low, hypnotizables reported significantly increased absorbed attention; greater altered experience (body image, time sense, perception, meaning); and increased alterations in state of awareness. High hypnotizables also reported significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. Medium hypnotizable Ss, vis-a-vis low hypnotizables, reported significantly more altered experience (body image, time sense, perception, meaning); absorbed attention; and altered state of awareness; and significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. High hypnotizable Ss, relative to medium hypnotizables, reported significantly more altered experience (perception, meaning) and absorption, and significantly less rationality, volitional control, and memory.

"Concerning the significant interactions ( $\alpha = .01$ ), graphs of the means indicated significant ordinal interactions between Conditions and Hypnotizability Groups for altered experience (perception), imagery (vividness), self-awareness, altered state of awareness, rationality, volitional control, and memory. For all of the PCI (sub)dimensions, the hypnotic induction condition (compared to eyes-closed) was associated with a significantly greater increase in altered experience (perception), and altered state of awareness; and a significantly greater decrease in imagery (vividness), rationality, volitional control, and memory for the high (and medium) hypnotizable groups relative to the low hypnotizable group.

"Significant disordinal interactions were found for absorption and unusual meanings. Whereas high hypnotizable Ss reported a more absorbed attentional focus and more unusual meaning during hypnosis, low hypnotizable Ss reported being less absorbed (or more distracted) during the induction than eyes-closed. Low hypnotizables reported more unusual meanings in reference to eyes closed" (pp. 84-85).

Correlations among the major PCI dimensions, absorption, and hypnotizability differ between the two conditions. In hypnosis, the hypnotizability correlations that reached the .001 level were: --Self Awareness -.55 --State of Awareness .60 --Altered

Experience .56 --Inward Absorbed Attention .44 --Rationality -.41 --Volitional control -.65 --Memory -.41 --Arousal -.28

In the eyes closed condition, the only PCI variables that Hypnotizability correlated with, at the .001 level, were: --Positive Affect .26 --Altered Experience .32

MANOVAs and ANOVAs were computed for Absorption groups in a similar fashion. Main effects but not interaction effects were significant. Results are not abstracted here.

In their Discussion, the authors note that "The three hypotheses were supported by the results. Several of the absorption group comparisons obtained in previous research (Pekala et al., 1985) involving alterations in subjective experience (body image, perception, meaning); state of awareness; and volitional control were replicated in the present research" (p. 85).

1986

Holroyd, Jean (1986). Hypnosis applications in psychological research. Imagination, Cognition and Personality, 5, 103-115.

It is proposed that hypnosis leads to altered cognition, affect, or motivation as reflected by changes in 1) reality orientation, 2) attention and awareness, 3) imagery, 4) dissociation, 5) suggestibility, and 6) mind-body interaction. Hypnosis may be used as an experimental method to effect such cognitive, affective and motivational changes in order to pursue research in learning, personality, physiological, and social psychology. Examples of possible applications of hypnosis are provided. The influence of individual differences in hypnotic responsivity on research also is discussed. NOTES 1:

NOTEST

he author concludes, "Contributions of hypnosis to research in psychology may have been diminished by the confusion inherent in searching for main effects while giving insufficient attention to interaction effects between personality variables and experimental manipulations. As psychology becomes more cognitive in orientation, the phenomena of hypnosis may seem less bizarre and more amenable to inclusion in psychological research. However great care must be taken not to confuse the contributions of hypnosis with the contributions of the hypnotically responsive personality" (p. 109).

Fromm, Erika; Brown, Daniel P.; Hurt, Stephen W.; Oberlander, Joab Z; Boxer, Andrew M.; Pfeifer, Gary (1981). The phenomena and characteristics of self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 189-247.

Self-hypnosis and hetero-hypnosis were compared, and self-hypnosis was studied longitudinally. Results indicated that absorption and the fading of the general reality orientation are characteristics of both hetero-hypnosis and self-hypnosis. The differentiating characteristics lie in the areas of attention and ego receptivity.

Expansive, free-floating attention and ego receptivity to stimuli coming from within are state-specific for self-hypnosis, while concentrative attention and receptivity to stimuli coming from one outside source--the hypnotist on whom the subject concentrates his attention--are state-specific for laboratory defined hetero-hypnosis. Attempts to produce age regression and positive or negative hallucinations are markedly more successful in hetero-hypnosis. Imagery is much richer in self-hypnosis than in hetero-hypnosis. Self-hypnosis requires adaptation to the state: in the beginning of self-hypnosis there is a good deal of anxiety and self-doubt. As the subject feels more comfortable in the self-hypnotic state, he spends less time worrying about failures in self-suggestion, his ability to enter trance quickly and easily increases, as does the fading of the general reality orientation, trance depth, and absorption. An attempt was also made in the present study to find personality characteristics related to the ability to experience self-hypnosis.

**1970**

Shor, Ronald E. (1970). The three-factor theory of hypnosis as applied to the book-reading fantasy and to the concept of suggestion. International Journal of Clinical and Experimental Hypnosis, 18, 89-98.

Maintained that many of the conflicting viewpoints in theories of hypnosis parallel the descriptive complexity of the phenomena. A 3-factor theory of hypnosis is surveyed in which hypnotic depth is conceived as a complex of 3 separate but complementary processes or dimensions. The theory is used to illuminate the book-reading fantasy and the concept of suggestion. (Spanish & German summaries) (16 ref.) (PsycINFO Database Record (c) 2003 APA, all rights reserved)

**1962**

Shor, Ronald E. (1962). Three dimensions of hypnotic depth. International Journal of Clinical and Experimental Hypnosis, 10, 23-28.

The writer extends his earlier presentation of a dual-factor theory of hypnosis to include archaic involvement. Although interactions occur among these factors, the depth of each may vary independently. The theory is properly seen as a synthesis and elaboration of many prior theories of hypnosis. **1960**

Conn, Jacob H. (1960). The psychodynamics of recovery under hypnosis. International Journal of Clinical and Experimental Hypnosis, 8, 3-16.

Defines hypnosis as primarily a change in reality testing, and considers it as both an altered state of consciousness and a multilevel dynamic relationship in which the S is always aware of the operator. Hypnosynthesis emphasizes the patient's values and expectations and his freedom to choose what to say and how he should be treated. Preference is given to terms of "more or less" consciousness. The patient does not receive any training in hypnosis and there is no encouragement of acting out in

hypnosynthesis. Attention is directed to repetitive patterns, and the hypnotic experience is utilized as a present dynamic experience. Hypnosynthesis demonstrates that symptom removal is possible without symptom substitution when there is an effective working relationship. The common factor in every psychogenic cure, including hypnotherapy, is the fostering of self-esteem and active participation, both of which are achieved by effective collaboration in the therapeutic situation. ## GENETICS

2000

Lichtenberg, P.; Bachner-Melman, R.; Gritsenko, I.; Ebstein, R. P. (2000). Exploratory association study between catechol-O-methyltransferase (COMT) high/low enzyme activity polymorphism and hypnotizability. American Journal of Medical Genetics, 96, 771-774.

Only recently have studies of electrocortical activity, event-related potentials, and regional cerebral blood flow begun to shed light on the anatomical and neurobiological underpinnings of hypnosis. Since twin studies show a significant heritable component for hypnotizability, we were prompted to examine the role of a common, functional polymorphism in contributing to individual differences in hypnotizability. A group of 109 subjects (51 male, 58 female) were administered three psychological instruments and tested for the high/low enzyme activity COMT val/met polymorphism. We observed a significant correlation between hypnotizability measured by the Stanford Hypnotic Susceptibility Scale (SHSS:C), ability to partition attention (Differential Attentional Processes Inventory or DAPI), and absorptive capacities (Tellegen Absorption Scale or TAS). The effect of COMT on the various dependent variables was initially examined by multivariate analysis that corrects for multiple testing. The dependent variables were SHSS:C hypnotizability scores, four attentional subscales of the DAPI, and TAS total score grouped by the COMT genotype (val/val, val/met, met/met) as the independent variable. Hotelling's Trace statistic was significant when scores were grouped by the COMT genotype (Hotelling's  $T^2 = 1.88$ ,  $P = 0.04$ ). Post-hoc testing using the Bonferroni correction shows that the only significant difference is between the val/met vs. the val/val COMT genotypes on hypnotizability. This association was significant for men but not for women. As for all case-control studies, these results need to be interpreted cautiously and require replication.

1990

Gil, Karen M.; Williams, David A.; Keefe, Francis J.; Beckham, Jean C. (1990). The relationship of negative thoughts to pain and psychological distress. Behavior Therapy, 21 (3), 349-362.

Examined the degree to which negative thoughts during flare-ups of pain are related to pain and psychological distress in 3 pain populations: sickle cell disease, rheumatoid arthritis, and chronic pain. 185 adults completed the Inventory of Negative Thoughts in Response to Pain (INTRP), a pain rating scale, the SCL-90 (revised), and a coping strategies questionnaire. Factor analysis of the INTRP revealed 3 factors: Negative Self-Statements, Negative Social Cognitions, and Self-Blame. High scorers on Negative Self-Statement and Negative Social Cognitions reported more severe pain and psychological distress. Ss with chronic daily pain had more frequent negative thoughts during flare-ups than those having intermittent pain secondary to sickle cell disease or rheumatoid arthritis. The INTRP appears to have adequate internal consistency and construct validity.

1989

Wallace, Benjamin; Persanyi, M.W. (1989). Hypnotic susceptibility and familial handedness. Journal of General Psychology, 116 (4), 345-350.

The possible relationship between hypnotic susceptibility and familial handedness was examined. In a mass testing session of students enrolled in introductory psychology, subjects were administered the Harvard Group Scale of Hypnotic Susceptibility and were also required to complete a questionnaire that ascertained information on their dominant handedness and that of their immediate family relatives. Subjects who had immediate sinistral relatives scored significantly lower in hypnotic susceptibility compared to those who had a history of familial dexterity. When immediate relatives of the original subject pool were tested on hypnotic susceptibility level, sinistral relatives scored lower in susceptibility than dextral relatives. The important implication is that this may indicate the existence of a familial component in hypnotic susceptibility.

1969

Duke, J. D. (1969). Relatedness and waking suggestibility. International Journal of Clinical and Experimental Hypnosis, 17, 242-250.

Volunteering pairs of Ss took 9 waking tests (WT) of hypnotic susceptibility. Pairs included siblings, friends, and strangers. Concordance correlations from 20 sibling pairs were positive for 7 of the 9 WT, 2 significantly so. For 19 pairs of strangers, correlations were insignificant, 5 positive, 4 negative. Data reopen nature-nurture questions about the origins of individual differences in hypnotic aptitude. For 20 pairs of cross-sex friends, 7 of 9 correlations were negative, 1 significant, and 2 approaching significance. 6 of 9 concordance correlations from 16 spouse pairs were also negative, but none was significant. ## GENITOURINARY/UROLOGY

2002

Ginandes, Carol (2002). Extended, strategic therapy for recalcitrant mind/body healing: An integrative model.. American Journal of Clinical Hypnosis, 45 (2), 91-102.

The development of the power therapies, behavioral medicine, and short term interventions have reported such success even with trauma cases that it is relevant to question the justification for lengthy psychotherapy. Yet some patients with complex mind/body conditions impervious to medical treatment/hypnosis may require extended, multi-modal, integrative therapy. This paper details a single complex case of paruresis as a prototype for illustrating a holographic treatment model for recalcitrant conditions: Component features of the proposed model presented include: 1) the sequential utilization of hypnbehavioral and analytic approaches; 2) uncovering work providing access to the somatic ego state associated with the illness condition; 3) the extended treatment time frame required for deep psycho-physiological change; and 4) the stages of counter-transference expectably evoked by such patients (e.g. urgency, exuberant optimism, frustration, discouragement), and the transformation of such reactions to achieve maximum therapeutic efficacy.

NOTES 1:

Paruresis is a social phobia involving urinary retention and "thought to affect some 17 million or 7% of the American population" (p. 92). Also known as "bashful bladder."

1965

Barber, Theodore Xenophon (1965). Physiological effects of 'hypnotic suggestions': A critical review of recent research (1960-64). Psychological Bulletin, 201-222.

Recent studies are reviewed which were concerned with the effectiveness of suggestions given under "hypnosis" and "waking" experimental treatments in alleviating allergies, ichthyosis, myopia, and other conditions and in eliciting deafness, blindness, hallucinations, analgesia, cardiac acceleration and deceleration, emotional responses, urine secretion to sham water ingestion, narcotic-like drug effects, and other phenomena. The review indicates that a wide variety of physiological functions can be influenced by suggestions administered under either hypnosis or waking experimental treatments, and direct and indirect suggestions to show the particular physiological manifestations are crucial variables in producing the effects.

#### Summary

"Blood and urine samples were obtained from 18 university students at the beginning and end of two experimental sessions, one with and one without hypnosis. Some of the subjects relaxed during the sessions; others imagined or hallucinated a traumatic experience.

"Of a variety of measurements made, urinary volumes and 17-ketosteroids, the eosinophil count and psychogalvanometer recordings appear to give useful information about any changes due to the hypnosis. The biochemical changes caused by the experimentally produced emotions seem to depend on the individual and his past experience rather than the hypnosis. The data suggest that if the experience hallucinated is known to the subject, the biochemical changes indicate a relaxed state during the hypnosis. The psycho-galvanometer recordings may indicate an agitated state while the biochemical indices suggest a relaxed state" (pp. 106-107).

Green, Joseph P.; Rasekhy, Rouhangiz; Johnson, Lissa; Bernhardt, Sarah E. (2002). Cultural views, attitudes, and beliefs about hypnosis. [Paper] Presented at the annual meeting of the American Psychological Association, Chicago.

"The present investigation surveyed attitudes and beliefs about hypnosis across four samples of students attending university at the University of New South Wales, Australia; Dortman University, Germany; The Ohio State University, United States; and Shaheed Behesti University of Medical Sciences, Iran. A total of 280 undergraduate students, ranging in age from 18 to 25 years old, completed three different questionnaires assessing their opinions and beliefs about hypnosis. Our findings show that myths and misconceptions about hypnosis abound and that such beliefs are not culture specific" (Bulletin of Division 30, Psychological Hypnosis, Fall 2002, Vol. 11, No. 3, p. 14).

1999

Kallio, Sakari P.; Ihamuotila, Mikko J. (1999). Finnish norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 47 (3), 227-235.

Finnish norms of the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) are presented. The aggregate sample of 285 subjects consisted of 3 groups (n = 129, n = 116, and n = 40) that were tested during 1996 and 1997. Comparisons are made with the original normative American sample, an Australian sample, and 3 translated adaptations of HGSHS:A in Danish, German, and Spanish. In the Finnish sample, Items 2 (eye closure), 11 (posthypnotic suggestion), and 12 (amnesia) received high passing percentage in comparison with the reference data, but generally the Finnish normative data were congruent with these index studies.

Rodriguez Sanchez, Rodriguez Rodriguez, Santana Mariqo, Piqueras Hernandez, Alvarez Ramirez (1999). Current tendencies and future directions of hypnosis in Cuba. Newsletter of the Erickson Foundation, Vol 2, 6.

Reviews the history of hypnosis in Cuba and the main tendencies and trends. There were no influences from Ericksonian hypnosis till recently when the first group of Ericksonians came to teach for the first time in Manzanillo, Granma Medicine University. The main approach is still the so called traditional hypnosis in which there is a development mainly in surgery and in some medical conditions. There are some strong places: Santiago de Cuba, where HipnoSantiago Hypnosis Workshop is held regularly, Manzanillo, where there is a Hypnosis Research group with publications in the country and abroad and experience in teaching hypnosis. The Hypnosis Society is located in Habana.

The group from Manzanillo is working in a Clinic Project with such themes as hypnoanesthesia in major surgery, models of groups learning under hypnosis, and some other therapies.

Hypnosis as the only anaesthetic procedure in major surgery. (Thesis)

1997

Jana, Hrishikesh (1997). The development of hypnosis in India. [Unpublished manuscript]

## NOTES

"Yoga (specially Meditative Yoga or Savasana) and Transcendental Meditation are integral parts of the cultural heritage of Indians. These and the state of hypnosis possess some of the characteristics in common and all these have been grouped under the heading 'Altered States of Consciousness' by the modern psycho-physiological and biological researchers. Hindu saints used to clothe sparsely even in the midst of extreme environmental conditions and the lying down of some yogis on the nail-bed are examples of their super-human tolerance to cold, pain, etc." (p. 2). Author cites the pioneering work of Dr. James Esdaile using hypnosis for surgical anaesthesia at Hooghly Hospital (1845-1850). Despite India's culture and the record of Dr. Esdaile, hypnosis often was regarded with suspicion in India. In the early and mid-20th century, physicians (e.g. Dr. N.V. Mody, an obstetrician) had difficulty having their work accepted, but since the early 1970s Dr. Jana and others have contributed to a renaissance in the use of medical, dental, and psychological hypnosis. This paper chronicles the history of hypnosis in the late 20th century in India.

Perry, Campbell (1997). Admissibility and per se exclusion of hypnotically elicited recall in American courts of law. International Journal of Clinical and Experimental Hypnosis, 45 (3), 266-279.

State v. Mack (1980) ruled that hypnotically elicited testimony is per se excluded from Minnesota law courts; this court also ruled that police could employ hypnosis in an attempt to construct an independently corroborated case. In recent years, there have been moves to rescind this exclusion; this raises a question of the probative value of such additional information when it is uncorroborated. This situation is compared with that of the polygraph as an index of deception: Like hypnosis, it is excluded per se in most American jurisdictions. Some legal decisions

in Wisconsin are used to illustrate one alternative to the per se exclusion approach. Admissibility of scientific evidence in American courts of law has been based on a criterion of "general acceptability within the relevant scientific community," as first elucidated in *Frye v. United States* (1923). Recently, the U.S. Supreme Court overturned the *Frye* decision in *Daubert v. Merrell Dow Pharmaceuticals, Inc.* (1993), by making general acceptability but one of several admissibility criteria. Three *Daubert*-based decisions, one involving hypnosis and all concerned with "recovered repressed memories," indicate some problems in law posed by *Daubert*. - Journal Abstract.

1996

Cardena, Etzel (1996). "Just floating on the sky:" A comparison of hypnotic and shamanic phenomena. In Quekelberghe, R. V.; Eigner, D. (Ed.), Yearbook of cross-cultural medicine and psychotherapy 1994 (pp. 85-98).

Despite the vastly different cultural contexts of hypnosis and shamanism, a comparison of the phenomenology of the two is warranted.

The author proposes that the two types of very hypnotizable individuals, one exhibiting vivid imagery and the other showing diminished memory and control, corresponds to the classical distinction between soul journey and spirit possession. Other cognitive traits, developmental histories and alternate experiences of hypnotic virtuosos and shamans imply other similarities. The resemblance between hypnotic and shamanic phenomenology strongly suggests a universal disposition that is independent of culture. Western culture should acknowledge, respect and study the potentials and risks of this ability.

Zachariae, Robert; Sommerlund, Bo; Molay, Francine (1996). Danish norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 44 (2), 140-152.

Norms for a Danish adaptation of the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) are presented. Four samples tested from 1988 to 1991 (n = 166, n = 54, n = 95, and n = 61) were pooled, resulting in an aggregate sample of 376 participants. The normative data were generally congruent with earlier normative studies with regard to score distribution, item difficulty levels, and reliability. Studies using the Danish adaptation of the HGSHS:A as a screening instrument have shown the predictive value of the instrument in a Danish context. Data for a comparable American sample of volunteers (n = 170) tested by the same hypnotist were included in the analysis. A comparison revealed a marked difference for the posthypnotic suggestion item, hinting that cultural differences between the Danish and American samples with regard to expectancies and attitudes toward hypnosis may play a role. Further studies comparing attitudes toward hypnosis across different cultural contexts are needed to clarify this issue. - Journal Abstract

1995

Watkins, John G. (1995). Organization and functioning of ISCEH, the International Society for Clinical and Experimental Hypnosis. International Journal of Clinical and Experimental Hypnosis, 43 (3), 332-341.

The first international society of hypnosis founded in this century, the International Society for Clinical and Experimental Hypnosis (ISCEH), was organized in 1958 as a direct result of societal conflicts between The Society for Clinical and Experimental Hypnosis (SCEH) and the American Society of Clinical Hypnosis (ASCH). Initially, it consisted of National Divisions built around key contributors in 30 different countries. This article describes the inception, organization, and development (including controversies and conflicts) of ISCEH up to 1973. At that time, through the cooperation of SCEH, ASCH, and other international groups, under the leadership of Dr. Ernest R Hilgard, ISCEH was reorganized, reconstituted, and renamed The International Society of Hypnosis (ISH). For the purpose of historical study, the society's voluminous correspondence, directories of officers and committees, awards, photographs, programs of congresses, election records, and other relevant documents have been cataloged and preserved in some 82 files in the Archives of the History of American Psychology at the University of Akron, Akron, Ohio.

1993

Cardena, Etzel (1993, October). Trance and possession as dissociative disorders: How exotic are they?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

Joke: "What happened to the possessed patient who didn't pay his exorcist?"  
Answer: "He got repossessed."

Began with a quotation of Lagerkvist's book describing possession of a Sybil in Greek temple. Possession is part of religious experience worldwide, that he is not discussing here.

The revised diagnostic manual, ICD-10, has included "dissociative trance disorders." To diagnose this one must have either trance (narrowing awareness or focusing and stereotyped movements, behaviors) or possession trance (replacement of sense of personal identity by a new identity, with stereotyped culturally-determined behaviors or movements that are experienced as being controlled by the possessing agent), \*and\* full or partial amnesia for the event. Cardena emphasizes it doesn't need to be full amnesia.

To be diagnosed as dissociative trance disorder, the trance or possession state observed cannot be a normal part of a broadly accepted cultural or religious practice, and it must produce distress or maladjustment.

These are the most common type of dissociative disorders in non-Western cultures, e.g. 90% in India. So this diagnosis in India is not "atypical." "Non-Western" applies to 80% of the World and 1/3 of the USA population. DSM is trying to expand cultural relevance.

Also, even in the Western culture Allison and others have published cases of dissociative trance disorder, and others have described trance disorders:

Spiegel & Spiegel's Grade 5 personality is vulnerable to dissociative disorder. Hartman's chronic nightmare patients have "boundary thinness" (i.e. they are not clear if they are awake or asleep, lack separation from themselves and others). Lynn & Rhue's fantasy prone individuals, 22% of people, are vulnerable to maladjustment.

Cardena's recommended change in diagnosis of dissociation is critiqued in Transcultural Psychiatric Research Review (1992). Criticisms of the new diagnosis, published in that journal, are: 1. Culture-bound syndromes cut across Western diagnostic boundaries. 2. The diagnosis may be insensitive to the cultural context in which phenomena occur (e.g. distress may lead a person to participate in a cult of affliction) and it may require anthropological sophistication of diagnosticians or consultation with someone who has that knowledge. 2a. It may disregard considerations such as who has the power to "authorize" the phenomenon, under what circumstances, etc. [That would be true with any diagnosis however.] 3. Dissociative Trance Disorder may assume greater within and across-culture uniformity for the conditions than is warranted. 4. It may give validity to metaphysical explanations for spirit possession. [But in psychiatry we often use terms that don't take into consideration validating metaphysical explanations, e.g. "phantom limb" pain. 5. The medical model that underlies DSM is inappropriate for ontological considerations on the nature of the self. [But those with this diagnosis give us some understanding, not what the ultimate nature of the self and consciousness are. Diagnoses are pragmatic ways of dealing with problems.]

At the present time, the diagnosis of Dissociative Trance Disorder is included in the Appendix of DSM-IV.

For further elaboration of this material, see Cardena, E. (1992). Trance and possession as dissociative disorders. *Transcultural Psychiatric Research Review*, 29, 283- 297.

1993

Don, Norman S. (1993, October). Trance surgery in Brazil. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

Showed a videotape of a Brazilian trance surgeon, who cuts without analgesia or asepsis. Patients later report no pain, infections, etc. The healer/surgeon is believed by everyone to be in a trance state, and the body is believed to be taken over by a spiritual doctor. The people involved deny that the patient is in trance.

Hilgard, Ernest R. (1993). History of research centers and professional hypnosis societies in the United States. *International Journal of Clinical and Experimental Hypnosis*, 41 (3), 173-190.

The brief history of hypnosis in America begins with William James's chapter in his *Principles of Psychology* that got hypnosis off to a good start as a legitimate part of psychology. In the 20th century, before World War II, the idea of performing scientific investigations of hypnosis took place at Harvard University through William McDougall, at the University of Wisconsin and Yale University under Clark Hull, and, in its clinical aspects particularly, through the personal efforts of Milton H. Erickson. The resurgence after World War II is related to the use of hypnosis with war casualties during the war and with the development of clinical psychology. The aspects of the history emphasized here are the founding of continuing institutes and research centers, some theoretical cleavages that have persisted to this day, and the establishment of hypnosis societies with their journals, annual meetings, and workshops, including an International Society of Hypnosis. The history of Division 30 within the American Psychological Association brings the story up to date.

1990

Adityanjee (1990). 'Multiple personality disorder in India': Reply. *American Journal of Psychiatry*, 147 (9), 1260-1261.

Replies to comments by J. Downs et al (see PA, Vol 78:4589) concerning the article on multiple personality and possession syndrome in India by Adityanjee et al (see PA, Vol 77:12344). Both syndromes reflect parallel dissociative disorder with similar etiologies. The present diagnostic classification for multiple identity phenomena is in need of revision.

Downs, John M.; Dahmer, Sharon K.; Battle, Allen O. (1990). Multiple personality disorder in India. *American Journal of Psychiatry*, 147 (9), 1260.

Comments on the article by Adityanjee et al (see PA, Vol 77:12344) on multiple personality vs possession syndrome in India. The history of the trends of these disorders is presented, and the differences between multiple personality and possession are described. The only fundamental difference between the 2 disorders may be in the voluntary type. NOTES 1: 1887, Dragutinovich & Sheehan, 1986

1989

Lamas, Juan R.; del Valle-Inclan, Fernando; Blanco, Manuel J.; Diaz, Antonio Albo (1989). Spanish norms for the Harvard Group Scale of Hypnotic susceptibility, Form A. *International Journal of Clinical and Experimental Hypnosis*, 37 (3), 264-273.

The results of administering the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962) to a Spanish sample are on the whole consistent with those results obtained in other normative studies, especially Bongartz's work with a German sample, and they confirm HGSHS:A's usefulness in non-Anglophone countries. The Spanish HGSHS:A's reliability and validity remain

within the limits reported for other locales, but there are certain discrepancies with respect to the difficulty of two HGSHS:A items. NOTES 1: In the Discussion section the authors note, "the relative difficulty of the items is comparable to that observed in other studies, except for Items 3 and 8. The reliability of the present version is somewhat less than that of the others, both with regard to the individual items and the scale as a whole. This is probably related to the value of the variance, which is likewise smaller than usual. The standard error of measurement and the validity estimate are practically identical to other published values.

"With regard to Item 3, the increase in the proportion of Ss passing the hand lowering suggestion seems to be attributable to the modifications of the usual English instructions, which were effective in making it clear to Ss that they had to raise their arms deliberately. Even so, only 60% of Ss passed this item, which contrasts with the fact that nearly all Ss administered SHSS:C lowered their arms 15 cm or more, the criterion for passing the suggestion. This discrepancy suggests that Ss may underestimate the distance they lower their hands. ... The problem with Item 8 seems more difficult. In the pilot study, its difficulty was somewhat less than in other studies but, since the difference was not very striking, no change was introduced to the first version. The Ss seemed to understand perfectly well what was being asked of them, and their efforts to move their heads were usually obvious, but they just did not seem to be able to do so. It is interesting, however, that the unusual easiness of the item does not affect its relative reliability .... As is usually found, suggestions that involve a challenge to Ss have the greatest correlation with the total hypnotizability score, and this was the case in the present study with Item 8" (p. 271).

Mackett, John (1989). Chinese hypnosis. British Journal of Experimental and Clinical Hypnosis, 6, 129-130.

#### NOTES

This is a brief report of observations made by the author during a tour of China. The author states, "Subsequent enquiries on our tour revealed that Qi Gong was a rare type of therapy and used in no other hospital or medical school that we visited. Lewis (1985) has confirmed the apparent absence of knowledge and practice of hypnosis as we know in China. He mentions the use of Qi Gong which he describes as an 'old Buddhist exercise'."

1987

Dobkin de Rios, Marlene; Friedmann, Joyce K. (1987). Hypnotherapy with Hispanic burn patients. International Journal of Clinical and Experimental Hypnosis, 35 (2), 87-94.

This paper examines a culturally sensitive hypnotherapeutic intervention for Hispanic burn patients who suffer symptoms of the post-traumatic stress disorder and discusses the outcome of 27 patients seen by the authors (a medical anthropologist and a clinical psychologist), over a 3.5-year period. Given the

difficulties of recent monolingual, Mexican migrants in responding to psychological interventions that are not culturally sensitive, the hypnotherapeutic interventions and procedures developed by the authors provide a plan for systematic desensitization and cultural concordance to make rehabilitation of Hispanic burn patients more effective.

Jana, Hrishikesh (1987). History and present state of hypnosis in India. [Lecture] Presented at the Department of Psychiatry, UCLA.

#### NOTES

Hypnosis is discussed in relationship to traditional Indian medical and psychological treatments. The following Table illustrates some of the relationships among Asian approaches, which also include philosophical and religious elements.

1985

Fellows, Brian J. (1985). Hypnosis teaching and research in British psychology departments: Current practice attitudes and concerns. British Journal of Experimental and Clinical Hypnosis, 2 (3), 151-156.

#### NOTES

The author mailed a questionnaire to 58 departments of psychology to determine the extent/nature of hypnosis teaching and research, and attitudes toward teaching and research on hypnosis. The author noted a general anxiety about teaching students how to do hypnosis (as contrasted with learning about hypnosis). "Some of the anxieties which departments have about the teaching of hypnosis seem to stem from some rather ancient and invalid conceptions about the nature of hypnosis and what it can do" (p. 153). The author also relates his personal experience teaching undergraduates "something about the procedures and phenomena which have been traditionally associated with hypnosis" (p. 153). They may use one of the standard hypnotizability scales, study a particular hypnotic phenomenon such as ideomotor action or age regression, or study an empirical issue such as facilitation of recall. He reports not meeting with "any particular difficulties," but also that he has seen two problems: the student who is anxious about doing the procedure, and an occasional subject who reports the experience was unpleasant or disturbing--e.g. during age regression. He reports teaching students to handle these events in a normalizing manner. J. Holroyd

Suryani, L. K. (1984). Culture and mental disorder: The case of bebainan in Bali. In Culture, medicine and psychiatry. D. Reidel Publishing Company.

#### NOTES

Bebainan is a form of dissociation which is culturally associated with Bali. Thought to be caused by sorcery, a bebainan attack lasts up to an hour and is manifested by confusion, crying, screaming, and shouting, with inability to control one's actions. However, it seems most victims maintain awareness of their own behavior and are not amnesic for it afterwards.

In this study, the author interviewed 27 people, mostly female, most of whom experienced their first attack between 16-30 years of age. The author concluded that the attacks permitted release of feelings of frustration and anger without stigma. Author concluded it is not a form of psychosis, is not organic, and is not a neurosis.

1983

Barabasz, Marianne; Barabasz, Arreed F.; Mullin, C. S. (1983). Effects of brief antarctic isolation on absorption and hypnotic susceptibility - preliminary results and recommendations: A brief communication. International Journal of Clinical and Experimental Hypnosis, 31 (4), 235-238.

Absorption scores were found to increase significantly for Ss exposed to brief summer Antarctic isolation. Contrary to wintering-over research, no significant increases in hypnotic susceptibility were found.

This paper reviews Soviet approaches to the unconscious and to hypnotic phenomena, before examining psychoanalytic theories of hypnosis which are generally based on transference. The author believes the existing theories are inadequate, arguing that there is a psychophysiological dimension to hypnosis; but what unconscious processes does this conceal? Psychoanalysis opened one road to the unconscious, but affect, nonverbal communication, and psychophysiological process are still uncharted territories towards which hypnosis may yet prove to be another royal road. NOTES

The author concludes, "hypnosis and the unconscious ... are closely linked. Historically, experiments on posthypnotic suggestion were in fact the starting point for the discovery of the unconscious. Posthypnotic suggestion is in effect one of the most irrefutable proofs that psychical contents can influence behavior, albeit eluding the subject's consciousness.

"In this paper, the present author provides a description of Soviet researchers' conceptions of the unconscious, and of the point of view from which they approach hypnotic phenomena. Psychoanalytic theories of hypnosis are then presented, which are essentially based on transference. It is shown why this notion seems to the present author powerless to account for the specific nature of the hypnotic relationship. There is, in effect, a psychophysiological dimension to hypnosis. It lies at the crossroads between the instrumental and the relational dimension. But nothing is known about what unconscious processes hide at the psychophysiological level. Psychoanalysis has brought to light the laws governing the functioning of unconscious representations. But the realm of the affect, the nonverbal communication, and bodily processes still remain beyond our knowledge. This is a hidden side of the unconscious, in relation to which hypnosis may serve as another 'royal road'" (pp. 104-105).

1982

Laurence, Jean-Roch; Perry, Campbell (1982). Montreal norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 30 (2), 167-176.

Norms are presented for the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGS: A) of Shor and E. Orne (1962). Comparisons are made on HGS: A between 3 Montreal samples (N = 220, N = 178, & N = 137) and the aggregate sample (N = 535). These are compared additionally with a normative group of Harvard students (Shor & E. Orne, 1963), a normative group of University of California at Berkeley students (Coe, 1964), a normative sample of Australian students (Sheehan & McConkey, 1979), and the original Stanford University normative sample which was tested individually on the Stanford Hypnotic Susceptibility Scale, Form A (Weitzenhoffer & Hilgard, 1959). Although the Montreal groups were heterogeneous in ethnic origin and first language, the present normative data are generally congruent with earlier studies.

**1981**

Hilgard, Ernest R.; Sheehan, Peter W.; Monteiro, K. P.; Macdonald, Hugh (1981). Factorial structure of the Creative Imagination Scale as a measure of hypnotic responsiveness: An international comparative study. International Journal of Clinical and Experimental Hypnosis, 29, 66-76.

The factor structure of the Creative Imagination Scale (CIS) of Wilson and Barber (1978) was investigated in two studies by correlating scores on it with scores on the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962), the Absorption scale of Tellegen and Atkinson (1974), and Sheehan's (1967) revision of Betts' (1909) imagery scale. One of the studies was conducted at the University of Queensland in Australia (N = 237), the other at Stanford University in California (N = 92). The major finding, consistent in both investigations, was that two factors accounted for the major portion of the variance, one factor designated as a Hypnotic Performance factor, the other designated as an Absorption/Imagination factor. The CIS was weighted highly on both factors, the data bearing on earlier claims that CIS represents a single-factor scale.

**1979**

Sheehan, Peter W.; McConkey, Kevin M. (1979). Australian norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 27, 294-304.

Australian norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962) are presented and results relating to score distributions, item difficulty level, reliability, and validity are considered for 3 distinct samples of Australian students. Data are compared with both the original norms (Shor & E. Orne, 1963) and additional American (Coe, 1964) normative data. Results indicated that, in the Australian context, HGS: A functions as a reliable, effective predictor of hypnotic susceptibility. The psychometric properties of the scale were uniform across all of the different samples and reference groups that were considered. The accuracy of the scale appears to be most obviously limited when it is employed as a sole predictor of Ss' special aptitude for hypnosis.

1966

Hoskovec, J. (1966). Hypnopedia in the Soviet Union: A critical review of recent major experiments. International Journal of Clinical and Experimental Hypnosis, **14**, 308-315. (Abstract in Psychological Abstracts 41: 149, and in American Journal of Clinical Hypnosis, 1967, 4, 295)

Major Soviet hypnopedia (sleep-learning) experiments were conducted by Balkhashov (1965); Khil'chenko, Moldavskaya, Kol'chenko, and Shevko (1965); Kulikov (1964); Svyadosch (1962); Zavalova, Zukhar', and Petrov (1964); Zukhar', Kaplan, Maksimov, and Puskna (1965). The results of these experiments show that learning during sleep is possible when a 'suggested set' to perceive and remember the learning material during sleep is involved. Selection of Ss according to hypnotizability or primary suggestibility seems to be an important prerequisite. The influence of hypnopedia on the mental health of Ss is evaluated. (Author's abstract, in AJCH.)

#### NOTES

The review of this book by Leo Wollman (American Journal of Clinical Hypnosis, 1965, vol. 8, pp. 146-147) states, "Many interesting theories about hypnosis are aired in this book. The opinions Pavlov propounded many years ago, about cortical inhibition are assiduously asserted, yet some statements made bear investigation. The mere sight of the experimenter in B. N. Birman's experiments with dogs put the dog into a hypnotic state. The appearance in the room of other people, who had not participated in the experiments, had no sleep inducing effect. For the experimental animal, therefore, the experimenter himself had been transformed into a conditioned hypnogenous stimulus. Similarly, in group hypnotherapy, the entrance of the physician-hypnotist into the room often effects a hypnotic state in some of the subjects. The doctor has become the stimulus for the conditioned response, that of hypnotic trance state induction.

" An interesting and perhaps little known fact elicited from Chapter III (Hypnotism and Suggestion) is the high percentage (12%) of those replies to questionnaires during the First International Congress on Experimental Psychology held in Paris in 1899, which indicated that 3,000 respondents had hallucinations while in a normal state of health. The majority were visual; auditory and tactile hallucinations were less frequent" (pp. 146-147).

1964

Ludwig, Arnold M. (1964). An historical survey of the early roots of mesmerism. International Journal of Clinical and Experimental Hypnosis, **12** (4), 205-217.

Many believe that Franz Anton Mesmer helped lay the foundations upon which modern hypnotic theory and practice evolved. However, as one views the history of healing through suggestion prior to Mesmer, it becomes apparent that neither his theories nor his practices showed much originality. In fact, there is good evidence that Mesmer plagiarized the work of others. With this in mind, it appears that Mesmer's contribution to later psychological healing and theory was related more to his personality than to his originality. (Journal Abstract)

1962

Hallaji, J, Ja'far (1962). Hypnotherapeutic techniques in a central Asian community. International Journal of Clinical and Experimental Hypnosis, 10, 271-274. (Abstracted in Index Medicus, 63, Mar. S-543)

The semimonastic Sufi practitioners of Afganistan treat physical as well as psychosomatic disorders by a method which is reminiscent of Mesmerism, and they claim cures even for illnesses such as tuberculosis and cancer. A treatment session for 18 patients is described. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1961

Bowers, Margaretta K. (1961). Hypnotic aspects of Haitian voodoo. International Journal of Clinical and Experimental Hypnosis, 9, 269-282.

The voodoo ritual is analyzed within the framework of hypnosis and hypnotically induced secondary personalities. The author contends that "If the hypnotic nature of voodoo and similar religious rites were better understood the problem of discarding the evil and nurturing the good in the cultural life of people would be facilitated." From Psyc Abstracts 36:04:4II69B. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

## GERONTOLOGY

1998

Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..

Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery,

hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-be patient/client that he or she has something to offer that can help take away pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

**1981**

Elkind, Leonard (1981). Effects of hypnosis on the aging process. Journal of the American Society of Psychosomatic Dentistry and Medicine, 28 (4), 132-137. (Also presented at the annual meeting of the Am Soc of Psychosomatic Dentistry and Medicine in San Francisco, CA)

This study investigated the possibility of altering physiological measures associated with aging through the use of posthypnotic suggestions of increased youthfulness and vitality. Subjects were 20 women ranging in age from 39 to 56 years old. They were tested individually on Morgan's Adult Growth Examination, the AGE. Test-retest scores of the Control group were not significantly different, the median change being zero. The Experimental group, however, showed a decrease in Body Age for all of the subjects, the range of change from -3 to -18 years with a median change of -11 years.

## **GOAL DIRECTED FANTASY**

**2001**

Gibbons, Don E. (2001). Experience as an art form: Hypnosis, hyperempiria, and the Best Me technique. San Jose CA: Authors Choice Press. ([available online:] <http://www.iuniverse.com/bookstore/marketplace>)

## **NOTES**

**1:**

The Best Me Technique is a procedure for constructing suggestions which incorporates many different dimensions of experience -- beliefs, emotions, sensations, thoughts, motives, and expectations -- for maximum involvement and effectiveness. Best Me suggestions may be used with either hyperempiria, an alert

induction based on suggestions of mind expansion and increased alertness and sensitivity, or with more traditional forms of hypnotic induction.

**1999**

Comey, Gail; Kirsch, Irving (1999). Intentional and spontaneous imagery in hypnosis: The phenomenology of hypnotic responding. International Journal of Clinical and Experimental Hypnosis, 47 (1), 65-85.

Students were given 1 of 2 versions of the Carleton University Responsiveness to Suggestion Scale (CURSS): (a) the original version, which contains instructions to intentionally imagine goal-directed fantasies, and (b) a modified version, in which instructions for suggestion-related imagery were deleted. Participants were asked to report their goal-directed fantasies and to indicate whether these occurred spontaneously or were generated intentionally. They were also asked whether they had tried intentionally to generate the suggested experience and to indicate whether they had believed that the suggested states of affairs were real (e.g., whether they thought a hallucinated cat really existed). The deletion of instructions for goal-related imagery significantly increased responsiveness to CURSS suggestions. Spontaneous goal-directed imagery was significantly correlated with behavioral response, but intentional imagery was not. Most successful responders tried to generate suggested experiences intentionally, indicated that they could have resisted challenge suggestions if they really wanted to, and reported believing in the reality of suggested ideomotor and challenge experiences but not of cognitive suggestions. Voluntary attempts to generate suggested experiences were correlated with subjective responding.

**1992**

Bowers, Kenneth S. (1992). Imagination and dissociation in hypnotic responding. International Journal of Clinical and Experimental Hypnosis, 40 (4), 253-275.

A neodissociative model of mind is better equipped than a social-psychological model to deal with the complexities of hypnosis, and of human behavior generally. It recognizes, as Coe's (1992) model does not, that behavior can be more automatically activated than strategically enacted. In particular, Coe's emphasis on human behavior as purposeful and goal directed does not distinguish between goal-directed behavior that serves a purpose, and goal-directed behavior that is performed on purpose. It is this distinction that permits goal-directed behavior to be dissociated from a person's conscious plans and intentions. In addition to offering a critique of Coe's "limited process" view of hypnosis, 4 main points are made in the interest of developing a slightly modified, neodissociation view of hypnosis. First, it is argued that goal-directed fantasies are more limited in their ability to mediate hypnotic responding than is commonly appreciated; as well, they do not seem to account for the nonvolitional quality of hypnotic responding. Second, it is argued that hypnotic ability is not unidimensional, with compliance and social influence more apt to account for the low than for the high hypnotizable's responsiveness to suggestion. Third, compared to low hypnotizables, the hypnotic responsiveness of high

hypnotizables seems more likely to result from dissociated control. In other words, for high hypnotizables, hypnotic suggestions may often directly activate subsystems of cognitive control. Consequently, the need for executive initiative and effort to produce hypnotically suggested behavior is minimized, and such responses are therefore experienced as nonvolitional. Fourth and finally, while goal-directed fantasies typically accompany hypnotically suggested responses, they are in many cases more a marker of dissociated control than a mediator of suggested effects.

Kirsch, Irving; Mobayed, C. P.; Council, J. R.; Kenny, D. A. (1992). Expert judgments of hypnosis from subjective state reports. Journal of Abnormal Psychology, 101, 657-662.

Suggestibility was assessed in 60 student subjects after a traditional hypnotic induction, an alert induction, progressive relaxation training, or instruction in goal-directed imagery. Responsiveness to suggestion did not differ between groups. Subjects also generated open-ended reports of their states of awareness and of their experience of three hypnotic suggestions. A sample of these reports from 24 moderately to highly suggestible subjects was evaluated by 18 experts in the field of hypnosis. Expert ratings of subjects' open-ended reports indicated that (a) traditional hypnotic inductions produce a state of consciousness that is indistinguishable from nonhypnotic relaxation training, (b) the subjective experience of hypnotic suggestions after imagination training is indistinguishable from that after hypnotic inductions, and (c) suggestibility is unrelated to state of consciousness as assessed by experts.

Lynn, Steven Jay; Sivec, Harry (1992). The hypnotizable subject as creative problem-solving agent. In Fromm, Erika; Nash, Michael R. (Ed.), Contemporary hypnosis research (pp. 292-333). Guilford Press.

## NOTES

1:

These notes are taken only from the section of this chapter that deals with Hypnotic Responding, Imaginative Activity, and Expectancies, and they treat of the concept of nonvoluntary responding (pp 315-316). Other topics covered in the chapter include: Imagination, Fantasy, and Hypnosis Theories; The Hypnotizable Subject as Creative Problem-Solving Agent; Hypnosis and Subjects' Capability for Imaginative Activity; Goal-Directed Fantasy: Patterns of Imaginative Activity during Hypnosis; Hypnosis and Creativity; and a Conclusion.

Several studies manipulated expectancies re the relationship between imagination and involuntariness. When Ss were told that "good" hypnotic subjects could (or could not) resist suggestions, "this information affected their ability to resist the hypnotist and tended to affect subjects' report of suggestion-related involuntariness ... [Lynn, Nash, Rhue, Frauman, & Sweeney, 1984]. Furthermore, subjects who successfully resisted suggestions and subjects who failed to do so reported comparable levels of hypnotic depth and imaginative involvement in suggestions.

"Spanos, Cobb, and Gorassini (1985) conducted a similar experiment in which they found that hypnotizable subjects who were instructed that they could become deeply

involved in suggestions and yet resist them successfully resisted 95% of the suggestions and rated themselves as maintaining voluntary control over their behavior. Thus, subjects are able to resist nearly all of the suggestions when resistance is facilitated by situational demands. It is worth noting that subjects in this research who resisted hypnotic suggestions rated themselves as just as deeply involved in the suggestions as Ss who failed to resist suggestions after being informed that deeply hypnotized subjects were incapable of resisting suggestions" (pp. 315-316).

Lynn, Snodgrass, et al. (1987). showed that hypnotizable Ss who were just "imagining" along with suggestions but instructed to resist responding to motoric suggestions acted the way hypnotized Ss did in their earlier countersuggestion research: imagining subjects tended to move in response to suggestion (that "good" Ss responded in certain ways), despite being instructed to resist. In this study, with instructions designed to increase the use of goal directed fantasies (GDFs), low and high hypnotizable subjects reported equivalent GDF absorption and frequency of GDFs. However, highs responded more and reported greater involuntariness than lows, even when their GDFs were equivalent.

"A number of other studies have examined the effects of expectancies on imaginings and hypnotic behavior. Spanos, Weekes, and de Groh (1984) informed subjects that deeply hypnotized individuals could imagine an arm movement in one direction while their unconscious caused the arm to move in the opposite direction. Even though subjects so informed moved in the opposite direction, they imagined suggested effects and described their countersuggestion behavior as involuntary" (p. 317).

1990

Heyneman, Nicholas E. (1990). The role of imagery in hypnosis: An information processing approach. International Journal of Clinical and Experimental Hypnosis, 38 (1), 39-59.

Imagery is widely agreed to be an important component of hypnosis. The theoretical framework from which to conceptualize the role of imagery in hypnosis, however, has remained controversial. A model is presented which attempts to reconceptualize hypnotic imaginal processing in terms of current theory and research in cognitive psychology and psychophysiology. This model draws from a propositional approach to imagery (e.g. Pylyshyn, 1973), particularly as adapted by Lang's (1979) bioinformational theory. It is argued that the hypnotic image is fundamentally more complex than simple iconic mental representation, containing instead both stimulus and response components. It is proposed that the critical properties of the hypnotic image are not the stimulus components or propositions which give rise to the experience of the image but instead are response propositions which are associated with overt behavior. Processing of these response propositions is conceptualized as a negative feedback system between the brain and effector site. Some preliminary sources of support as well as implications and research suggested by this model are discussed.

NOTES

1:

## NOTES

The author notes that the brain does not store a kind of "photograph," but rather stores "meanings" (Anderson, 1978); and that images actually represent response processes, as observable in physiological concomitants (Lang, 1977).

The hypnotic suggestion that a Subject's arm is being pulled up into the air by a large helium balloon is represented by two separate propositions: "There is a helium balloon tied to your arm" (a stimulus proposition) and "Your arm is moving up into the air" (a response proposition). According to Peter Lang (1979), an image is not a mental stimulus to which a response is made, but is in itself an active response process, accompanied by physiological activity. Verbal instructions to a Subject determine whether they will access stimulus propositions or response propositions. "Lang et al. (1980) found that only those Ss given response training coupled with response proposition scripts showed significant physiological arousal. These Ss were presumably better able to access and process that portion of the propositional network which controls visceral and motoric responding" (p. 46).

This author proposes that cognitive processing of a hypnotic image involves (internal) responding, and that 'responsive propositions' provide the basis for understanding the function of imagery in hypnosis, and are more important to hypnotic imagery than stimulus propositions. "In other words, the experience of a visual image and thus the vividness or controllability of that image is not critical for hypnosis. What is important to note is that the hypnotic behavior is not a response to a visual image but is instead a function of the processing of the image itself (cf. Lang, 1979)" (pp. 47-48).

In explaining how an image might facilitate amplification of a subtle response (such as in arm levitation), the author suggests that physiological and external feedback systems are involved--principally a neural feedback loop between brain and target organ (in this case, arm muscles). "Efferent signals, which are activated by processing response propositions, initiate the overt behavior while afferent signals feed back to the brain and modulate further input to the effector system. The process progressively reduces the mismatch between the image instructions and behavior until the hypnotic task is completed" (p. 48). The feedback loop "provides information on the discrepancy between desired behavior and actual behavior:  $e = B_d - B_a$ , where  $e$  = error,  $B_d$  = desired behavior, and  $B_a$  = actual behavior (Arbib, 1972). The error signal generated by this discrepancy modifies the efferent output so as to eventually approximate  $e = 0$ " (p. 49). The author notes that this complex process of physiological feedback may be "augmented by external feedback such as modified verbal instructions or vocal intonations of the hypnotist and self-observation by S" (p. 49).

The author's model is summarized as: "1. The context, setting, and expectations implied by being hypnotized as well as the wording of the hypnotic suggestions provides S with: (a) explicit or implicit instructions to use imagery, (b) repetitious wording which may increase the probability of fully accessing the relevant propositions, and (c) instructions that task completion is expected. This may function to increase the probability that the deep structure of the response propositions will be processed. 2. The hypnotic suggestion proper is composed of stimulus and response propositions embedded within a propositional network. 3.

Stimulus propositions give rise to the phenomenological characteristics or the percept- like experience of the image but may be unimportant in determining hypnotic behavior. 4. Processing of the response propositions includes an active response. This response process is facilitated by S's expectation to become actively involved in the imagined scene. Response propositions are the critical features of hypnotic imagery. 5. During hypnosis, the propositional network may be systematically modified by physiological or external feedback regarding the relative progress of the behavior toward task completion. This processing of response propositions is conceptualized as a negative feedback system. Efferent signals are delivered to the appropriate effector site while afferent signals feed back to the brain in order to modify further neural input, functioning to reduce the error between image and behavior. While the initial feedback is probably physiological, additional feedback may be obtained from the hypnotist's instructions and S's self-observations. 6. If stimulus propositions are simultaneously accessed, S experiences an image" (p. 51).

NOTES

1:

The authors present a model to account for the subjective experience of nonvolition. The model rests on four observations: (1) nonvoluntary responses "have all of the properties of behavior that is typically defined as voluntary" (p. 108); (2) "hypnotizable subjects can resist suggestions when resistance is defined as consistent with the role of a 'good' hypnotized subject" (p. 108); (3) "Hypnotic behaviors are neither reflexive/automatic ... nor manifestations of innate stimulus-response connections" (p. 108); (4) "Hypnotic performances consume attentional resources ... in a manner comparable to nonhypnotic performances" (p. 108). They continue, "At the same time, many of the cognitive operations and affective reactions that accompany hypnotic responding are not readily accessible to consciousness" (pp. 108-109).

1988

Gorassini, Donald R.; Hooper, Cynthia L.; Kitching, Kathleen J. (1988). The active participation of highly susceptible hypnotic subjects in generating their hypnotic experiences. Imagination, Cognition and Personality, 7 (3), 215-226.

Hypnotized individuals have traditionally been considered to be detached from the control of their own suggested behavior. We tested this and the alternative notion that hypnotized subjects attempt to self-generate the experiences (i.e., mainly of involuntariness) as well as produce the behaviors thought to be prototypical of high hypnotic ability. In an experimental investigation, highly susceptible hypnotic subjects were found to engage in the kind of imaginative activity that would be

expected of individuals who were attempting deliberately to generate their experiences of involuntariness; they engaged as actively in imagery-generation as did subjects who were specifically instructed to imagine during suggested responding, and they experienced as much involuntariness as subjects in whom suggested movements were produced by an external physical force. The implications of these findings for the neodissociation and social psychological theories of hypnotic responding are discussed.

1984

Crouse, Eric; Kurtz, Richard (1984). Enhancing hypnotic susceptibility: The efficacy of four training procedures. American Journal of Clinical Hypnosis, 27, 122-136.

In this study, we have compared the effects on hypnotic susceptibility of several components of training procedures based on a social learning model, which have been reported to be successful in enhancing hypnotic susceptibility. These included: 1) attitude-conception of hypnosis information, 2) involvement instructions, 3) goal-directed fantasy instructions, and 4) practice vs. no practice in responding to hypnotic suggestions. A 3 x 2 x 2 repeated measures factorial design was used for the experiment with 60 female volunteers serving as subjects in the study. Contrary to expectations, no differential treatment effects were obtained on either objective or subjective measures of hypnotizability. Furthermore, it was questionable whether or not any of the three information-based components even produced gains in hypnotic susceptibility. None produced clinically significant gains. They also were not found to alter either the subjects' attitudes or their use of hypnosis-related skills. Similarly, practice was found to be ineffective in enhancing responsiveness to suggestions. Taken as a whole, the results of this study suggest that the gains in hypnotic susceptibility reported for social learning-type training procedures may be due to causes other than those posited by social learning theory.

#### NOTES

Diamond (1977) posited 3 core components to modification procedures: attitudinal and set factors, cognitive strategy factors, and optimal learning factors (specific ways subjects are taught the internal responses).

"The present study was undertaken to more fully clarify the extent to which each of the critical components hypothesized by Diamond contributes to increasing susceptibility. It was predicted that subjects receiving attitude-conception of hypnosis information and subjects receiving involvement instructions would show a significantly greater gain in hypnotizability than Ss receiving goal-directed fantasy instructions. Secondly, it was predicted that a significantly greater gain in subjects' hypnotizability would result from an opportunity to practice responding to hypnotic suggestions when coupled with involvement instructions than when accompanied by goal-directed fantasy instructions or attitude-conception of hypnosis information" (p. 125).

A revised SHSS:C was used; it deleted words that explicitly suggested goal directed fantasies (GDF's) on several items: hand lowering, moving hands apart, taste

hallucinations, arm rigidity, arm immobilization. Experimenters used audiotaped presentation. Subjects in 3 of 6 experimental groups were also given opportunity to practice 30 minutes on 3 occasions spaced no more than one week apart. They were given 2 practice trials on each of 5 hypnotic suggestions taken from several different scales.

"While differential treatment effects were not found, there was a general facilitation of hypnotic responsiveness for all Ss across treatment conditions on both objective and subjective hypnotizability measures. The mean change in the objective hypnotizability score for all subjects was +.68, ... $p < .001$ ; the corresponding mean change in the subjective hypnotizability scores was +3.11 ...  $p < .001$ . Although statistically significant, neither of the shifts appear to indicate clinically significant shifts in hypnotic responsiveness" (p. 129).

The changes in the positive direction in hypnotizability were not correlated with hypnotizability. Subjects appear to change in their conceptualization of hypnosis, in the direction of it being more a self-induced phenomenon ( $p < .001$ ).

In their Discussion, the authors write, "Taken as a whole, results of this study challenge assumptions which have been made about how training procedures based on a social learning model affect gains in hypnotic susceptibility" (p. 131). Each experimental manipulation was intended to influence a mediating variable, and that apparently did not happen. Teaching subjects to use GDFs on a few items did not generalize so that subjects would generate GDFs on novel items. The results suggest "caution against assuming that social learning base training procedures are effective in altering subjects' attitudes and/or their use of skills thought to mediate hypnotic responsiveness" (p. 133). Nevertheless, the correlational data support previous studies that relate hypnotizability to the mediating factors under investigation.

Continuing their Discussion, the authors write, "Clearly, more attention should be paid in future studies to assessing changes in mediating variables produced by such training procedures. This is particularly important in terms of subjects' use of GDF's and their use of cognitive strategies to increase the extent of their involvement in the hypnotic experience. It is significant that in this study neither involvement instructions nor GDF instructions were found to alter subjects' use of cognitive strategies. Changes in these skill-related factors need to be demonstrated if social learning based training procedures are to be proven effective in altering subjects' hypnotic abilities rather than simply in raising subjects to their optimal level of responsiveness.

"One explanation which has been offered for the reported success of such training procedures is that they work by changing subjects' attitudes, motivation and/or expectations of hypnosis while leaving any aptitudinal component to hypnosis unaltered (Perry, 1977). From this point of view the gains in susceptibility reported for such procedures result from subjects moving closer to their optimal or 'plateau' level of responsiveness rather than from real changes in subjects' hypnotic abilities" (p. 134).

Alternatively, it is possible that the increases observed following training programs have something to do with the hypnotist-subject relationship. For example, increases in hypnotizability are more modest when the training is given in written instructions than when it is given in person by a hypnotist.

1976

Spanos, Nicholas P.; Spillane, Jeanne; McPeake, John (1976). Cognitive strategies and response to suggestion in hypnotic and task-motivated subjects. American Journal of Clinical Hypnosis, 18, 254-262.

Thirty-two male and 32 female subjects, exposed to an hypnotic induction or task-motivational instruction, were administered either three suggestions which provided a cognitive strategy (i.e., a goal-directed fantasy, GDF) for experiencing suggested effects, or three suggestions that did not provide such a strategy. Subjects provided with GDF strategies were more responsive overtly and subjectively to two out of the three suggestions. Subjects in the No GDF Strategy treatment who spontaneously devised their own goal-directed fantasies were more responsive to suggestions than subjects who failed to devise such a strategy. These results support the contention that goal-directed fantasy helps both hypnotic and non-hypnotic subjects experience suggested effects.

NOTES 1:

NOTES: The suggestions were for arm levitation, arm rigidity, and amnesia.

1975

Barber, Theodore Xenophon (1975). Responding to 'hypnotic' suggestions: An introspective report. American Journal of Clinical Hypnosis, 18 (1), 6-22.

The author first presents an introspective report which describes some of his attitudes, motivations, and expectancies and ongoing thought processes while he is responding to 'hypnotic' suggestions. The introspective report indicates that (a) suggested effects are experienced when a person thinks with and imaginatively focuses on those things that are suggested and (b) a person imaginatively focuses on the suggestions when he sees the test situation as useful and worthwhile and when he wants to and expects to experience those things that are suggested. It is then argued that the responsive subject in a hypnotic situation differs in every important respect from the sleepwalker and closely resembles the person who is involved in reading an interesting novel or in observing an interesting motion picture. Finally, the author outlines a course, now being developed, that aims to teach individuals how to respond to suggestions.

1974

Spanos, Nicholas P.; Barber, Theodore Xenophon (1974). Toward a convergence in hypnosis research. American Psychologist, 29 (7), 500-511.

NOTES

1:

The authors believe that there is general agreement that "responding to suggestions involves at least two interrelated factors. The first can be conceptualized as a willingness on the part of the subject to cooperate with the experimenter in fulfilling the aims of the suggestions. The second can be described as a shift in cognitive orientation from an objective or pragmatic perspective to one of involvement in suggestion-related imaginings" (p. 500).

They suggest that the two major theoretical positions lead to different approaches to research. "The construct trance or hypnotic state, despite its inherent vagueness and lack of amenability to operational definition, continues to dominate state conceptualizations of hypnosis. This construct seems to refer to a state that differs, not simply quantitatively, but in some basic, qualitative way, from waking states and from states of sleep. As Bowers (1966) noted, 'Most [present-day] investigators interested in hypnosis believe that there is an hypnotic state which fundamentally differs from the waking state [p. 42].' This belief makes it much more likely that it will be state theorists who will conduct studies aimed at establishing a physiological basis for the hypothesized fundamental alteration. The state theorists are also more likely than the nonstate theorists to pursue research that might indicate that hypnotic performance involves unique or highly unusual changes in perceptual functioning or in cognitive functioning, such as trance logic (Orne, 1959). Although studies of this type have generally produced negative or inconclusive findings (Barber, 1979, 1970a, 1973; Barber & Ham, 1974; Hilgard, 1972; Johnson, 1972; Johnson, Maher, & Barber, 1972; Sarbin & Slagle, 1972), they have on occasion yielded some provocative results (Graham, 1979).

"On the other hand, the guiding assumption of the nonstate theorists -- that the good hypnotic subject is not fundamentally different from the normal individual who is cooperating in a social situation in which he is asked to experience suggested effects -- will lead these investigators to continue their studies of situational and social-psychological antecedents of hypnotic performance. The nonstate investigators may be expected to probe further into the effects of such variables as how the situation is defined to the subject, what attempts are made to remove fears and misconception, and how the suggestions are worded (Barber & DeMoor, 1972; Spanos, 1973). The basic assumption of the nonstate theorists will also continue to influence their conceptualization of hypnotic performance as a set of socially influenced cognitive skills or abilities. However, despite these differences in the research proclivities of state and nonstate investigators, theoretical convergences of the type outlined in this article indicate that a good deal of the future research carried out by proponents of both paradigms will dovetail in focusing on the role of imaginative processes in hypnotic performance" (pp. 508-509).

1972

Barber, Theodore Xenophon; de Moor, Wilfried (1972). A theory of hypnotic induction procedures. American Journal of Clinical Hypnosis, 15 (2), 112-135.

The first part of the paper delineates nine variables in hypnotic induction procedures that give rise to heightened responsiveness to test-suggestions: (a) defining the situation as hypnosis; (b) removing fears and misconceptions; (c) securing cooperation; (d) asking the subject to keep his eyes closed; (e) suggesting relaxation, sleep, and hypnosis; (f) maximizing the phrasing and vocal characteristics of suggestions; (g) coupling suggestions with naturally-occurring events; (h) stimulating goal-directed imagining; and (i) preventing or reinterpreting the failure of suggestions. Data are presented to support the theory that the nine variables augment responsiveness to test-suggestions by giving rise to positive

attitudes, motivations, and expectancies which, in turn, tend to produce a willingness to think with and vividly imagine those things that are suggested. The second part of the paper specifies situational variables and variables involved in induction procedures that produce a trance-like appearance, changes in body feelings, and reports of having been hypnotized.

The manual and response booklet for the Waterloo-Stanford Group Scale of Hypnotic Susceptibility, Form C (WSGC) is presented. The WSGC is a group adaptation of the individually administered Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C).

**Kirsch, Irving; Milling, Leonard S.; Burgess, Cheryl (1998). Experiential scoring for the Waterloo-Stanford Group C Scale. International Journal of Clinical and Experimental Hypnosis, 46 (3), 269-279.**

A scale is presented that assesses subjective experiences associated with the test suggestions contained in the Waterloo-Stanford Group C scale (WSGC), a group adaptation of the Stanford Hypnotic Susceptibility Scale: Form [C] (SHSS:C). This scale, along with the standard behavioral scoring system of the WSGC, was given to 926 students at the University of Connecticut. Normative data from this sample indicate that the experiential scoring scale is both reliable and valid as a measure of suggestibility. It is suggested that it may be useful to supplement behavioral scoring with experiential scoring when the WSGC is used.

**1993**

**Bowers, Kenneth S. (1993). The Waterloo-Stanford Group C (WSGC) Scale of Hypnotic Susceptibility: Normative and comparative data. International Journal of Clinical and Experimental Hypnosis, 41 (1), 35-46.**

The Waterloo-Stanford Group C (WSGC) hypnotic susceptibility scale was developed as a substitute for the individually administered Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C). A first investigation with WSGC reports

normative data on 259 subjects, and the results indicate that it is comparable in most important respects to the norms of SHSS:C. A second investigation directly compared WSGC and SHSS:C in a counterbalanced design on 65 subjects, and the two scales correlated .85. It is argued that, when used as a follow-up to the Harvard Group Scale of Hypnotic Susceptibility, Form A, WSGC provides a valid criterion of hypnotic ability.

**Kirsch, Irving; Council, James R.; Wickless, Cynthia (1990). Subjective scoring for the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 38 (2), 112-124.**

A scale is presented which assesses subjective experiences associated with the test suggestions contained in the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962). This scale, along with the standard HGSHS:A self-scoring test booklet, was administered to 479 students at the University of Connecticut and 618 students at North Dakota State University, and normative data from these samples are reported. Correlational analyses indicated that the scale was both reliable and valid as a measure of hypnotic responsiveness. It is suggested that it may be useful to supplement behavioral scoring of hypnotizability with subjective scoring.

**1989**

**Palan, B.M.; Chandwani, S. (1989). Coping with examination stress through hypnosis: An experimental study. American Journal of Clinical Hypnosis, 31, 173-180.**

Fifty-six volunteer medical students participated in three groups balanced for number of subjects, performance at last examination, and hypnotizability. The hypnosis and waking groups attended eight group sessions once a week with general ego-strengthening and specific suggestions for study habits, with a ninth session of age progression and mental rehearsal. Subjects in these two groups practiced self-suggestions (in self-hypnosis or waking respectively) daily for the study period of 9 weeks. The control group experienced sessions of passive relaxation induced by light reading for the same period of time. The hypnosis group improved significantly in coping with examination stress, but there was no significant change in performance on examinations by any of the groups.

**Spiegel, David; Bloom, J. R.; Kraemer, H. C.; Gottheil, E. (1989, October 14). The beneficial effect of psychosocial treatment on survival of metastatic breast cancer patients: A randomized prospective outcome study. Lancet, 888-891.**

The effect of psychosocial intervention on time of survival of 86 metastatic breast cancer patients was studied using randomized prospective design. The one-year treatment consisted of weekly supportive group therapy with training in self-hypnosis for pain management, and resulted in significant reductions in mood

disturbance and pain. Both the treatment and control groups had routine oncologic care. At ten-year follow-up, only three of the original 86 patients were still alive, and death records were obtained for the other 83. Survival from the time of randomization and onset of intervention was 36.6 (sd = 37.6) months for the treatment group, compared with 18.9 (sd = 10.8) months for the control group, and this difference was highly significant ( $Z = 3.94$ ,  $p < .0001$ ) using the Cox life table regression model. Kaplan-Meier survival analysis indicated that the divergence in survival began at 20 months after entry into the study, or 8 months after the treatment intervention ended. These unexpected findings suggest that intensive psychosocial support affects the course of the illness, although the mechanism by which it does so is not clear.

1988

Azuma, Nagato; Stevenson, Ian (1988). 'Psychic surgery' in the Philippines as a form of group hypnosis. American Journal of Clinical Hypnosis, 31, 61-67.

Psychic surgeons and their patients were observed in the Philippines during a variety of procedures of 'minor surgery.' In six cases, subcutaneous tissues (cysts and benign tumors) were removed. Histological examination confirmed the gross diagnoses and left no doubt that the skin had been penetrated. Although the psychic surgeons used no analgesics or anesthetics, the patients appeared to experience little or no pain and only slight bleeding. The authors believe that a supportive group 'atmosphere' enables the patients to enter a quasi-hypnotic state that reduces pain and facilitates healing.

Bowers, Patricia G.; Laurence, Jean-Roch; Hart, David (1988). The experience of hypnotic suggestions. International Journal of Clinical and Experimental Hypnosis, 36, 336-349.

The experience of nonvolition in response to hypnotic suggestions was investigated for 126 Ss. 2 different scales, a new scale providing discrete options for response and a previously used volition rating scale, gave Ss an opportunity to describe some of their subjective experiences after completion of a 12-item adaptation for group administration of the Stanford Hypnotic Susceptibility Scale, Form C (Weitzenhoffer & Hilgard, 1962). Ratings of depth of hypnosis were also obtained. Ss had been previously administered the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962). Distribution of descriptions of experience for passed and failed items were obtained. Total scores on subjective indices were found to be highly correlated with the behavioral score on the Waterloo-Stanford Scale of Hypnotic Susceptibility: Group C. Items differed, however, in the degree to which responses seem to occur effortlessly. Some suggestions have a substantial number of passed responses lacking the "classic suggestion effect," but only 7% of Ss have more than 2 such responses. NOTES 1: NOTES: Earlier research on the subjective perception of voluntary enactment of suggestions found from 20% (K. Bowers, 1981; P. Bowers, 1982) to 55% (Spanos, Radtke, Hodgins, Stam, & Bertrand, 1983) of hypnotic responses were described as voluntary in nature. Methodological differences could account for the range in

probability levels, and rating scales used did not provide for absence of behavioral response to a particular suggestion.

This research investigated three issues: "1. Using a choice format to describe experiences during hypnosis, what is the distribution of the different descriptions used to index the construct of nonvolition? When S gives a mid-point rating on a volition rating scale, to what experiences does he/she refer? 2. How do two aspects of subjective experience: nonvolitional experience descriptions and hypnotic depth reports, covary with behavioral passing and failing of items and with levels of hypnotizability? 3. How frequently does S pass an item behaviorally but indicate either that he/she did not experience the response or that he/she purposefully enacted it? On what items is this a more or less frequent occurrence? Are there just a few people who pass items in this fashion or is it a common observation?" (p. 339). The Ss were seen in small groups. Immediately after hypnosis they scored their own hypnotizability scales. Then they were asked to rate their subjective response to each suggestion: - how much they had experienced the suggestion (1-5) - how involuntary their response had been (1-5) (These two items comprised the Voluntary Rating Scale (VRS) used by K. Bowers, 1981, and P. Bowers, 1982.) - how deeply hypnotized they had felt (1-10, Perry & Laurence format, 1980) - Choice Scale (example from the hand magnetism item below) "Choice Scale of Nonvolitional Experience:

Listed below are various ways people experience the hands together item. Please check the description(s) that most closely describe your experiences: (1) My hands did not move together at all. (2) I purposefully directed the movement of my hands most of the time. (3) I found I directed the movement of my hands and then later they continued to move together with no effort on my part. (4) I found my hands moving together without my helping them. (5) During this experience, the feelings of purposefully moving my hands were completely mixed with feelings that they were moving on their own. None of the above" (p. 340).

Considering both the passed and failed items, and after excluding the 'None of the above' category, "37% of items [on the W-SGSHS:C] were not experienced, 12% were enacted purposefully, 14% were experienced as intertwined volition and nonvolition, 17% were experienced as beginning purposefully but becoming nonvolitional, and 20% 'happen by themselves'" (p. 341). See Table 2, taken from the article.

Table 2 Average Percent of Ss per Item Choosing Each of the Options Begins

No Purposeful Completely Purposefully; Happened Itself

Exper. Enactment Mixed Continues On NoTryng

Own Passed 7.5 12.2 21.8 26.2 32.2 Failed 60.4 13.9 10.4 9.3 5.9

Passed Items 3.0 10.7 30.0 47.2 9.1 Rated 3 on Volition Rating Scale

Thus of those failing an item, 60% reported that they did not experience the suggestion, while almost 26% reported some level of subjectively experienced nonvolition.

This research demonstrated that the Choice Scale is an improvement over the Voluntary Rating Scale, which has an ambiguous midpoint of '3' between voluntary and nonvoluntary extremes (on a 5-point scale). Almost half of the ambiguous '3'

responses on the VRS were associated with a more meaningful response on the Choice Scale, indicating that the response started off voluntarily but then continued 'on its own.' Another third of the Ss indicated that there was an intertwining of volition and nonvolition.

The Choice Scale (transformed into an ordinal scale) was correlated with the VRS and hypnotizability and depth estimate scales. The correlations were "consistently high, suggesting that typically one reports feeling more deeply hypnotized when many suggestions are performed and passed, and more deeply hypnotized Ss report feeling that suggestions occur more 'by themselves' than do less hypnotizable Ss" (p. 342).

The authors note the complex relationship between behavioral and subjective experience. High hypnotizables report experience of nonvolition even with some failed items, and rate themselves as deeply hypnotized even when failing items. This is not true for low hypnotizables, whose self-rated depth varies directly with passing or failing items.

Mismatches were defined as passing an item behaviorally but reporting either that it was not experienced (Choice 1) or purposefully enacted (Choice 2). 93% of Ss had less than 3 mismatches; of the 8 Ss exhibiting 3 or more mismatches, 3 were medium-low hypnotizables, 4 were medium-highs, and 1 was highly hypnotizable. When one corrects their total hypnotizability score for the mismatch, people remain close to their original score however.

Some items had many more mismatches than others (See Table 6). The 'classic suggestion effect' reflected in a low percentage of mismatches (3-9%) was found for five items; three items had a moderate level of mismatches (16-22%); but four suggestions had mismatches on 34-41% of the passed responses. Item difficulty could not account for whether the classic suggestion effect occurred: two very difficult items were at opposite ends of the spectrum--positive music hallucination had the fewest and negative visual hallucination the most frequent mismatches. "One might speculate that the nature of one's ordinary imaging during the day makes some hallucinations well practiced and easier to produce, while others are rarely practiced and seem to require cognitive effort to reconstruct. ... Thus, instead of a mismatch representing 'faked' responses, it may at times represent S's report of a hallucination's seeming real while simultaneously requiring effort. Ideomotor suggestions have few mismatches. If they feel 'real,' it is by virtue of their seeming to occur without effort or volition" (pp. 346-347).

Table 6 Item % Mismatch Hand Lowering 2.9 Hands Together 4.8 Arm Rigidity 5.6 Music Hallucination 7.7 Dream 8.7 Arm Immobilization 15.5 Amnesia 21.6 Age Regression 21.8 Taste Hallucination 33.8 Negative Hallucination 34.6 Mosquito 38.1 Post-hypnotic Suggestion 40.8

Since highly hypnotizable people experience nonvoluntariness even when they fail items, tested hypnotizability must reflect more than simply passing test items on suggestion. "Research focusing exclusively on the nonvolitional aspect of hypnotic experience may be somewhat 'off the mark,' at least for some types of suggestions. Reports of nonvolition may be tracking the experience of effortless responding which may be just one aspect of a complex hypnotic response to cognitive suggestions. ... It may be that studies using free reports from Ss responsive to

hallucination suggestions would be necessary prior to devising an appropriate 'choice' scale for these items. The work of Sheehan and McConkey (1982) provides a solid basis for such a task. The Choice Scale in the present study was derived from an understanding of the 'classic suggestion effect,' the concept of which is closely tied to ideomotor suggestions. This concept may or may not prove to be of central relevance to hypnotic hallucinations or more generally to cognitively demanding suggestions" (p. 347).

Neufeld, V.; Lynn, Steven Jay (1988). A single-session group self-hypnosis smoking cessation treatment: A brief communication. International Journal of Clinical and Experimental Hypnosis, 36 (2), 75-79.

This study was designed to assess the efficacy of a manual-based, single-session group of self-hypnosis intervention. At 3 months follow-up, 25.92% of the total number of participants (14 male, 13 females) reported continuous abstinence, and at 6 months, 18.52% of the participants reported continuous abstinence. Reported social support and motivation to quit were both associated with successful outcome. Comparison of the current data with other findings reported by the American Lung Association (Davis, Faust, & Ordentlich, 1984) suggests that treatment effects may not be solely attributable to the use of a maintenance manual, education, and attention. Limitations of the research associated with issues of experimental control, generalizability of the findings, and outcome measures are discussed.

Spinhoven, Philip; Baak, Diana; Van Dyck, Richard; Vermeulen, Peter (1988). The effectiveness of an authoritative versus permissive style of hypnotic communication. International Journal of Clinical and Experimental Hypnosis, 36, 182-191.

The differential effectiveness of an authoritative versus permissive style of hypnotic communication was investigated, with locus of control as a moderator variable. 44 Ss received in counterbalanced order both the more authoritatively worded Harvard Group Scale of Hypnotic Susceptibility, Form A and the Wexler-Alman Indirect Hypnotic Susceptibility Scale (WAIHS), which is a more permissive scale with the same item content as HGSHS:A. Permissively worded suggestions did not enhance the level of hypnotic responsiveness. Locus of control did not predict the response level on one of the scales. Unexpectedly, significantly more female Ss preferred the WAIHS, and more male Ss preferred HGSHS:A. It is concluded that Ss' characteristics (i.e., hypnotizability) are more important for hypnotic responsiveness than variations in style of hypnotic communication or scale preference."

**1986**

Radtke, H. Lorraine; Spanos, Nicholas P.; Malva, C. Lori Della; Stam, Henderikus J. (1986). Temporal organization and hypnotic amnesia using a modification of the Harvard Group Scale of Hypnotic Susceptibility. International Journal of Clinical and Experimental Hypnosis, 34, 41-54.

The Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962) was modified to permit better assessment of amnesia and changes in temporal organization during amnesia. First, a baseline measure of recall was obtained before administration of the amnesia suggestion. Second, on the recall trial following cancellation of the suggestion, Ss recalled everything they could remember. Amnesia was assessed by comparing recall during the suggestion with recall before it and after it was canceled. Temporal organization was assessed by correlating the order of item administration with Ss' recall orders. Hypnotic susceptibility and amnesia were independently related to temporal organization. Overall, high hypnotizable Ss organized less than medium or low hypnotizables, and amnesics showed less temporal organization than nonamnesics, but neither of these variables interacted with recall trial. The results are discussed in terms of recent theories of hypnotic amnesia.

NOTES

1:

#### NOTES

Subjects in general tended to use less temporal organization during the suggestion compared to the baseline and postsuggestion trials. Although they did not obtain a disorganization effect comparable to that found in the clustering studies (e.g., Spanos & Bodorik, 1977), the results "replicated past studies that found differences in the recall organization of high and low hypnotizables during an amnesia suggestion" (p. 50), while suggesting that "the previous findings were not due to hypnotic amnesia" (p. 50).

"The baseline differences replicated Schwartz (1980) who found similar differences between high and low hypnotizable Ss following a hypnotic induction procedure but in the absence of an amnesia suggestion. Since we also found differences posthypnotically, it is questionable whether the hypnotic induction procedure was a causal factor in the Schwartz study. Furthermore, the presence of such differences on the postsuggestion trial represents a failure to replicate Evans's (1980) finding of no differences between high and low hypnotizable Ss under comparable nonhypnotic conditions. The present results are also contrary to those of two other studies that found no differences between high and low hypnotizables on rho scores on the amnesia trial (Radtke & Spanos, 1981; St. Jean & Coe, 1981) and a recent study using word stimuli which found a significant correlation between hypnotizability and temporal organization only during the amnesia suggestion (Kihlstrom & Wilson, 1984). Taken together these studies suggest that temporal organization (at least when hypnotic experiences are recalled) varies as a function of hypnotizability and therefore may be attributed to an individual difference factor" (p. 50).

The authors go on to say they have replicated other studies (p. 50), noting that the Harvard may not be the best method for investigating this issue, and individual testing of memory may be better (p. 51).

1985

Bongartz, Walter (1985). German norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 33 (2), 131-139.

German norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962) are presented. 3 samples (N = 108, N = 103, and N = 163) were pooled resulting in an aggregate sample of 374 Ss which was in general congruent with earlier normative studies (Laurence & Perry, 1982; Sheehan & McConkey, 1979; Shor & E. Orne, 1963) with regard to score distribution and item difficulty level. Reliability of the German adaptation of HGSHS:A was somewhat lower than the reliabilities reported by the 3 cited studies, but in terms of standard error of measurement (estimated for each study by using the corresponding reliability coefficient), the German and the other studies were quite comparable. Results show that HGSHS:A is a useful instrument for initial screening of hypnotizability in a German context.

Jeffrey, Timothy B.; Jeffrey, Louise K.; Greuling, Jacquelin W.; Gentry, William R. (1985). Evaluation of a brief group treatment package including hypnotic induction for maintenance of smoking cessation: A brief communication. International Journal of Clinical and Experimental Hypnosis, 33 (2), 95-98.

Hypnotic, cognitive, and behavioral interventions were used in a 5-session treatment program to assist 35 Ss with maintenance of smoking cessation. 63% of the treated Ss discontinued smoking, and 31% maintained abstinence for 3 months ( $p < .005$ ). These results include 13 dropouts, all of whom were smoking at 3 months follow-up. No S in the waiting-list-control group quit smoking. The results demonstrate that a brief, group treatment program, including hypnotic techniques, can be effective for smoking cessation.

Jupp, J. J.; Collins, J. K.; McCabe, M. P. (1985). Estimates of hypnotizability: Standard group scale versus subjective impression in clinical populations. International Journal of Clinical and Experimental Hypnosis, 33 (2), 140-149.

The relationship between hypnotic responsiveness as measured by the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962) and global depth estimates derived from an 11-point scale were explored in 2 clinical samples. In one case, depth estimates were made just before, and in the other, immediately following the patients' focus on aspects of hypnotic responsiveness. The responsiveness-depth relationship was moderate and consistent across both samples, a finding which in itself is consonant with previous findings employing experimental Ss. When HGSHS:A performance and depth estimates were less proximate, the relationship between them remained significant but was substantially reduced in magnitude. Data suggest that low hypnotizable Ss increase their estimates of depth, and that higher hypnotizable Ss retain relatively stable estimates with increased exposure to hypnosis in a clinical context.

1983

Saavedra, Ramon Luis; Miller, R.J. (1983). The influence of experimentally induced expectations on responses to the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 31, 37-46.

A sample of 75 female and 63 male undergraduates were told that their hypnotizability was predictable through the application of a battery of questionnaires and physiological measures. Three levels of hypnotizability expectations were created, with 3 groups of Ss informed that they were highly hypnotizable, moderately hypnotizable, or low in hypnotizability, respectively. A control group received no such expectations. All Ss were then administered the Harvard. Results indicated a significant main effect due to the assigned hypnotizability expectations. Only Ss in the low expectation group, however, scored significantly differently from the other groups on the Harvard. Four other variables were examined as covariates: locus of control, attitude toward hypnosis, absorption, and self-predictions of hypnotizability. All but locus of control correlated significantly with the Harvard. It also was shown that the degree to which assigned expectations influenced Harvard scores was a function of the confidence Ss had in those expectations.

#### NOTES

The authors state that research has shown that it is easier to lower hypnotizability scores by providing negative expectancies than to increase hypnotizability scores through provision of positive expectancies. In this study, very little of the variance of hypnotizability scores was accounted for by the expectancy manipulation

Farthing, G. William; et al. (1982, October). Voluntariness-involuntariness on the Harvard Group Scale of Hypnotic Susceptibility. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Indianapolis, IN.

#### NOTES

Challenge items were equal to ideomotor items in percentage of Ss who felt the (passed) response was at least 75% nonvoluntary.

1982

Laurence, Jean-Roch; Perry, Campbell (1982). Montreal norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 30 (2), 167-176.

Norms are presented for the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSH:A) of Shor and E. Orne (1962). Comparisons are made on HGSHS:A between 3 Montreal samples (N = 220, N = 178, & N = 137) and the aggregate sample (N = 535). These are compared additionally with a normative group of Harvard students (Shor & E. Orne, 1963), a normative group of University of California at Berkeley students (Coe, 1964), a normative sample of Australian students (Sheehan & McConkey, 1979), and the original Stanford University

normative sample which was tested individually on the Stanford Hypnotic Susceptibility Scale, Form A (Weitzenhoffer & Hilgard, 1959). Although the Montreal groups were heterogeneous in ethnic origin and first language, the present normative data are generally congruent with earlier studies.

**1980**

McConkey, Kevin M.; Sheehan, Peter W.; Law, H. G. (1980). Structural analysis of the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 28 (2), 164-175.

Multiple samples of Ss were tested on the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne, (1962) to examine the nature of the dimensions underlying the scale. Data were analyzed by the principal components method, the alpha factoring technique, and the Rasch model of analysis. The Rasch model was used to specifically test the hypothesis that HGSHS:A measures just one dimension with items varying along a difficulty continuum. Results indicated that either a 2- or 3-factor solution is appropriate to HGSHS:A and that performance on the test cannot be explained in terms of a single dimension even when item difficulty is taken into account. Greatest instability of structure across both samples and methods of analyses was evident for the cognitive-delusory items on the scale. Implications for hypnotic theory and test construction are discussed.

**1979**

Araoz, Daniel L. (1979). Hypnosis in group-therapy. International Journal of Clinical and Experimental Hypnosis, 27 (1), 1-13.

Therapeutic groups are defined to include both therapy groups and enrichment or extensional groups, either goal-specific or goal-individualized. After reviewing the literature, 3 modalities for the use of 6 hypnotherapeutic techniques are presented. These modalities are: (a) simultaneous group hypnosis, (b) working with one member and then fostering group interaction, and (c) cooperative group self-hypnosis. The 6 group hypnotherapy techniques are: (a) relaxation, (b) positive revivification, (c) dream production, (d) age regression and recovery of early recollections, (e) age progression and mental rehearsal, and (f) ego strengthening. The need for research in group hypnotherapy is stressed, especially in the areas of transference, countertransference, and 'co-transference.'

McConkey, Kevin M.; Sheehan, Peter W.; White, K. D. (1979). Comparison of the Creative Imagination Scale and the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 27 (3), 265-277.

237 Ss were administered both the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962), and the Creative Imagination Scale (CIS) of Barber and Wilson (1977) and Wilson and Barber (1978) in separate

testing sessions. Results were analyzed to assess the extent of relationships between the 2 scales and particular attention was paid to the question of whether, or not, CIS can be said to be an index of hypnotizability as traditionally measured by HGSHS:A. Data indicated that performance on CIS relates positively ( $r = .28$ ) to success on HGSHS:A, but the 2 tests are independent in their underlying dimensions. The CIS appears to tap primarily the processes of imagery and imagination which are only partly related to performance on the more complex scales which measure hypnosis as generally conceptualized.

Sheehan, Peter W.; McConkey, Kevin M. (1979). Australian norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 27, 294-304.

Australian norms for the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. Orne, 1962) are presented and results relating to score distributions, item difficulty level, reliability, and validity are considered for 3 distinct samples of Australian students. Data are compared with both the original norms (Shor & E. Orne, 1963) and additional American (Coe, 1964) normative data. Results indicated that, in the Australian context, HGSHS:A functions as a reliable, effective predictor of hypnotic susceptibility. The psychometric properties of the scale were uniform across all of the different samples and reference groups that were considered. The accuracy of the scale appears to be most obviously limited when it is employed as a sole predictor of Ss' special aptitude for hypnosis.

1976

Ihalainen, O.; Rosberg, G. (1976). Relaxing and encouraging suggestions given to hospitalized chronic schizophrenics. International Journal of Clinical and Experimental Hypnosis, 228-237.

3 groups of hospitalized chronic schizophrenic patients received "the taped hypnotic treatment" twice a week for 4 weeks. The treatment differed for each of the 3 groups of 18 patients, but neither the patients nor the nursing staff were informed of this difference. The first group was exposed to music only, the second group was given music with superimposed hypnotic suggestions, and the third group heard music with superimposed hypnotic suggestions for improving self-confidence. The staff filled in an evaluation form about the patient's health beforehand, immediately afterward, and then 1 month after the treatment program. No difference between the groups was found if the comparison was based only upon the directions of the changes. However, twice as many positive changes as negative ones were observable in every group after the control period. If the changes noted are restricted only to those attaining the statistically significant ( $p < .05$ ) level, the majority of positive ones was more evident. From this point of view, the reactions of the groups to the treatments were also different. Improvement appeared directly after the treatment of the Music and Self-confidence groups, but was not evident during the observation time 1 month later. In the Relaxing group, there was, on the contrary, only slight improvement directly after the treatment, but 1 month later during the follow-up

observation time, the improvement was considerable. Thus, while encouraging hypnotic suggestions proved on the follow-up to be ineffective, hypnosis appeared to have a real influence when only relaxing suggestions were used. NOTES 1:

#### NOTES

This is a controlled clinical outcome study of psychotherapy involving the use of hypnosis

Illovsy, J.; Fredman, N. (1976). Group suggestion in learning disabilities of primary grade children. International Journal of Clinical and Experimental Hypnosis, 24, 87-97.

This study reports the effects of tape-recorded hypnotic suggestions given to 48 hyperactive children between the ages of 6 and 8 from 3 public schools. The children had short attention spans, low frustration and tolerance [sic], and poor learning motivation. They were taught by the same method in class and received remedial instruction as in the previous year. In order to participate in this study, the children were brought from their regular classrooms every morning to listen in groups of 9, 10, or 19 -- according to the available accommodation in the school -- to suggestions of relaxation, to ideas of coping with emotional problems, and to suggestions of modifying attitudes towards learning. The corrective reading teachers conducted these 15-minute sessions. After the session was over, the children were returned to their respective classes. At the beginning and at the end of the school year, the classroom teachers evaluated the children's behavior in class and their attitudes toward learning. The addition of the modified hypnotic technique enabled 45 of 48 children to function better in school. The improvement ranged from decreased hyperactivity to better than average performance in class. Significant correlations were found between percent of relaxation with increased attention span ( $r = .40$ ) and number of sessions attended with increased self-confidence ( $r = .46$ ).

#### NOTES

The paper is reprinted from Med. J. Aust., 1971, 2, 675-676 with permission of Editor. The author discusses theoretical concepts, techniques and patient selection for this method. "I avoid all logical communication, as this would only keep the patient alert, and so prevent the atavistic regression which is the essential factor in hypnosis" (p. 139). He moves from patient to patient, saying little except "Good--easy--natural" etc. and he uses touch to reinforce their development of hypnotic state. To ratify the trance and make sure they are hypnotized, not just relaxed, he places a clip on forearm skin for a few moments. "This potentially painful stimulus has the effect of further deepening hypnosis" (p. 139). After about 35-40 minutes he alerts the group. Patients are taught self hypnosis to extend the results into daily life.

#### 1970

Kline, Milton V. (1970). The use of extended group hypno-therapy sessions in controlling cigarette habituation. International Journal of Clinical and Experimental Hypnosis, 18, 270-282.

Results of the present experimental approach to the treatment of smoking habituation tend to be consistent with the view of smoking habituation as a dependence reaction, parallel to drug addiction, and with the concept that habituation must be examined as a psychosomatic entity. Therapeutic approaches must take into account the psychophysiological characteristics of deprivation behavior. Hypnosis, and particularly extended periods of hypnotherapy involving the reduction and control of deprivation behavior, seems to offer a promising approach to the therapeutic treatment of smoking habituation. Vingoe, Frank J. (1968). The development of a group alert-trance scale. International Journal of Clinical and Experimental Hypnosis, 16, 120-132.

PRESENTS A VERBATIM ALERT-TRANCE INDUCTION PROCEDURE IN WHICH SUGGESTIONS FOR MIND ALERTNESS ARE MADE CONCURRENTLY WITH SUGGESTIONS FOR BODY RELAXATION. DIRECT AND INDIRECT SUGGESTIONS OF SLEEP ARE AVOIDED. A DISCUSSION OF MIND AND BODY IS THUS SUGGESTED WITH THE STIPULATION THAT IN DOING THIS S''''''''''''''''S BODY WILL MAINTAIN ITSELF WITHIN THE LIMITS OF NORMAL PHYSIOLOGICAL FUNCTIONING AND, IN AN EMERGENCY, WILL REACT SO AS TO ENSURE SELF-PRESERVATION. EMPHASIS IS PLACED ON S''''''''''''''''S MIND BEING ALERT SO AS TO ENGAGE IN ANY MENTAL WORK EITHER DURING OR AFTER THE HYPNOTIC TRANCE. DATA OBTAINED FROM 150 SS WHO RESPONDED TO A SHORT SELF-REPORT SCALE ARE PRESENTED. (SPANISH + GERMAN SUMMARIES) (21 REF.) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1966

Evans, Frederick J.; Schmeidler, D. (1966). Relationship between the Harvard Group Scale of Hypnotic Susceptibility and the Stanford Hypnotic Susceptibility

Scale: Form C. International Journal of Clinical and Experimental Hypnosis, 14, 333-343.

3 SUBGROUPS OF 20 SS WITH HIGH, MEDIUM, OR LOW SCORES ON A SLIGHTLY MODIFIED, TAPE-RECORDED VERSION OF THE HARVARD GROUP SCALE OF HYPNOTIC SUSCEPTIBILITY, FORM A (HGSHS:A) WERE LATER ADMINISTERED THE STANFORD HYPNOTIC SUSCEPTIBILITY SCALE, FORM C (SHSS:C). THE 2 SCALES CORRELATED .59, WHICH IS LOWER THAN WOULD BE PREDICTED BY SCALE RELIABILITIES. THIS, TOGETHER WITH OTHER DATA BASED ON ITEM CHARACTERISTICS, INDICATES THAT THE 2 SCALES ARE NOT EQUIVALENT, BUT IN PART MEASURE DIFFERENT ASPECTS OF HYPNOTIC PERFORMANCE. SCORES ON HGSHS:A FOR LOW SS ARE PREDICTIVE OF SHSS:C SCORES, BUT THE STABILITY OF PERFORMANCE BETWEEN HGSHS:A AND SHSS:C IS NOT AS MARKED FOR MEDIUM AND HIGH SS ON HGSHS:A. THIS IS PARTLY A RESULT OF THE FAILURE OF PASSIVE MOTOR (PRIMARY) SUGGESTIBILITY TO DISCRIMINATE BETWEEN LEVELS OF SUSCEPTIBILITY, ALTHOUGH CHALLENGE ITEMS DO. THE 2 CLUSTERS OF ITEMS CORRELATE .23 AND .43 IN HGSHS:A AND SHSS:C, RESPECTIVELY. THE PASSIVE SUGGESTIBILITY ITEMS DETRACT FROM THE VALIDITY OF THE 2 SCALES. (SPANISH + FRENCH SUMMARIES) (20 REF.) Scott, E. M. (1966). Group therapy for schizophrenic alcoholics in a state-operated outpatient clinic: With hypnosis as an integrated adjunct. International Journal of Clinical and Experimental Hypnosis, 3, 232-242.

Because Alcoholics Anonymous has been so unsuccessful with the schizophrenic alcoholic, no therapeutic modalities structured to fit this population have reached the literature. For 3 yr. specific therapeutic techniques, among them hypnosis, have

been employed, and the results appear to be rather encouraging. (Spanish & German summaries) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Vasiliev, L. (1965). Mysterious phenomena of the human psyche. New York NY: University Books. (Reviewed by Leo Wollman in *American Journal of Clinical Hypnosis*, 1965, 8 (2), 146-147)

#### NOTES

AJCH Abstract by Leo Wollman: Many interesting theories about hypnosis are aired in this book. The opinions Pavlov propounded many years ago, about cortical inhibition are assiduously asserted, yet some statements made bear investigation. The mere sight of the experimenter in B.N. Birman's experiments with dogs put the dog into a hypnotic state. The appearance in the room of other people, who had not participated in the experiments, had no sleep-inducing effect. For the experimental animal, therefore, the experimenter himself had been transformed into a conditioned hypnogenous stimulus. Similarly, in group hypnotherapy, the entrance of the physician-hypnotist into the room often effects a hypnotic state in some of the subjects. The doctor has become the stimulus for the conditioned response, that of hypnotic trance state induction.

An interesting and perhaps little known fact elicited from Chapter III (Hypnotism and Suggestion) is the high percentage (12%) of those replies to questionnaires during the First International Congress on Experimental Psychology held in Paris in 1899, which indicated that 3,000 respondents had hallucinations while in a normal state of health. The majority were visual; auditory and tactile hallucinations were less frequent.

Dr. P. P. Podyapolsky, in 1905, wrote 'I tried unsuccessfully to induce in a peasant a reddening of the skin from a mock mustard plaster not only was there no reddening, there wasn't even any appropriate sensation of burning or smarting. I surmised that this simple man had probably never experienced a mustard plaster; therefore, his mind lacked the corresponding images and the ability to reproduce them with all their consequences... And so it turned out--he had never experienced a mustard plaster. It happened that he later had occasion to put a mustard plaster on his chest, and when I hypnotized him thereafter, suggestion quickly created not only the appropriate burning sensation but also reddening of the skin where the mock mustard plaster was applied.' This phenomenon is explained by the fact that the connection between the skin and cerebral cortex by means of neural conductors may, under certain circumstances, alter the activity of different organs. The alteration operates, apparently, in the category of conditioned-reflex formation.

This book is interesting reading and from a historic point of view is worth having in one's library.

#### 1964

Coe, William C. (1964). Further norms on the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 12 (3), 184-190.

The Harvard Group Scale of Hypnotic Susceptibility, Form A was administered to 168 upper level college students. Findings are congruent with the original normative data reported by Shor and E. C. Orne. Differences between the 2 samples' mean scores and distributions are discussed in terms of sample composition. Further support for the group scale as an accurate predictor of hypnotic susceptibility was indicated by a significant relationship between the group scale and the individually-administered Stanford Hypnotic Susceptibility Scale, Form C. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Ludwig, Arnold M.; Lyle, William H., Jr.; Miller, Jerome S. (1964). Group hypnotherapy techniques with drug addicts. International Journal of Clinical and Experimental Hypnosis, 12 (2), 53-66.

This study was designed to investigate the appropriateness of a number of group hypnotherapeutic techniques which might be used in the treatment of addict patients. It is the belief of the investigators that the more "magical," "authoritative," and practical-oriented techniques seem more appropriate and useful than techniques designed to elicit deep, insightful understanding of the emotional problems underlying drug addiction. Many of the specific hypnotherapeutic techniques used are described, and some of the difficulties and advantages of group hypnosis as a treatment method are discussed. 1963

Bentler, P. M.; Hilgard, Ernest R. (1963). A comparison of group and individual induction of hypnosis with self-scoring and observer-scoring. International Journal of Clinical and Experimental Hypnosis, 11, 49-54. (Abstracted in Index Medicus, 63, June, S-1599)

45 volunteer Ss were hypnotized in small groups and were subsequently hypnotized in individual sessions. In both sessions observer- and self-scores were recorded for all suggestions of the Harvard Group Scale adaptation of the Stanford Hypnotic Susceptibility Scale. The correlation between observer- and self-scores indicated that hypnotic susceptibility in the 2 sessions was very similar. Group self-scores were also found to predict quite accurately objective hypnotist scores of the subsequent individual session. A 2nd sample of 34 nonvolunteer male Ss were hypnotized individually following Form A of the Stanford scale. Self-scoring was found to be remarkably similar to observer ratings, and the results of group administration very comparable to those of individual administration of hypnotic susceptibility tests. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Shor, Ronald E.; Orne, Emily C. (1963). Norms on the Harvard Group Scale of Hypnotic Susceptibility, Form A. International Journal of Clinical and Experimental Hypnosis, 11, 39-48.

Norms are presented on an adaptation for group administration with self-report scoring of Weitzenhoffer and Hilgard's Stanford Hypnotic Susceptibility Scale, Form A. Comparisons are made between a sample of 132 undergraduates given the new group-administered version and 4 reference samples including the original Stanford University normative group. Findings indicate that the group-administered version yields norms congruent with the individually-administered original. Diagnostic evaluations of hypnotic depth after one or more additional hypnotic training sessions tentatively indicate that the adapted scale is an effective predictor of subsequent hypnotic depth. ## **GUIDED IMAGERY**

**2001**

Fredericks, Lillian E. (2001). The use of hypnosis in surgery and anesthesiology. Springfield IL USA: Charles C Thomas.

Gibbons, Don E. (2001). Experience as an art form: Hypnosis, hyperempiria, and the Best Me technique. San Jose CA: Authors Choice Press. ([[available online:] <http://www.iuniverse.com/bookstore/marketplace>])

## **NOTES**

The Best Me Technique is a procedure for constructing suggestions which incorporates many different dimensions of experience -- beliefs, emotions, sensations, thoughts, motives, and expectations -- for maximum involvement and effectiveness. Best Me suggestions may be used with either hyperempiria, an alert induction based on suggestions of mind expansion and increased alertness and sensitivity, or with more traditional forms of hypnotic induction.

**1998**

Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..

## **NOTES**

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative

experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

The effectiveness of different pain-distraction tasks was compared as a function of level of hypnotizability, using the cold-pressor pain-testing procedure. Selected high, medium, or low hypnotizable participants first underwent a 1-minute baseline immersion of a hand in ice water, with periodic pain ratings. Independent groups were then given 4-minute test immersions under one of five conditions. Analgesia suggestion and guided imagery were conceived to be internal distractors, whereas word memory and pursuit-rotor tasks were external distractors. Placebo-control groups were given permission to let their minds wander. All four experimental treatments reduced pain significantly for highly hypnotizable participants, compared to the control group, whereas none of the experimental treatments were effective for low hypnotizables. The different treatment instructions did not produce different preimmersion anxiety state ratings, so the treatment effects on pain ratings could not be explained in terms of their effects on anxiety. It appears that high hypnotizables are more effective than low hypnotizables at diverting attention to control pain, regardless of whether internal or external distractor tasks are used. Treatment effects on pain ratings did not change between 1 and 4 minutes of test immersion.

1994

Sapp, Marty (1994). The effects of guided imagery on reducing the worry and emotionality components of test anxiety [Abstract]. Journal of Mental Imagery, 18 (3&4), 165-180.

This study investigated the effects of guided imagery on reducing the worry and emotionality components of test anxiety. Subjects receiving guided imagery were compared to a Hawthorne control group on the worry and emotionality components of test anxiety and academic achievement. The guided imagery subjects showed significant reductions in levels of worry and emotionality, and a significant increase

in academic performance. The treatment gains were maintained at a 6-week follow-up.

1988

Donovan, David (1988). Factor analytic structure of attitudes towards hypnosis, guided imagery, and relaxation. [Unpublished manuscript] (Paper written for Comrey's Factor Analysis Course, UCLA) Keywords: attitudes, factor analysis, guided imagery, relaxation

NOTES

Factor analysis of semantic differential responses of 212 adults regarding 3 terms (hypnosis, imagery, relaxation) placed imagery in an intermediate position between the extremes of hypnosis and relaxation. Both common and unique factors extracted are discussed.

1986

Thompson, Cynthia K.; Hall, Howard R.; Sison, Cecile E. (1986). Effects of hypnosis and imagery training on naming behavior in aphasia. Brain and Language, 28, 141-153.

The effects of hypnosis and imagery training on the naming behavior of three subjects with Broca's aphasia were investigated using a multiple baseline design across subjects. Treatment consisted of the induction of hypnosis, followed by guided imagery focused on the physical and functional attributes of stimulus objects. Measures of naming ability on both trained and untrained items were taken at baseline, after every training session, and a few hours after training each day. Measures were also taken of imagery ability, hypnotic susceptibility, and psychological state. Results indicated that treatment facilitated improvement in naming ability, over baseline level, for two subjects. In the case of the third subject, the verbal label was incorporated into the imagery procedure following 10 training sessions. Subsequently, this subject's naming behavior improved over baseline level. The results are discussed in terms of current theory and research in neuropsychology and cognitive psychology.

Schandler, Steven L.; Dana, Edward R. (1983). Cognitive imagery and physiological feedback relaxation protocols applied to clinically tense young adults: A comparison of state, trait, and physiological effects. Journal of Clinical Psychology, 39, 672-681.

Examined changes in targeted and general tension behaviors as well as reductions in physiological tension associated with cognitive imagery and electromyographic biofeedback relaxation procedures. Three groups of 15 female college students participated. During three weekly sessions each person received either guided cognitive imagery relaxation, frontalis muscle feedback relaxation, or a self-rest control procedure. The Anxiety Differential was administered before and after each session, while frontalis EMG, heart rate, and skin temperature were monitored

continuously. A second Temperament Analysis was administered after the final session. The imagery procedure was associated with moderate reductions in physiological tension and significant reductions in state anxiety and three tension-related personality dimensions. Self-rest persons displayed lesser reductions in general tension with little physiological change. While biofeedback persons showed the largest reductions in physiological tension, they displayed only small and variable changes in state anxiety and personality dimensions. The data raise continued questions about the application of physiologically based operant relaxation procedures and support the use of cognitively mediated protocols for the treatment of specific or general anxiety behaviors.

1982

Brown, Daniel P.; Forte, Michael; Rich, Philip; Epstein, Gerald (1982-83). Phenomenological differences among self hypnosis, mindfulness meditation, and imaging. Imagination, Cognition and Personality, 2 (4), 291-309.

A survey of 122 subjects was conducted to investigate the differences in the phenomenological quality of the experiences engendered by three types of awareness discipline: self-hypnosis (21 Ss), waking dreaming (49 Ss) and mindfulness meditation (25 Ss from a 2-week retreat, and another group of 27 Ss from a 2-day weekend retreat). A questionnaire, the profile of Trance, Imaging, and Meditation Experience (TIME) was used in the survey. Discriminant analyses were used to construct models of the differences in the phenomenological quality of the experiences among the three groups. A number of phenomenological dimensions, in the major areas of attention, thinking, memory, imagery, body sensations, emotions, time sense, reality sense, and sense of self, were found which could accurately distinguish among the experiences of practitioners of the three types of awareness training. Results show that while self hypnosis involves self-referential thinking, memory changes, and intense emotions, waking dreaming emphasizes the immediate impact of emerging images, which unfold in a thematic manner and have a sense of their own reality. Mindfulness meditators have difficulty managing distractions, but with experience learn greater awareness of bodily processes, and experience changes in the perception of time and self; mental processes seem to slow down, and awareness assumes an impersonal quality. No attributions as to the causes or sources of these phenomenological differences are made, as the survey was not large enough to provide comparison groups, subject matching, or other statistical controls necessary for causal analyses. Lyles, Jeanne Naramore; Burish, Thomas G.; Krozely, Mary G.; Oldham, Robert K. (1982). Efficacy of relaxation training and guided imagery in reducing the aversiveness of cancer chemotherapy. Journal of Consulting and Clinical Psychology, 50, 509-524.

Fifty cancer patients receiving chemotherapy, 25 by push injection and 25 by drip infusion, were assigned to one of three conditions for their chemotherapy treatments: (a) progressive muscle-relaxation training plus guided-relaxation imagery; (b) therapist control, in which a therapist was present to provide support and encouragement but did not provide systematic relaxation training; and (c) no-treatment control. Patients participated in one pretraining, three training, and one follow-up session. Results indicated that during the training sessions, patients who received relaxation training, relative to patients in either of the other two conditions, (a) reported feeling significantly less anxious and nauseated during chemotherapy, (b) showed significantly less physiological arousal (as measured by pulse rate and systolic blood pressure) and reported less anxiety and depression immediately after chemotherapy, and (c) reported significantly less severe and less protracted nausea at home following chemotherapy. The attending nurses' observations during chemotherapy confirmed patient reports. In general, patients in the therapist control condition and the no-treatment control condition did not differ significantly from each other. The differences among conditions generally remained significant during the follow-up session. The data suggest that relaxation training may be an effective procedure for helping cancer patients cope with the adverse effects of their chemotherapy.

1978

Porter, J. W. (1978). Suggestions and success imagery for study problems. International Journal of Clinical and Experimental Hypnosis, 26, 63-75.

A procedure is presented for dealing with study problems in cases where patients come with an expectancy of help through hypnosis. Specific suggestions directly related to the study difficulty are given. "Success imagery" is outlined for use under hypnosis and by the student himself in his daily life. Two self-management techniques associated with the relaxation induced by exhalation are given further strength by being made posthypnotic suggestions. A direct posthypnotic suggestion for "concentration and recall" is combined with contingency management to effect more efficient performance when the decision is made to study. Four sessions are shown by clinical experience to be generally adequate to allow a transition from therapy to self-management of the problem aided by the student's own use of self-hypnosis. A general outline of how this is achieved for the first three sessions incorporates both Wolberg's (19656) suggestions to remove barriers preventing progress and Stanton's (1977) Rational-Emotive Therapy suggestions to strengthen the person's belief in himself.

## H RESEARCH

2000

Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)

This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; (3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

1996

Spiegel, Sharon B. (1996). Uses of hypnosis in the treatment of uncontrollable belching: A case report. American Journal of Clinical Hypnosis, 38 (4), 263-270.

Uncontrollable belching is frequently benign in origin, but can be distressing in its psychosocial consequences. Physicians have little to offer in the way of medical treatment. This is a case report of a 71-year-old woman with incessant eructation of four months duration treated with brief psychotherapy utilizing hypnosis. The patient was symptom-free at termination, and this improvement was sustained at six month follow-up. This paper includes a detailed description of some of the hypnotic suggestions as well as a discussion of the factors that may have contributed to change.

1995

Holroyd, Jean (1995). Handbook of clinical hypnosis, by Judith W. Rhue, Steven Jay Lynn, & Irving Kirsch (Eds.) [Review]. International Journal of Clinical and Experimental Hypnosis, 43 (4), 401-403.

NOTES

1:  
"This is a book for the thinking clinician" (p. 401). "The editors are to be congratulated for making this volume much more coherent than most edited books" (p. 402). "My impression is that the book is best suited for an intermediate or advanced course on hypnotherapy, or for people who are already using hypnosis in

treatment. Although there is some material on the basics of hypnotic inductions and a few introductory sample scripts for inductions, a beginners' course should probably use a different book, or this book could be accompanied by an inductions manual. ... I recommend it very highly" (p. 403).

1994

LaCrosse, M. B. (1994). Understanding change: Five-year follow-up of brief hypnotic treatment of chronic bruxism. American Journal of Clinical Hypnosis, 36 (4), 276-281.

In this paper I describe the treatment of a 63-year-old woman with a 60-year history of nocturnal bruxism. Treatment included assessment, two psychotherapy sessions, including a paradoxical behavior prescription to reduce daytime worrying, hypnotic suggestions for control of nocturnal grinding, and reinforcement of the patient's expectations for success. This case demonstrates how enduring change may occur rapidly in spite of the chronicity of a patient's complaint. Follow-up assessments at 2, 3, and 5 years revealed that she continued to be symptom-free with her self-reports corroborated by her spouse and family dentist. I discuss implications for understanding the role of hypnosis in therapeutic change.

Wagstaff, Graham F.; Royce, C. (1994). Hypnosis and the treatment of nail biting: A preliminary trial. Contemporary Hypnosis, 11, 9-13.

A clinical trial was conducted examining the relative efficacy of therapeutic suggestions preceded by and without a hypnotic induction in the treatment of nail biting in 17 students. Outcomes showed a hypnotic induction added significantly to therapeutic benefits and was the only condition that resulted in symptom improvement. Results from only one session showed that 7 of 11 hypnosis subjects stopped nail biting compared to only 1 of 6 control subjects. Reports of "believed in efficacy" predicted treatment success better than ratings of motivation, hypnotic induction per se, or scores on the Creative Imagination Scale. However, within the group receiving hypnotic induction, hypnotic- depth scores significantly correlated with treatment success, suggesting that state factors such as dissociation might be involved.

NOTES

1:

NOTES

The hypnotized Ss were given the T. X. Barber (1969) induction, a request for their depth estimate on a scale of 0-10, and then a set of suggestions to discourage nail biting. The suggestions were of four types: (1) to have a positive attitude, that nail biting is a habit that can be broken and that stopping will enhance attractiveness and self esteem; e.g., 'With just a little self control you will stop biting your nails and feel better about yourself.' (2) to stop the habit; e.g. to say to themselves, 'I will not bite my nails today/tomorrow,' five times each morning and at night, and whenever the temptation arose. (3) to improve feelings of self-efficacy; e.g., 'If you ever feel the urge to bite your nails tell yourself that you want to break the habit and that you are perfectly capable of doing so. You are not weak.' (4) that the results would be

outstanding; e.g. 'After only ten days or so ... you will have no desire to bite your nails, indeed the very thought of doing so will repulse you.'

Control subjects received the same instructions, without a hypnotic induction; the procedure was labeled a 'positive attitude for self discipline' technique.

Judges rated improvement without being aware of the Ss' self-report on whether they had stopped biting their nails. Judges' ratings correlated  $r = .94$  with Ss' statements about whether they had stopped the habit. Improvement scores also correlated significantly with belief the treatment would be effective ( $r = .60$ ) and Creative Imagination Scale scores ( $r = .53$ ), but not with motivation. The hypnosis group had significantly higher belief scores than the control group. Within the hypnosis group itself, hypnotic depth was the only variable to correlate significantly with improvement.

The Discussion stated, "However, taken together, the findings indicate that hypnotic induction added significantly to the therapeutic benefits of suggestions for the cessation of nail biting, and that Johnson and Barber's (1978) concept of 'believed-in efficacy' was more important in accounting for therapeutic success than motivation (at least as measured here), hypnotic induction per se, or the subject's proclivity for imaginative involvement. Nevertheless, belief still accounted for less than 40% of the variance in improvement. This may have been due to measurement error or insensitivity in the measures. Alternatively, or additionally, other factors may have been influential. For example, if CIS scores are considered to be indirect measures of hypnotic susceptibility, then belief was more influential than hypnotic susceptibility; however, from a hypnotic state theory perspective, the significant correlation between hypnotic depth (LSS scores) and improvement within the hypnosis group might suggest that some further feature of the 'hypnotic state' could still have been at work, such as a dissociative process (Hilgard, 1986). On the other hand, from a non-state perspective, perhaps subjects receiving hypnotic induction and reporting high depth scores might have felt more obliged to respond to the demand characteristics of the study, and tried harder to please the experimenter (Wagstaff, 1981); the general motivation questions used here could have been insensitive to such an effect" (p. 12).

1993

LaGrone, Randy G. (1993). Hypnbehavioral therapy to reduce gag and emesis with a 10-year-old pill swallower. American Journal of Clinical Hypnosis, 36, 132-136.

A 10-year-old child experienced severe nausea and psychogenic vomiting that resulted in refusal to take oral medication in pill form. The youngster was treated with hypnbehavioral therapy consisting of mental imagery, relaxation, direct suggestion, adaptive self-talk, self-monitoring, and self-reinforcement. The child's parents were instructed to reinforce approximations of successful pill swallowing while withdrawing attention for avoidance, whining, gagging, and vomiting. A one-year follow-up revealed successful pill swallowing without significant distress.

1992

Page, Roger A. (1992). Clark Hull and his role in the study of hypnosis. American Journal of Clinical Hypnosis, 34, 178-184.

## NOTES

1:

The contributions of Hull include his attempts to dispel misconceptions about hypnosis, comparisons of capacities in the hypnotic state with those in the awake state, a sampling of early findings that are still valid today, and examples of his contributions to methodology. Additionally, the roots of many modern-day models and concepts are to be found in his early works.

"Bernheim (1902) had believed hypnosis was identical to natural sleep, while Braid (1899) had believed the resemblance between hypnosis and natural sleep was just superficial. Pavlov (1923) held an intermediate position; he hypothesized that hypnosis was a transition to true sleep involving selective inhibition of certain brain centers" (p. 179).

"His proposition that hypnosis conforms to the basic principles of habit formation was supported by his own work (1933) and, with few exceptions, holds true today. For example, many studies have found that hypnotic responding improves with practice and eventually reaches a plateau (e.g., As, Hilgard, & Weitzenhoffer, 1963; Evans & Schmeidler, 1966). Parenthetically, one can see a resemblance here to the later notion of 'plateau hypnotizability' (Shor, Orne, & O'Connell, 1966). Although Barber and Calverley (1966) did demonstrate that an exception to this proposition will occur if subjects become bored and disinterested, it is still true that hypnosis is generally facilitated by practice" (p. 181).

"Yet another example from the same work can be found in the following description of the results of a conditioning experiment: '... it is possible that the hypnotic group were conditioned more readily because they were the kind of individuals who are susceptible to hypnosis rather than because they were actually in the trance when subjected to the conditioning procedure.' (p. 219) In this statement, one can see the now taken-for-granted distinction between hypnotic susceptibility and being hypnotized, as discussed, for example, by Graham and Leibowitz (1972)" (p. 182).

"Still other now familiar concepts can be gleaned from his 1933 book. One would be the notion of trance having a kind of 'inertia.' Yet another stems from his hypothesis that hypnotic suggestions produce relaxation, which in turn suppresses '... the spontaneous activity of the symbolic or thought processes.' (p. 310) This may well be the first conceptualization of what most recently has been referred to by Plotkin and Schwartz (1985) as the lack of a disposition or capacity to generate final-order appraisals" (p. 183).

## 1991

Clarke, J. H.; Reynolds, P. J. (1991). Suggestive hypnotherapy for nocturnal bruxism: A pilot study. American Journal of Clinical Hypnosis, 33, 248-253.

Although one can find many case reports of hypnotherapy for bruxism, there is a paucity of scientific research on the subject. This study describes the use of suggestive hypnotherapy and looks at its effectiveness in treating bruxism. Eight subjects who reported bruxism with symptoms such as muscle pain and complaints

of bruxing noise from sleep partners were accepted into the study. An objective baseline of the bruxing was established using a portable electromyogram (EMG) detector attached over the masseter muscle during sleep. Hypnotherapy was then employed. Both self-reports and posttreatment EMG recordings were used to evaluate the hypnotherapy. Long-term effects were evaluated by self-reports only. The bruxers showed a significant decrease in EMG activity; they also experienced less facial pain and their partners reported less bruxing noise immediately following treatment and after 4 to 36 months.

Somer, Eli (1991). Hypnotherapy in the treatment of the chronic nocturnal use of a dental splint prescribed for bruxism. International Journal of Clinical and Experimental Hypnosis, 39, 145-154.

A behavioral medicine case is described in which the patient was treated with a combined approach involving both hypnoanalytic and hypnbehavioral techniques. A 55-year-old man with bruxism was referred after 10 years of craniomandibular treatment because of his dependency on a dental splint prescribed for nocturnal use. A projective hypnoanalytic exploration helped to uncover and consequently resolve an earlier conflict that had been reactivated in the patient's work situation and which had become a constant source of mental and muscular tension. The hypnoanalytic exploration was followed by a cognitive-behavioral hypnotic intervention that was tape-recorded and prescribed for bedtime practice. Pre- and posttherapy psychological, physiological, and self-report measurements corroborated the patient's sense of well being that came with his newly found ability to sleep without the dental splint. The importance of considering multiple etiological factors in the treatment of such psychosomatic disorders as bruxism is discussed.

1989

Holroyd, Jean; Maguen, Ezra (1989). And so to sleep: Hypnotherapy for lagophthalmos. American Journal of Clinical Hypnosis.

We used hypnosis to facilitate eye closure during sleep for a 44-year-old woman whose nocturnal lagophthalmos prevented use of a contact lens following cataract surgery and could have resulted in severe corneal damage. On three separate occasions the symptoms remitted following a very brief course of treatment. We discuss the results in terms of alternate theories of hypnotic performance.

#### NOTES

The Discussion section notes, "There was an excellent correlation between the onset of hypnotherapy and the cessation of the recurrent corneal erosion secondary to nocturnal lagophthalmos. Healing of corneal erosion, disappearance of the superficial punctate keratopathy, and alleviation of ocular foreign body sensation occurred promptly following hypnotherapy (with two separate therapists)" (pp. 267-268). The authors present the view that "heightened suggestibility, more vivid imagery, and more specific influence of thoughts upon organ systems probably came into play (Brown &

Fromm, 1986; Holroyd, 1987). Social influence explanations (role taking, expectancy, compliance) seem less relevant as explanations. This highly motivated patient had not been able to keep her eyes closed during sleep despite her conscious efforts, her "good-patient" role, her positive expectations about the benefits of standard treatments, and respectful incorporation of the assistance provided by her ophthalmologist" (p. 268).

Jupp, J. J.; Collins, J. K.; Walker, W. L. (1989). Relationships between behavioural responsiveness to hypnotic suggestions and estimates of hypnotic depth following 11 sequential instances of hypnosis. Australian Journal of Clinical and Experimental Hypnosis, 17, 93-98.

Behavioral responsiveness to suggestions was assessed in an initial hypnosis session, and hypnotic depth was assessed in this session, followed by 10 weekly standardized hypnotic experiences. Correlations were calculated between behavioral responsiveness, initial and subsequent depth estimates, and between successive trance depth estimates. Levels of trance depth estimates were found to increase through weeks 1 to 11. Significant positive correlations were found between behavioral responsiveness scores and trance depth estimates to the fourth week but not beyond. Significant positive relations were found between successive estimates of trance depth except for the correlation between estimates for the fourth and fifth weeks. These results are discussed in terms of the estimates of trance depth being attributions from self-observations of behavioral responsiveness to hypnotic suggestions.

1987

Barabasz, Marianne (1987). Trichotillomania: A new treatment. International Journal of Clinical and Experimental Hypnosis, 35 (3), 146-154.

The details of easily replicable interventions using hypnosis and restricted environmental stimulation therapy in the treatment of 4 cases of trichotillomania are presented. Hypnosis or hypnosis combined with brief restricted environmental stimulation appeared to be effective in 3 of the 4 Patients were given practice with hypnosis and also restricted environmental stimulation sessions to maximize response to hypnotic suggestions, as previous research indicated that only highly hypnotizable people responded to hypnotherapy for trichotillomania. The treatment itself consisted of simple posthypnotic suggestions, as "You will be acutely aware whenever you put your hand to your head, then it is entirely up to you, you have the power, the control, no one else, no habit controls you. You can pull your hair if you want to or you can choose to control the habit" (p. 149).

1983

Spiegel, David (1983). Hypnosis with medical/surgical patients. General Hospital Psychiatry, 5, 265-277.

The role of hypnosis as a tool in the treatment of problems commonly encountered among medical and surgical patients is examined. Hypnosis is defined as a change in state of mind far more akin to intense concentration than sleep. Diagnostic implications of differences in hypnotic responsivity are explored, and scales suitable for use in the clinic are examined. Uses of hypnosis in treating anxiety, pain, childbirth, psychosomatic symptoms, seizure disorders, neuromuscular dysfunction, and habits are described and evaluated. The phenomenon of hypnosis is presented as a means of exploring the mind-body relationship in a controlled fashion, providing information of diagnostic importance while at the same time allowing hypnotizable patients to intensify their concentration and interpersonal receptivity in the service of a therapeutic goal.

1980

Bornstein, P. H.; Rychtarik, R. G.; McFall, M. E.; Winegardner, J.; Winnett, R. L.; Paris, D. A. (1980). Hypnobeavioral treatment of chronic nailbiting: A multiple baseline analysis. International Journal of Clinical and Experimental Hypnosis, 28 (3), 208-217.

3 highly hypnotizable Ss were administered a hypnobeavioral treatment package in an attempt to alleviate chronic nailbiting behavior. The combined hypnotic and behavioral procedures included standard induction and deepening techniques, motivation enhancement, time-projection, self-reinforcement, aversion-relief, coping self-instructions, and posthypnotic suggestion. A multiple baseline design across Ss was employed as a means of evaluating the treatment intervention. Results for all Ss indicated immediate and dramatic increase in fingernail lengths concomitant with the introduction of treatment. At 3-month follow-up, 1 S demonstrated a moderate reversal effect while the remaining 2 Ss continued to indicate substantial progress. These findings were discussed with regard to the efficacy of hypnobeavioral treatment strategies and utilization of single-case experimental designs in future hypnotherapy research.

1977

Barkley, R. A.; Hastings, J. E.; Jackson, T. L., Jr. (1977). The effects of rapid smoking and hypnosis in the treatment of smoking behavior. International Journal of Clinical and Experimental Hypnosis, 25 (1), 7-17.

29 Ss were assigned to one of 3 treatment conditions and treated for their cigarette smoking over a 2-week period. These conditions were: group rapid smoking, group hypnosis, and an attention-placebo control group. All treatments produced significant reductions in average daily smoking rates during the treatment phase but all Ss returned to near baseline levels of smoking by the 6-week follow-up. The rapid smoking and hypnosis groups did not differ from the control group in smoking rates at treatment termination or at the 6-week follow-up. They also did not differ from the control group in the number of Ss abstaining from smoking by treatment termination but did differ at follow-up. Eventually, at the 9-month follow-up, only Ss from the group rapid smoking condition had significantly more

abstainers than the control group. The results suggested that rapid smoking can work as effectively in group procedures as previous individualized approaches had demonstrated. Group hypnosis, while less effective than some previous individualized approaches had indicated, was nevertheless only marginally less effective than the group rapid smoking procedure. The use of abstinence rates as opposed to average rates of smoking was strongly recommended as the best measure of treatment effectiveness for future research in this area.

1976

Laguaite, J. K. (1976). The use of hypnosis with children with deviant voices. International Journal of Clinical and Experimental Hypnosis, 24, 98-104.

Hypnosis was used with 18 children aged 4 years, 7 months to 10 years, 1 month, with a mean age of 6 years, 8 months. All children had deviant voices -- 7 had vocal nodules, 4 had hypertrophy of the vocal bands, 5 had normal larynges, and 2 could not be visualized adequately. All but 1 of the children responded by entering some degree of trance state. The younger children responded better when eye closure was not suggested. Post-therapy judgments of voice quality and laryngeal examinations showed that only 2 had shown no improvement. The 2 were the least responsive to hypnosis. Factors thought to be important in influencing the children's responses are discussed.

Barber, Theodore Xenophon; Calverley, David S. (1966). Toward a theory of hypnotic behavior: Experimental evaluation of Hull's postulate that hypnotic susceptibility is a habit phenomenon. Journal of Personality, 34, 416-433.

NOTES

Examines Hull's 1933 theory that hypnotic susceptibility is a habit phenomenon, which he derived from a review of the literature and an experiment. Also presents his own experiment to test it.

1965

Gruenewald, Doris (1965). Hypnotherapy in a case of adult nailbiting. International Journal of Clinical and Experimental Hypnosis, 13 (4), 209-219.

A middle-aged female nailbiter was treated in short-term hypnotherapy. Hypotheses and observations postulated in the literature for the dynamics of the symptom in children and young adults were shown to be valid in this case of more advanced age. Light-to-medium trance proved adequate for exploration and resolution of conflicts of which nailbiting was symptomatic. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Vasilev, L. (1965). Mysterious phenomena of the human psyche. New York: University Books. (Abstracted in American Journal of Clinical Hypnosis, 1965, 8:2, 146-147)

The review of this book by Leo Wollman (*American Journal of Clinical Hypnosis*, 1965, vol. 8, pp. 146-147) states, "Many interesting theories about hypnosis are aired in this book. The opinions Pavlov propounded many years ago, about cortical inhibition are assiduously asserted, yet some statements made bear investigation. The mere sight of the experimenter in B. N. Birman's experiments with dogs put the dog into a hypnotic state. The appearance in the room of other people, who had not participated in the experiments, had no sleep inducing effect. For the experimental animal, therefore, the experimenter himself had been transformed into a conditioned hypnogenous stimulus. Similarly, in group hypnotherapy, the entrance of the physician-hypnotist into the room often effects a hypnotic state in some of the subjects. The doctor has become the stimulus for the conditioned response, that of hypnotic trance state induction.

" An interesting and perhaps little known fact elicited from Chapter III (Hypnotism and Suggestion) is the high percentage (12%) of those replies to questionnaires during the First International Congress on Experimental Psychology held in Paris in 1899, which indicated that 3,000 respondents had hallucinations while in a normal state of health. The majority were visual; auditory and tactile hallucinations were less frequent" (pp. 146-147).

1955

Hart, Hornell (1955). Measuring some results of autohypnosis. *Journal of Clinical and Experimental Hypnosis*, 3 (4), 229-242.

#### NOTES

The author developed self ratings for mood (euphoria-dysphoria) and alertness-fatigue, which were administered to college students in neutral conditions and after self-hypnosis conditions. The self hypnosis, or "auto-conditioning" usually involved deep relaxation self suggestions followed by other suggestions. The suggestions involved using the word 'you' to be able to re-instate the autoconditioning more and more effectively; suggestions for attitude change (e.g. that 'No matter what comes, we will grapple with it courageously'); and euphoria auto-suggestions (e.g. that 'you will come out of this deep relaxation, feeling rested, alert, cheerful and courageous'). In both single session experiments, as with a class of nurses who experienced an 8 minute auto-conditioning procedure, and in experiments extending over time, depression decreased. He noted that "for various reasons, the students who participated in autoconditioning experiments between February and May, 1955, were in many respects less successful than some of the previous experimental groups had been" (p. 235).

Increased alertness and diminished fatigue was also observed.

Many students chose to give themselves suggestions to correct the habit of procrastination. Two-thirds of the participants reported complete success, up to the level specified, and only one of 43 experiments on correcting procrastination was a "flat failure."

McCord, Hallack (1955). Hypnotherapy and stuttering. Journal of Clinical and Experimental Hypnosis, 3, 210-214. (Abstracted in Psychological Abstracts, 57: 1368)

#### NOTES

Reviews literature and concludes: "On the basis of the evidence presented, it would seem indicated hypnotherapy is a technique deserving further attention by research-minded speech pathologists with hypnotherapeutic training and skill.

"In this connection, no doubt, special attention should be given to the relative permanency of the so-called 'cures,' for frequently the hypnosis literature is not clear on this point. ...

"Also, it is indicated speech pathologists who research in hypnotherapy should select and report on their techniques with care. Many hypnotherapists agree, for example, that a straight suggesting-away-of-symptoms technique seldom results in a lasting behavior change with many subjects. Unfortunately, this relatively 'weak' technique is often the only one known to persons not familiar [sic] with the hypnosis literature.

"However, authorities indicate more lasting behavior changes are often brought about when more sophisticated hypnotherapeutic techniques are used -- techniques such as psychotherapy under hypnosis, abreaction, hypnoanalysis, emotion intensification, projective hypnoanalysis, memory change during age regression, attitude modification, etc. ...

"Finally, research workers should investigate the possible value of providing even temporary freedom from stuttering symptoms for some patients. Perhaps some individuals would find it desirable to return for further hypnotherapy periodically, even as the hayfever sufferer returns to his allergist each year for a shot in the arm with the onset of the ragweed season" (pp. 212-213).

Krueger, R. G. (1931). The influence of repetition and disuse upon rate of hypnotization. Journal of Experimental Psychology, 14, 260-269.

#### NOTES

In this research, Krueger and his advisor, Clark Hull, used good hypnotic subjects to demonstrate that such selected Ss close their eyes more and more quickly when given standardized suggestions of relaxation, sleep, and eye-closure in repeated sessions.

#### HALLUCINATIONS

2003

Whalley, Matthew; Oakley, David (2003). Psychogenic pain: A study using multidimensional scaling. Contemporary Hypnosis, 20, 16-24

Hypnotic suggestions designed to induce a sensation of pain were given to eleven highly hypnotisable participants and produced the intended effect in six of them.

Subjective aspects of the pain experiences were investigated using conventional pain questionnaires and a multidimensional scaling technique. The implications are discussed in terms of a model of consciousness and the aetiology of chronic pain.

**Kirsch, Irving; Wickless, Cynthia; Moffitt, Kathie H. (1999). Expectancy and suggestibility: Are the effects of environmental enhancement due to detection?. International Journal of Clinical and Experimental Hypnosis, 47 (1), 40-45.**

This study replicated the effect of Wickless and Kirsch's experiential expectancy manipulation, in which lights and music from hidden sources were used to convince participants that they were responding successfully to suggestions for visual and auditory hallucinations. The hypothesis that the effect is mediated by detection of the manipulation was tested by providing some participants with cues that their experiences were due to actual changes in the physical environment rather than to their responses to suggestion. This hypothesis was not confirmed. A significant effect on suggestibility was obtained only among participants not given cues aimed at enabling detection of the manipulation, and among those provided with the cues, suspicion of the manipulation was negatively correlated with response to suggestion.

**Perugini, Eve Marie; Kirsch, Irving; Allen, Sarah T.; Coldwell, Eleanor; Meredith, Janelle M.; Montgomery, Guy H.; Sheehan, Julia (1998). Surreptitious observation of responses to hypnotically suggested hallucinations: A test of the compliance hypothesis. International Journal of Clinical and Experimental Hypnosis, 46 (2), 191-203.**

Suggestions for arm levitation and for visual, auditory, tactile, and taste hallucinations were administered twice via audiotape to a group of high suggestible students and low suggestible simulators. During one of the administrations, participants were led to believe they were alone, but their behavior was surreptitiously recorded on videotape and observed on a video monitor. During the other administration, they were observed openly by an experimenter who had not been informed about group assignment. When unaware that they were being observed, simulators were significantly less responsive to suggestion and engaged in substantially more role-inappropriate behavior. In contrast, the responsiveness of nonsimulating students was not affected by the presence of an experimenter, and they exhibited little role-inappropriate behavior even when alone. These data indicate that the responses of suggestible individuals reflect internally generated changes in experience and are not due to simple intentional compliance (i.e., faking).

## NOTES

1:

We studied the relationship between selective attention and hypnotic processes. Michael Posner's theory has different centers for different kinds of attentional processes. Posterior (anterior to the occipital) cortex seems related to arousal. Anterior system has 2 loci: anterior cingulate and [missed words] pole, which relates to the narrowing of attention in hypnosis. We used cued target detection tasks, with MRI measures.

We think hypnotic attention is related to the anterior system.

In an earlier study we used 10 Highs, measured their visual ERPs, with both hypnotic obstructive hallucination and normal attention conditions. We found early and late evoked potential wave component differences: P100, P200, and P300. We were surprised by the P100 or attentional component.

Steven Hilliard's work used an ERP model, and an attentional paradigm with only 1/2 visual field involved. Usually N1 and P1 loci of EEG are the most affected in attentional studies using the evoked response potential measure.

He compared hypnotic attention with hypnotic obstruction (which was a suggestion that a brick wall was "covering" the L or R visual field). They found a difference between attended and ignored stimuli in the Frontal area ERP!

However, there are problems with ERPs and localization due to diffusion of signal throughout the scalp.

In a hypnotic obstruction condition the effect is a bit later than in selective inattention; and it is more posterior than in selective inattention. Thus, if we find a difference due to hypnotic obstruction at P100, it may be due to selective inattention. The difference we can produce with hypnotic obstruction comes at P200 and posterior in the occipital cortex, where a visual stimulus is processed. Generation of internal images may contribute. Are there differences if you tell yourself not to see vs to see something obstructing the image?

Ability to do the hypnotic obstruction is related to the eyeroll item on the Hypnotic Induction Profile (HIP). (High eyeroll score makes it easier to reduce P200 amplitude in response to the obstruction suggestion.) So eyeroll score on the HIP has some validation as a biological marker.

Effects of supportive group therapy for cancer patients study: anxiety and depression modulate the pain more than the location of the cancer. Melzack's theory indicates input from cortex can modulate pain. We taught Self Hypnosis for pain control: used metaphors that induce relaxation, suggestions to filter hurt out of the pain, not fight the pain, focus on a competing sensation. By end of year the intervention group had half the pain that the non-intervention group had. The frequency and duration of pain attacks were not different.

We are now in year 5 of a 10 year replication study.

1994

DePascalis, Vilfredo (1994). Event-related potentials during hypnotic hallucination. International Journal of Clinical and Experimental Hypnosis, 42 (1), 39-55.

Event-related potentials were elicited by visual stimulation and recorded at frontal, central, and posterior scalp sites so as to study the psychophysiological process

associated with hypnotic hallucination. Subjects were screened using two measures of hypnotic susceptibility (Harvard Group Scale of Hypnotic Susceptibility, Form A and the Stanford Hypnotic Susceptibility Scale, Form C). Seven high and 9 low hypnotizable right-handed females participated in the experiment. Eight intermediate hypnotizable right-handed females served as controls. Peak amplitudes and latencies of P1, N1, P2, N2, and P3 components were compared in two hypnotic conditions (obtained by means of hypnotic suggestions): stimulus enhancement and stimulus elimination. High hypnotizable subjects displayed a significant attenuation of the P1 and N1 amplitudes of the evoked response while experiencing stimulus elimination. The effect for the P1 component was greatest at the posterior sites compared to that found at the anterior and central sites. A similar trend across condition was also observed for P3 peak amplitude, even though the Group x Condition interaction was only marginally significant ( $p < .07$ ). During negative hallucination, P3 peak latency for high hypnotizables was shorter than that obtained during stimulus enhancement. This effect was more pronounced across the right hemisphere. These results are discussed in light of previous findings.

1992

Page, Roger A.; Handley, George W. (1992). Effects of 'deepening' techniques on hypnotic depth and responding. International Journal of Clinical and Experimental Hypnosis, 40, 157-168.

The present study attempted to assess the effectiveness of commonly used deepening techniques and of surreptitiously provided stimulation on hypnotizability scores, in-hypnosis depth reports, retrospective realness ratings, and the Field Inventory of Hypnotic Depth (Field, 1965). High, medium, and low hypnotizables were assigned in equal numbers to 1 of 3 groups, each containing 54 Subjects. Controls were compared to Subjects receiving 2 deepening techniques or 2 suggestions for positive and negative hallucinations that were surreptitiously enhanced. Of the 4 dependent measures employed, the only significant difference between groups related to a change in depth reports for the manipulation items themselves, leading to the conclusion that the effect of the techniques was at best minimal and transient. Some methodological and conceptual issues are also discussed.

Spanos, Nicholas P.; Burgess, C. A.; Cross, P. A.; MacLeod, G. (1992). Hypnosis, reporting bias, and suggested negative hallucinations. Journal of Abnormal Psychology, 101, 192-199.

Examined the role of reporting bias in hypnotic negative hallucinations by using a paradigm in which reporting bias was assessed independently of perceptual change. In Experiment 1, highly hypnotizable subjects reported significant loudness reductions when tested for hypnotic deafness. Later, however, these subjects biased their reported loudness reductions in the absence of perceptual change, and their reporting bias scores were almost as large as their hypnotic deafness reports. Subjects also biased their ratings of strategy use. In Experiment 2, ratings of blindness given in response to a hypnotic negative visual hallucination suggestion

were significantly correlated with reporting bias scores obtained in this paradigm. Although hypnotic blindness and hypnotic deafness correlated significantly, the partial correlation between these variables was nonsignificant when reporting bias scores were statistically controlled. Results are used to support a skeptical view of hypnotic response as being based on compliance.

1991

Kunzendorf, Robert G.; Beltz, Susan McLaughlin; Tymowicz, Gina (1991-92). Self-awareness in autistic subjects and deeply hypnotized subjects: Dissociation of self-concept versus self-consciousness. Imagination, Cognition and Personality, 11, 129-141.

By refining past tests of self-awareness in mirrors, current testing demonstrates that autistic subjects' percepts are dissociated from self-concept, whereas hypnotized subjects' sensations are dissociated from self-consciousness. In the current test of self-concept, subjects could not directly see a line inside the box on their lap, but subjects could see the line indirectly in a televised mirror image. When instructed to touch the line, autistic subjects reached towards the televised line, whereas nonautistic subjects reached towards the actual line occluded inside the box. This first result suggests that the autistic subject's visual percept of the televised line is dissociated from its spatial relationship to the subject's self-concept. In the current test of self-consciousness, subjects were told to use a televised mirror-image to move their hands together until touching, but were not told that they were actually seeing a pre-recorded tape of their hands struggling unsuccessfully to touch. When queried, hypnotized subjects denied that their tactually joined hands were touching, whereas nonhypnotized subjects confirmed that their hands were touching. This latter result suggests that the hypnotized subject's hand-touching sensations are dissociated from the immediate and incontrovertible self-consciousness that one is perceiving the hands touching (not imaging them touching).

Ross, Colin A.; Miller, S. D.; Reagor, P.; Bjornson, L.; Fraser, G. A.; Anderson, G. (1990). Schneiderian symptoms in multiple personality disorder and schizophrenia. Comprehensive Psychiatry, 31, 111-118.

#### NOTES

Schneiderian first-rank symptoms of schizophrenia were equally common among 102 patients with multiple personality disorder in all four centers where data was collected. The average multiple personality disorder (MPD) patient had experienced 6.4 Schneiderian symptoms. When these 102 cases are combined with two previously reported series of MPD cases, an average of 4.9 Schneiderian symptoms in 368 cases of MPD is noted. This compared with an average of 1.3 symptoms acknowledged by 1,739 schizophrenics in 10 published series. Schneiderian symptoms are more characteristic of MPD than of schizophrenia.

1989

Bryant, Richard A.; McConkey, Kevin M. (1989). Hypnotic blindness: A behavioral and experiential analysis. Journal of Abnormal Psychology, 98, 71-77.

#### NOTES

"This research examined the influence of visual information on a decision task that subjects were administered during hypnotically suggested blindness. Real, hypnotizable subjects and simulating, un hypnotizable subjects were tested in two experiments. Experiment 1 focused on behavioral responses, and Exper. 2 focused on experiential reactions. In both experiments, the findings indicated that the behavioral responses of reals were influenced by visual info. despite their reported blindness. The behavioral responses of reals and simulators were essentially similar. The experiential data in Experiment 2 provided information about the phenomenal nature of subjects' reported blindness. The experiential reactions of reals and simulators were essentially different. The research is discussed in terms of the issues that need to be considered in the development of a model of hypnotic blindness" (p. 71).

Bryant, Richard A.; McConkey, Kevin M. (1989). Visual conversion disorder: A case analysis of the influence of visual information. Journal of Abnormal Psychology, 98, 326-329.

#### NOTES

"examined the influence of visual information on a decision task that was administered to an individual with monocular visual conversion disorder. Findings indicated that his performance was influenced by the visual information and by motivation instructions. The findings are discussed in terms of a model of hysterical blindness that recognizes the interplay of cognitive and motivational processes" (p. 326).

Spanos, Nicholas P.; Lush, Nancy I.; Gwynn, Maxwell I. (1989). Cognitive skill-training enhancement of hypnotizability: Generalization effects and trance logic responding. Journal of Personality and Social Psychology, 56 (5), 795-804.

Compared low-hypnotizable subjects who simulated hypnosis, underwent cognitive skill training, or served as no- treatment controls to subjects who scored as high hypnotizables without training (natural highs) on response to analgesia, age-regression, visual hallucination, selective amnesia, and posthypnotic suggestions. Subjects who attained high hypnotizability following skill training (created highs) did not differ from natural highs on any response index. Natural and created highs scored lower than simulators but higher than controls on the behavioral and subjective aspects of test suggestions. Simulators, however, were significantly less likely than natural highs or skill- trained subjects to exhibit duality responding or incongruous writing during age regression or transparent hallucinating. Results suggest that the hypnotic responses of natural and created highs are mediated by the same cognitive variables and that enhancements in hypnotizability produced by skill training cannot be adequately explained in terms of compliance.

1988

Lynn, Steven Jay; Rhue, Judith W. (1988). Fantasy proneness: Hypnosis, developmental antecedents, and psychopathology. American Psychologist, 43 (1), 35-44.

This article presents a summary of the findings of our ongoing research program on the fantasy-prone person. In seven studies, nearly 6,000 college students were screened in order to obtain five samples of 156 fantasy-prone subjects. Fantasy-prone subjects (fantasizers) were selected from the upper 2%-4% of the college population on a measure of imaginative involvement and contrasted with nonfantasizers (lower 2%-4%), and medium fantasy-prone subjects (middle range). General support was secured for Wilson and Barber's construct of fantasy proneness: Fantasizers were found to differ from nonfantasizers, and in many cases also from medium-range subjects, on measures of hypnotizability, imagination, waking suggestibility, hallucinatory ability, creativity, psychopathology, and childhood experiences. Differences in hypnotizability were most reliable when subjects participated in a multisession study and were screened not only with the screening inventory, but also with an interview that substantiated their fantasy-prone status. However, our findings indicated that less correspondence between fantasy proneness and hypnotizability exists than Wilson and Barber suggested. Hypnotic responsiveness is possible even in the absence of well-developed imaginative abilities, and not all fantasizers were highly hypnotizable. Fantasizers recollected being physically abused and punished to a greater degree than other subjects did and reported experiencing greater loneliness and isolation as children. Many fantasizers appeared to be relatively well-adjusted; however, a subset of fantasizers were clearly maladjusted based on self-report, Minnesota Multiphasic Personality Inventory (MMPI), and Rorschach test data. Because of the diversity inherent in the fantasy-prone population, it is misleading to think of individuals at the extreme end of the fantasy-proneness continuum as conforming to a unitary personality type.

Spiegel, David; Barabasz, Arreed F. (1988). Effects of hypnotic instructions on P300 event-related-potential amplitudes: Research and clinical applications. American Journal of Clinical Hypnosis, 31, 22-27.

Apparently conflicting findings in two recent studies of the effects of hypnotic hallucination on the P300 component of cortical event-related potentials are examined. In one study, Barabasz and Lonsdale (1983) found an increase in P300 amplitude in response to hypnotic anosmia instructions. However, Spiegel, Cutcomb, Ren, and Pribram (1985) obtained a decrease in P300 amplitude after instructing high hypnotizables that an imaginary cardboard box blocked their view of the stimulus generator. These differences are reconciled on the basis of differences in the hypnotic instructions given. The former study employed language which emphasized negation ("You will not smell anything at all"), while the latter had subjects focus on a competing obstructive hallucination. The anosmia subjects were surprised when they smelled anything at all, leading to an enhanced P300

response, while the subjects in the visual study were so absorbed in the hallucinated obstruction that perception of the stimulus was reduced. Clinical implications of these two studies are examined.

1987

Hilgard, Ernest R. (1987). Research advances in hypnosis: Issues and methods. International Journal of Clinical and Experimental Hypnosis, 35, 248-264.

There are substantial areas of agreement upon the classical phenomena of hypnosis, illustrated by what we now have learned about hypnotic talent, amnesia, hallucinations, analgesia, and dissociative processes. While genuine advances in knowledge about hypnosis have been made in recent decades, differing orienting attitudes have kept some controversy alive, particularly in the interpretation of empirical findings. Differences of interpretation of the phenomenal and behavioral facts are to be expected in the present stage of developmental, cognitive, and social psychology.

#### NOTES

The author writes of the "domain of hypnosis" as within the larger domain of social psychology (because it is usually interpersonal); cognitive psychology (because of alterations in perception, imagination, memory, and thought); developmental and personality psychology (because of individual differences); and physiological psychology (because of neurophysiological aspects).

In terms of what we know about hypnotic talent, he notes that high hypnotizability is not generally associated with psychopathology; that it may however be associated with a personality measure called absorption; and that there may be some inherited ability (Morgan, 1973). In the author's view, hypnosis is no longer considered simply a response to suggestion, since imagination and/or fantasy are very important.

In reviewing evidence of posthypnotic amnesia the author writes, "Subtleties in language require making careful distinctions among concepts such as compliance, suggestion, compulsivity, belief, self-deception, automaticity, the voluntary, the involuntary, and a happening. If these distinctions are glossed over, the choice of words (e.g., substituting compliance for response to suggestion) may give the impression that a finding departs more widely from conventional views than it does. We, too, have found that Ss used varied strategies or skills during amnesia, but this need not deny augmentation by suggestion.

"It takes genuinely high Ss to illustrate truly high posthypnotic amnesia... Many of the truly high hypnotizable individuals cannot break amnesia, no matter how hard they try" (p. 253).

Regarding the evidence for hypnotic hallucinations and trance logic, the author suggests that trance logic is not a clear concept because the Subject is capable of good logic while tolerating some inconsistencies. "It is ordinary logic to assume that if your hallucination is your own construction, it is you who can influence it by your own wishes. In the rare cases of transparent or diaphanous hallucinations there is still an 'out there' quality. People who report that they see wispy ghosts also see them as 'out there,' so that they qualify as hallucinations. The distinction appears to

be one of perception and perception-like experiences within hypnosis rather than of logic" (p. 256).

In reviewing the evidence for hypnotic analgesia, the author acknowledges that pain relief is available with other kinds of interventions, or by using other kinds of psychological processes, but that does not diminish the contribution of hypnosis (which has a long and impressive clinical history). Following laboratory studies, it is noted that "the amount of alleviation of pain through hypnosis is positively correlated with the hypnotizability of the candidate for pain reduction. This result is not universally accepted, because some clinicians are convinced that those unsuccessful in hypnotic pain reduction are resisting hypnosis" (p. 256-257). In the present paper he acknowledges but does not review physiological literature on hypnoanalgesia.

Regarding the concept of dissociation, the author indicates that he considers it a more useful concept than the concept of trance or hypnotic state "when a person is only slightly or moderately involved in hypnosis ... . The advantage is that dissociations, as compared with altered states, can be described according to limited or more pervasive changes in the cognitive or motor systems that are being activated or distorted through suggestion in the context of hypnosis. Perhaps when all-inclusive enough, such changes can justify the use of the term trance or altered state, but I believe that these terms should be used, if at all, only for those for whom the immersion in the hypnotic experience is demonstrably pervasive" (pp. 258-259).

The author goes on to describe his initial discovery of the 'hidden observer' in an experimental context, and to relate the 'hidden observer' to others' earlier observations of a secondary report of an experience previously concealed from S's consciousness (Binet, 1889-1890/1896; Estabrooks, 1957; James, 1899; Kaplan, 1960). "The issues are still being worked on, but as in the case of trance logic the heart of the problem is not whether to speak of a hidden observer, but to recognize that there may be cognitive distortions in hypnosis even while some more realistic information is being processed in parallel, so that everything is not reportable by S" (p. 260).

Nash, Michael R.; Lynn, Steven Jay; Stanley, Scott; Carlson, Victor (1987). Subjectively complete hypnotic deafness and auditory priming. International Journal of Clinical and Experimental Hypnosis, 35 (1), 32-40.

The present study examined the cognitive and attentional mechanisms by which auditory information is maintained out of awareness during complete hypnotic deafness. Adopting a methodology from recent work on subliminally presented pattern-masked words and dichotic listening, the study tested whether spoken words presented during complete hypnotic deafness affect lexical decisions concerning subsequently presented word choices. The response of 9 hypnotized and 15 simulating Ss to spoken stimulus words presented following hypnotic deafness instructions was compared to the response of 20 baseline control Ss who never were exposed to the stimulus words. While the response pattern of hypnosis Ss appeared different from that of baseline control Ss, hypnotic Ss showed no evidence of the priming effect found in subliminal perception and dichotic listening studies.

Simulator response deviated significantly from hypnotized and baseline control responses.

#### NOTES

10 highs capable of hypnotic deafness, screened by Harvard Group and Stanford Profile Scales (Means 11.0 and 24.7, respectively) and 15 lows (means 1.7 and 1.7, respectively) participated in the study; the low hypnotizables being in the simulation group. For the experimental session, a different E administered a standard hypnotic induction and the deafness suggestion, testing for deafness by snapping fingers near S's ear and making loud requests for motor responses.

An experimental trial consisted of tapping an S on the hand, saying the stimulus word out loud, and visually presenting four words for the S to read out loud and circle one. "Of the 18 main experimental trials, the four-word array consisted of two words which were related to the stimulus (one word which was semantically related to the spoken stimulus word and one word which was phonetically related), and two neutral unrelated words" (p. 34). For example, if the spoken word were 'dream,' the word array might include 'cream, tennis, sell, sleep.' There also were "3 phonetically unrelated trials (whose arrays consisted of one phonetically related choice and 3 unrelated choices) and 2 stimulus word-unrelated trials (whose arrays consisted of the stimulus word and 3 unrelated choices) ... [and] 7 dummy trials with 4 unrelated choices only" (p. 34). Ss rated their degree of deafness on a 10-point scale after hypnosis was terminated.

Possible sources of bias were examined by having 20 control Ss respond to blank tachistoscopic slides with the instructions that they were participating in a study of 'subliminal perception.' Another 22 Ss were asked to identify the semantically and phonetically related words from the word array, which for the most part they did successfully.

All Ss rated themselves as '10' on the deafness scale, indicating total deafness. The principal results are seen in Tables 1 and 2.

Table 1 Mean Number of Related and Unrelated Responses (Percentage of Responses) for all S Groups on the 18 Mean Experimental Trials

Response Category S Group N Related Unrelated Total

Hypnotized 9 7.22 10.78 18

(40.13%) (59.88%) (100%)

Simulating 15 12.13 5.87 18

(67.43%) (32.61%) (100%)

Baseline 19 8.79 9.21 18 Controls (48.82%) (51.17%) (100%)

Table 2 Mean Number of Phonetic and Semantic Responses within the Related Response Category on the 18 Main Experimental Trials

Related Responses S Group Phonetic Semantic Hypnotized 1.78 5.44

(9.89%) (30.24%) Simulating 7.07 5.07

(39.27%) (28.16%) Baseline 4.21 4.58 Controls (23.38%) (25.44%)

Hypnotized Ss were significantly different from simulators (Table 1) in number of related responses. Simulators gave significantly more related responses than baseline controls. Simulators also gave more phonetically related words than either

the hypnotized or baseline Ss (Table 2); there was no difference between groups on semantically related words. (Authors performed other useful and detailed analyses.) In their Discussion section, the authors note that they did not obtain the expected results of hypnotized Ss producing more related responses than baseline Ss. "In fact, internal analyses of hypnotized and baseline responses revealed that the pattern of choices for hypnotic deaf Ss was opposite to the direction predicted by subception. Hypnotic Ss appeared to avoid phonetically related word choices, even for items on which baseline control Ss scored above chance. ...

"This kind of non-baseline performance by hypnotic Ss can be accounted for by either a strategic enactment conceptualization of hypnosis (Spanos, 1982; Wagstaff, 1981) or Hilgard's (1979) neo-dissociation theory. Spanos might emphasize the hypnotic S's active strivings to meet the hypnotist's perceived expectations. ... Neo-dissociation theory might stress the mechanisms by which processing of auditory inputs are maintained outside of awareness via a dissociative barrier.

" ... Given the tendency for simulating Ss to 'overplay' hypnotic phenomena (Levitt & Chapman, 1979), one might have expected simulators to pointedly avoid related responses, thus producing a lower frequency of related words than either the hypnotic Ss or the baseline controls (in effect being more deaf than the deaf). Just the opposite occurred. One possible explanation for this behavior presents itself: In their work with posthypnotic suggestion and the 'disappearing hypnotist' ... M. T. Orne and others found that simulating Ss may be more alert and responsive to demand cues than are hypnotic Ss. In the present study, the authors' original hypothesis was that hypnotic Ss might reveal a subception effect by above-chance responding on related word choices. If we assume that this expectation was somehow communicated to Ss by some subtle aspect of the experimental procedure, then it is conceivable that simulating Ss were able to detect and act upon these cues, while hypnotized Ss remained relatively unattuned to such subtleties.

"In sum, the priming effect noted in the subliminal perception research does not appear to be a feature of complete hypnotic deafness, at least as measured in this study. The behavior of simulating Ss in the present study should be another caution to researchers that differences between hypnotized and simulating Ss may reflect simulation effects in addition to, or instead of, hypnotic effects" (pp. 37-38).

1985

Spiegel, David; Cutcomb, Steven; Ren, Chuan; Pribram, Karl (1985). Hypnotic hallucination alters evoked potentials. Journal of Abnormal Psychology, 94 (3), 249-255.

Brain electrical potentials evoked by visual stimulation were analyzed to study the neurophysiological mechanism associated with hypnotic hallucination. The visual evoked responses of 6 high- and 6 low-hypnotizable subjects were compared in three hypnotic conditions: stimulus enhancement, stimulus diminution, and stimulus elimination (obstructive hallucination). High-hypnotizable individuals demonstrated significant suppression of the later components of the evoked response (N1 and P3) while experiencing obstructive hallucinations, indicating a change in information

processing. This effect was significantly greater in the right, as compared to the left, occipital region.

#### NOTES

In the stimulus enhancement condition, Ss were told that one of two colored stimuli would appear unusually bright and interesting. In the stimulus diminution condition, Ss were told that the alternate color stimulus would appear drab, dull, uninteresting. In the obstructive hallucination condition, Ss were told to visualize a box that blocked their view of the TV monitor, making it impossible to see anything on the TV screen. The stimuli were 8 cm x 8 cm squares (colored gratings) presented 1 meter in front of S: 50% were blue vertical gratings, 50% were pink horizontal gratings.

Ss were told to press a button in response to any stimulus they happened to see; hence all stimuli were potential targets. To control for the effect of motor potentials when they pressed the button, a button-pressing/passive-attention control group was added. Only results significant beyond this control group were attributed to a hypnotic hallucination effect. A second control group of medium level hypnotizable Ss were required to (a) button press after each stimulus presentation and (b) attend passively to the TV monitor screen without button pressing. "Thus, we had three control conditions: (a) for attentional demands, comparing the performance of high hypnotizables in the obstructive hallucination versus the hypnotic stimulus enhancement condition, (b) for hypnotizability, in comparing the high hypnotizables in the obstructive hallucination condition versus the low hypnotizables in the same condition, and (c) for button-pressing behavior, comparing the performance of the high hypnotizables to that of control subjects in press versus no-press conditions" (p. 250).

In their discussion, the authors state, "Our results are consistent with the hypothesis that an hypnotic instruction of obstructive hallucination among high- hypnotizable subjects is accompanied by a decrease in the amplitude of the P3 component of the evoked response throughout the brain, and of the N2 and P3 components in the occipital region. This dampening of amplitude is particularly notable among high hypnotizables in the right, as compared with the left, occipital area, suggesting greater inhibition of scalp-recorded response to a visual stimulus in the right hemisphere.

"These data show that while experiencing an obstructive hallucination blocking the stimulus, high-hypnotizable subjects demonstrate a change in the information-processing components of the evoked response (Baribeau-Braun, Picton, & Gosselin, 1983), rather than primarily in channel selection, which is reflected more by P1 and N1 (Ford, Roth, Dirk, & Kopell, 1978; Hillyard & Picton, 1979). Although there were differences at P1 and N1 between high and low hypnotizables, they were not significantly greater than those observed in the press/no-press control group. These observations make it possible to address several alternative explanations for the findings, such as the possibility of differences in nonspecific arousal leading to a differential preparation (Naatanen, 1969), which should be reflected primarily in changes in the early components, as would any differences in pupil size. Drowsiness or inattention in this condition should be associated with an increase, rather than a

decrease, in response amplitudes (Schacter, 1976). The possibility that high hypnotizables might have defocused their view of the monitor (Schulman-Galambos, & Galambos, 1978) is made less likely by the fact that defocusing is accompanied by increases in P1 latency (Sokol & Moskowitz, 1981), whereas there were no P1 latency differences in the obstructive hallucination condition" (p. 254).

Zamansky, Harold S.; Bartis, Scott P. (1985). The dissociation of an experience: The hidden observer observed. Journal of Abnormal Psychology, 94 (3), 243-248.

Addressed methodological weaknesses in previous studies of the hidden observer phenomenon presented by E. R. Hilgard (1977) using a modified procedure with 11 undergraduates highly susceptible to hypnosis. The critical modifications were that no prior practice in dissociation was given before the hidden observer was assessed, the notion of hidden information was introduced only after the stimulus was no longer present, and independently verifiable stimuli were employed. Despite this more rigorous procedure, a hidden observer response was still observed in more than 90% of Ss. This finding makes much less tenable interpretations that attribute the hidden observer effect solely to social expectancies and situational demands. It is concluded that it is possible for some hypnotized individuals to monitor the actual state of events while experiencing a variety of perceptual distortions.

1983

Nash, John (1983). Negative visual hallucination and concomitant changes in cortical event-related potentials (Dissertation, University of California, Santa Barbara). Dissertation Abstracts International, 45 (2), 716-B. (Order No. DA 8411224)

"The purpose of this investigation was to examine the effects of negative visual hallucination (NVH) on cortical event-related potentials (ERPs), and to compare these effects with those of selectively attending to and ignoring stimuli. Five highly hypnotically susceptible subjects, four female and one male, were trained to block from subjective experience, i.e., negatively hallucinate, a ring of strobe-illuminated circles surrounding a central, independently strobe-illuminated circle. This stimulus array was modeled after part of the Titchener-Ebbinghaus circle illusion, since previous research had shown that subjects could attenuate the effects of the optical illusion via NVH of the outer, illusion-producing circles. "Analysis of the ERP data revealed amplitude and latency changes in various ERP components across the three experimental conditions (Attend, Ignore, NVH) for the four female subjects, a negative result which is explained in motivational terms. "The most noteworthy finding was the selection of the P3 amplitude variable at C2 by stepwise discriminant analysis for the four females, and the fact that this amplitude systematically decreased across conditions from largest in Attend to smallest in NVH. A variety of individual patterns were observed in terms of other ERP components which allowed discrimination (successful classification) among the three conditions. The results suggest that both Ignoring and NVH of a stimulus result in a decrease in the subjective certainty of perception of the stimulus. Individual

differences in patterns of ERP changes are interpreted in terms of differing strategies for execution of the experimental instructions. The results support the view that NVH instructions produce distinctive ERP effects and that NVH generally can be viewed as an extreme level of ignoring" (p. 716).

1982

Cunningham, Paul V.; Blum, Gerald S. (1982). Further evidence that hypnotically induced color blindness does not mimic congenital defects. Journal of Abnormal Psychology, 91, 139-143.

Six undergraduate women, highly skilled in hypnotic techniques, were trained under hypnosis with a color mixer to experience red, green, blue, and total color blindness and were then programmed for the same responses in the posthypnotic state under conditions of amnesia. After awakening they were shown pseudoisochromatic plates as a preliminary check on the efficacy of the prior hypnotic instructions. The experiment consisted of successive administrations of the Farnsworth-Munsell 100-hue test, initially under normal baseline viewing conditions followed by each of the color-blind conditions in turn. Results indicate that although the observers subjectively experienced the varieties of color blindness as instructed, their responses differed from specimen responses of individuals with congenital defects in color discrimination. Implications for interpreting hypnotic alterations of perception are discussed.

Spanos, Nicholas P.; Bridgeman, M.; Stam, H. J.; Gwynn, M. I.; Saad, C. I. (1982-83). When seeing is not believing: The effects of contextual variables on the reports of hypnotic hallucinations. Imagination, Cognition and Personality, 2, 195-209.

When administered a hallucination suggestion most high susceptible hypnotic and task-motivated subjects reported that they "saw" the suggested object. When asked what they meant by "saw," however, almost all indicated that they had imagined the object but did not believe that it had actually been present. On the other hand, simulating subjects maintained that the suggested object had been "really there." Simulators were also more likely than non-simulators to provide "life-like" descriptions of the suggested object (e.g., solid rather than transparent, colored, highly vivid). These findings are consistent with the view that hypnotic hallucinations are context-generated imaginings. They also indicate that unique or unusual psychological processes like "trance logic" need not be posited to account for the descriptions of "hallucinatory" experiences proffered by hypnotic subjects.

#### NOTES

It was observed that hypnotized Ss reported more vivid (and longer sustained) imagery than task motivated Subjects. Hypnotized Ss did not differ from high susceptible simulators on vividness of imagery or how long they experienced the imagery, but did report shorter and less vivid imagery than simulators who were low hypnotizables.

1981

Blum, Gerald S.; Nash, John; Jansen, Robert D.; Barbour, John S. (1981, June). Posthypnotic attenuation of a visual illusion as reflected in perceptual reports and cortical event-related potentials. Academic Psychology Bulletin, 3, 251-271.

Highly selected and trained hypnotic subjects, capable of ablating portions of visual stimuli from conscious awareness, showed varying degrees of ability to attenuate the Titchener-Ebbinghaus circles illusion post-hypnotically under a negative visual hallucination instruction. The presence or absence of such inhibitory skill, inferred from perceptual reports, was differentially reflected in changes in cortical event-related potentials not typically associated with shifts in selective attention. These findings point to the cognitive operation of a distinctive mechanism of selective inattention.

#### NOTES

Blum et al. postulate an inhibitory mechanism of the central nervous system with stages of amplification and attenuation. They suggest that individual differences in inhibitory skill may be improved with practice even for very skilled Subjects. They studied this type of inhibition using a visual illusion (the Titchener-Ebbinghaus circles) because the neural locus of such illusions is thought to be more central in the nervous system rather than at the level of the retina.

Experiment 1. Three Ss trained in using hypnosis viewed stimuli in waking and posthypnotic negative visual hallucination (NVH) conditions. All three had previously passed a negative hallucination item (not seeing a playing card of three such cards placed on a table). Training included practice sessions applying NVH to the experimental stimuli. S1 reported immediate success; S2 experienced some initial difficulty ("I have a feeling something's there") but then reported success; S3 required a couple of long practice sessions.

The classic Titchener-Ebbinghaus illusion stimuli were used. Stimuli were ten slides with drawings of a standard 17-mm-diameter black circle on the left and a comparison black circle on the right. The black circle on the right was either 14, 15, 16, 17, or 18 mm in diameter, skewed intentionally around 17, to compensate for the proportion of smaller and larger judgments applied to the comparison figure in relation to the standard. One black comparison figure was surrounded by seven 15-mm diameter white circles; the other by seven 10 mm diameter white circles. The key drawings were both black circles of 17 mm. The second set of five drawings, used as a control, contained the same black circles but lacked outer rings of white circles.

The Subject was to state whether the black circle on the right appeared larger, smaller, or the same as the standard black circle on the left. Slides were shown for 4 seconds each, with 6 seconds in between slides.

Alternating blocks of trials were given under baseline (B) condition and a posthypnotically programmed negative hallucination condition (NVH). In the NVH condition, "the rings of white circles surrounding the standard and comparison black inner circles were 'ablated' from consciousness. The observers were amnesic in the waking state for their prior hypnotic instructions and were cued in advance of a block of trials simply by the phrases 'This will be a mixed series' (referring to B, in

which the stimuli appeared as they really were, some with outer rings of white circles present and others not), or 'This will be a black only series' (referring to NVH, in which all stimuli appeared to the observer as black circles only, whether the outer rings were physically present or not)" (pp. 254- 255). Sessions were spread out over 8-12 months for each observer, interspersed with a variety of other experiments.

In one session the Experimenters used a selective attention instruction, with Ss given posthypnotic suggestions to regulate their cognitive arousal to a peak of mental alertness and concentration (+AA) and focus on the inner black circles but not to negatively hallucinate the outer white circles.

Although all three Ss showed the illusion effect, they varied in ability to attenuate the illusion when negative visual hallucination suggestions were given. "S1 showed a very greatly reduced frequency of reports in the illusory direction under the NVH condition, a less marked reduction under +AA concentration, and no reduction at all under a waking instruction to ignore the outer circles; S2 revealed a moderate but significant reduction under NVH but not under +AA; S3 gave no evidence of attenuation in either condition" (p. 258). The response times for the two more successful Ss (1 and 2) with the 17 mm stimuli under NVH conditions were not different when the outer circles were either present or absent.

Experiment 2. The next year S1 and S2 returned but S3 was no longer available as a Subject; S4 and S5 were added and trained in hypnosis skills. EEG evoked response potentials (ERPs) were recorded while Ss made size judgments as in Experiment 1. Averaged ERPs for each block of 100 stimulus presentations were obtained for the first 500 milliseconds following stimulus onset. Judges blind to the experimental conditions evaluated the ERP records.

All Subjects experienced the Titchener-Ebbinghaus illusion, but again there were individual differences in ability to attenuate the illusion: S1 was the most successful; S2 gave significantly fewer responses in the larger category under NVH than B conditions; and both S1 and S2 improved attenuation performance over the previous year. S4 fell between S1 and S2 in ability; S5 was unable to attenuate the illusion in the NVH condition.

Results. "All three observers whose perceptual reports indicated some attenuation of the visual illusion during the NVH condition also showed a consistent reduction of the P2-N2 amplitude during NVH" (p. 262) at the Occipital sites. Median amplitude reduction was 36%, 40%, and 36% for S1, S2, and S4; only 7% for S5. There were no similar reductions for the other electrode sites, though "enhancement of P2-N2 amplitudes occurred in the lateral prefrontal and frontal areas in the two most successful individuals, S1 and S4" (p. 263). There was also a lag in N2 peak latencies for the three best subjects. The Experimenters noted that the N2 peak occurred 50 msec later in the frontal and prefrontal areas than in the occipital area.

In their Discussion, the authors express the view that it is not likely that faking could have occurred, for several reasons: 1. The Subjects were trained to report honestly, and they often had reported failures to experience hypnotic phenomena suggested during training sessions. 2. The task elicited rapid responses, usually in less than 2 seconds, to 10 different slides in randomized blocks of 100 trials, which would make self monitoring of responses extremely difficult. 3. Subjects exhibited a

consistency of responses over experimental sessions that were widely separated in time, making conscious or unconscious deception unlikely. 4. The finding of no difference in latency between 17 mm stimuli with and without outer rings of white circles supports an interpretation of reliable reporting. 5. Differences in ERP data between the B and NVH conditions were obtained only for those Ss who successfully attenuated the illusion.

The authors also state, "In terms of our conceptual model of the mind, inhibitory skill is attributable to the capacity for invoking inhibitory action earlier in the sequence as signals are processed through stages of amplification and attenuation en route to consciousness (Blum & Barbour, 1979). In the NVH condition of the present task, first- stage attenuation ... [Subject 1] ... occurs in time to negate the illusion as well as preventing conscious awareness of the outer white circles, second-stage attenuation takes place too late to disrupt the illusion but still in time to keep the outer circles from consciousness" (p. 265). Note that the unsuccessful Subject 5 had the highest score on the screening hypnotizability tests. The variation among very high hypnotizables casts doubt on the practice of grouping Ss who score between 9 and 12 on the SHSS. "It is perhaps not surprising that many previous hypnotic studies involving alterations in such subtle phenomena as visual illusions have yielded negative results." p. 266.

N.B. None of the Ss was able to eliminate the illusion under a strong waking instruction to ignore the outer circles while judging the inner black ones. "These different results for AA and NVH instructions pinpoint the contrast between selective attention (+AA) and selective inattention (NVH)" (p. 266).

The ERP changes seen in occipital and frontal areas were in opposite directions. Thus "the data suggest an effect which seems to parallel both investment of attention (increases in late components over frontal cortex) and withdrawal of attention (relative decreases in late components over occipital cortex). This parallel leads us to speculate that our occipital decreases may have been due to active inhibition of information-processing in the occipital regions, and that the late component enhancement over frontal areas may have been due to the mobilization of resources in these areas necessary to accomplish the tonic inhibition of visual input. ... Activity in the frontal cortex apparently 'programs' inhibition on the specific sensory nuclei of the thalamus, in a modality specific and topographical way, accomplishing gating of sensory information to primary sensory cortex" (p. 268).

Bauer, Herbert; Berner, Peter; Steinringer, Hermann; Stacher, Georg (1980). Effects of hypnotic suggestions of sensory change on event-related cortical slow potential shifts. Archiv fur Psychologie, 133 (3), 161-169.

"The purpose of this study was to evaluate whether cortical slow potentials related to a S1-S2 paradigm are influenced by hypnotic suggestions of sensory change. Five healthy subjects susceptible to hypnosis participated each in two identical experiments with three conditions. In condition (1) and (2) each three intensities of 800 and 4000 Hz tones were presented. Preceding condition (2) hypnosis was

induced and the subjects received the suggestion to hear the 800 but not the 4000 Hz tones. In condition (3), the tones were presented as S1 and a flash as S2. The subjects received the same suggestions as in (2) and a motor response to S2 was required. EEG was recorded from Cz. In (1) 800 and 4000 Hz tones caused negativities of equal amplitude, in (2) only minute negativities developed, possibly due to hypnosis induced deactivation. In (3) the S1-S2 related negativities were significantly smaller in amplitude during 4000 Hz tones than during 800 Hz tones, while the negativities preceding S2 differed only after the most intense S1. Hypnotic suggestions attenuate S1-S2 related negative potentials, possibly by affecting cognitive functions.

Wallace, Benjamin (1980). Autokinetic movement of an imagined and an hypnotically hallucinated stimulus. International Journal of Clinical and Experimental Hypnosis, 28 (4), 386-393.

Autokinetic movement (AKM) of an imagined or an hallucinated stimulus was assessed as a function of hypnotic susceptibility level. 3 groups of Ss were asked to produce an image of a small, pinpoint spot of light and to monitor any activity of the stimulus. The stimulus was produced by imagination for a group of Ss judged high in hypnotic susceptibility and for a second group of Ss judged low in hypnotic susceptibility. A third group of Ss, highly susceptible to hypnosis, was asked to hallucinate the pinpoint spot stimulus with the aid of instructions administered by E. Instructions by which movement reports were elicited were kept equal and open-ended for all 3 groups of Ss. Results indicated that form of the stimulus (imagined or hallucinated) did not affect reports of AKM. Hypnotic susceptibility level, however, was a major factor in influencing resultant reports. The Ss judged high in hypnotic susceptibility reported a significantly greater number of direction changes of AKM than Ss low in hypnotic susceptibility. The data are interpreted in terms of the possible differences in stimulus monitoring ability as a function of hypnotic susceptibility level.

1979

**Karlin, Robert A. (1979). Hypnotizability and attention. Journal of Abnormal Psychology, 88 (1), 92-95.**

**An attentional explanation of cognitive hypnotic phenomena (e.g., hallucinations and amnesia) based on the ability to shift the pertinence of stored information was developed. It was hypothesized that individuals who were successful at a difficult attentional task would also succeed on cognitive hypnotic items. The Harvard Group Scale of Hypnotic Susceptibility, Form A was used to assess hypnotizability. To measure pertinence-shift ability, two tape recordings made by the same person were played through a single sound source. One tape was designated the target tape. Amount remembered and perceived task ease were summed to form an additive score of task success. Subjects above the median on the task were assigned to the good pertinence shift group (GP); those below the median were assigned to the poor pertinence shift group (PP). As predicted, GP subjects passed significantly more cognitive hypnotic items than did PP subjects ( $p < .05$ ). When task difficulty and compliance were controlled for, the results remained significant ( $p < .05$ ). These results were replicated in a second study. NOTES 1: A brief version of this paper was presented at the Annual Meeting of the Society for Clinical and Experimental Hypnosis, Asheville, North Carolina, October, 1978**

**1978**

**Blum, Gerald S.; Porter, M. L.; Geiwitz, P. J. (1978). Temporal parameters of negative visual hallucination. International Journal of Clinical and Experimental Hypnosis, 26, 30-44.**

**Negative visual hallucination was investigated by hypnotically programming two highly trained undergraduates not to see the colored lines of consonants while perceiving clearly a set of dots superimposed on the lines in another color. Effects of three temporal parameters were noted in tachistoscopic presentations of the consonants: priming time, i.e., opportunity for the subject to prepare to execute the negative visual hallucination after the posthypnotic cue was flashed and before the consonant appeared; duration of consonant exposure; and intensive practice over protracted periods of time. Signal strength and inhibitory skill emerged as significant variables.**

**NOTES**

**This paper reports 4 experiments with two highly trained subjects. The authors conclude, "From these observations, signal strength and inhibitory skill emerge as major determinants of the outcome in NVH. The stronger the input, the greater the likelihood of insufficient inhibitory action. Differences in skill show up at both the intra- and inter-individual levels of analysis. Even the initially skilled F1 improved her NVH ability with practice, as inferred from the disappearance of undercalling. The lesser skill of F2 was evidenced in her longer required priming time, higher accuracy of color guesses, greater number of color breakthroughs, and reported feeling of mental strain" (p. 42).**

1976

Slade, P. D. (1976). An investigation of psychological factors involved in the predisposition to auditory hallucinations. Psychological Medicine, 6 (1), 123-132.

Previous research by the author (Slade, 1972, 1973) and others has suggested that psychological stress plays an important role in triggering off the experience of auditory hallucinations. Clearly, however, predispositional factors are involved as well. The present study is an attempt to investigate some of the psychological factors which may predispose the individual to such experiences. A battery of tests involving cognitive, personality and mental imagery variables and the verbal transformation effect was administered to two small groups of psychotic patients differing only in respect of a history of auditory hallucinations and a normal control group. The main conclusion was that the results lend direct support to the proposition of Mintz & Alpert (1972) that a combination of vivid mental imagery and poor reality-testing in the auditory modality provides the basic predisposition for the experience of auditory hallucinations.

1970

Gray, Arne L.; Bowers, Kenneth S.; Fenz, Walter D. (1970). Heart rate in anticipation of and during a negative visual hallucination. International Journal of Clinical and Experimental Hypnosis, 18 (1), 41-51.

Gave 10 stimulating control and 10 hypnotic undergraduates a suggestion to negatively hallucinate. Heart rate responses recorded prior to and including the hallucination period indicated consistent differences between groups. Hypnotic Ss responded with heart rate acceleration in anticipation of the hallucination, while controls responded with heart rate deceleration during the same period. It is suggested that these differences reflect differences in the subjective experiences of hypnotic and simulating Ss. Sarbin, Theodore R.; Juhasz, Joseph B. (1970). Toward a theory of imagination. Journal of Personality, 38 (1), 52-76.

Imagination refers to (1) forming mental pictures (imaging) and creative innovating. The authors focus on "the more literal meaning of imagining, that is, 'having mental pictures,' for [they] believe that a clarification of that concept is basic to any further discussion of the psychology of the imagination.

"Before continuing, let us establish some reference cases for what a psychologist would call instances of imaging or imagining.

1. In a psychophysical experiment, a subject declares that he hears an auditory signal when no signal is presented. The experimenter scores the response as a 'false alarm.'
2. A patient in a mental hospital reports seeing the Mother of God. The psychiatrist classifies the report as a hallucination.

3. A novelist describes his work habits as involving conversations with imaginary characters. The critic calls this creative work.
4. A three-year-old child engages in play with a fictitious invisible rabbit. She is said to have an imaginary playmate" (p. 54).

1969

Barber, Theodore Xenophon (1969). An empirically-based formulation of hypnosis. American Journal of Clinical Hypnosis, 12 (2), 100-130.

A formulation is presented which does not invoke a special state of consciousness ("hypnosis" or "trance") to account for the behaviors that have been historically associated with the word hypnotism. Instead, so-called hypnotic behaviors - e.g., "analgesia," "hallucination," "age-regression," and "amnesia" - are conceived to be functionally related to denotable antecedent variables which are similar to those that control performance in a variety of interpersonal test-situations. The antecedent variables which determine behavior in a "hypnotic" situation include Ss' attitudes, expectancies, and motivations with respect to the situation, and the wording and tone of instructions- suggestions and of questions used to elicit subjective reports. The formulation is exemplified by several dozen experimental studies, and prospects for further research are delineated.

Graham, Kenneth (1969). Brightness contrast by hypnotic hallucination. International Journal of Clinical and Experimental Hypnosis, 17, 62-73

Tested the veridicality of a hypnotic hallucination elicited by a buzzer through a conditioning procedure. The stimulus to be hallucinated consisted of 2 gray circles, 3 in. in diameter, mounted on a white card. 11 highly susceptible Ss were able to produce this hallucination upon hearing the buzzer during a series of test trials following the training. Following a 2nd training series, a black and white background was provided for the hallucination and Ss tended to report the hallucinated circles as a brightness contrast. A 2nd group of highly susceptible Ss was not hypnotized, but was asked to respond as if hypnotized. These Ss tended not to report the contrast. Scheibe, Karl E.; Gray, Arne L.; Kleim, C. Stephen (1968). Hypnotically induced deafness and delayed auditory feedback: A comparison of real and simulating subjects. International Journal of Clinical and Experimental Hypnosis, 16, 158-164.

PRELIMINARY RESEARCH INDICATES THAT HYPNOTICALLY INDUCED DEAFNESS MAY REDUCE THE SPEECH INHIBITING EFFECTS OF DELAYED AUDITORY FEEDBACK (DAF). REAL AND SIMULATING HYPNOTIC SS WERE COMPARED WITH RESPECT TO THE IMPROVEMENT IN SPEECH CONSEQUENT TO THE SUGGESTION OF DEAFNESS. RESULTS INDICATE VERY SIMILAR IMPROVEMENTS OF DAF SPEECH FOR BOTH GROUPS. AN INCIDENTAL FINDING IS THAT REAL SS HAD LONGER SIMPLE READING TIMES UNDER HYPNOSIS THAN DID SIMULATING SS. (GERMAN + SPANISH SUMMARIES) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1967

Bowers, Kenneth S. (1967). The effect for demands of honesty upon reports of visual and auditory hallucinations. International Journal of Clinical and Experimental Hypnosis, 15, 31-36.

SS, UNSELECTED FOR HYPNOTIC SUSCEPTIBILITY AND SIMPLY TOLD TO HALLUCINATE, MADE PRETEST RATINGS ON THE REALITY OF VISUAL AND AUDITORY HALLUCINATIONS. ALL SS WERE THEN TASK MOTIVATED TO HALLUCINATE. BEFORE THE RETEST RATINGS WERE MADE, 1/2 OF THE SS WERE CONFRONTED BY A 2ND E WITH DEMANDS FOR REPORT HONESTY. FOR BOTH SENSORY MODALITIES, THE MEAN CHANGE IN RATINGS FROM PRETEST TO RETEST WAS SIGNIFICANTLY GREATER FOR THE TASK-MOTIVATED THAN FOR THE HONESTY-REPORT CONDITION. RATINGS OF THE REALITY OF HALLUCINATIONS

ARE EVIDENTLY HIGHLY SUSCEPTIBLE TO THE CONTEXT OF DEMANDS IN WHICH THE REPORT IS MADE. IT IS ARGUED THAT, IN THIS AND PREVIOUS EXPERIMENTS UTILIZING UNSELECTED SS, REPORTS OF HALLUCINATORY ACTIVITY ARE LESS APT TO REFLECT PERCEPTUAL ALTERATIONS THAN RESPONSE MODIFICATION IN ACCORDANCE WITH REGNANT EXPERIMENTAL DEMANDS. (GERMAN + SPANISH SUMMARIES) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Davison, Gerald C.; Singleton, Lawrence (1967). A preliminary report of improved vision under hypnosis. International Journal of Clinical and Experimental Hypnosis, 15 (2), 57-62.

REPORTS AN ACCIDENTAL FINDING WHICH WAS FELT TO BE PROVOCATIVE AND WORTHY OF FURTHER, MORE CONTROLLED, INVESTIGATION. THE EMPHASIS IS ON DETAILED DESCRIPTION OF THE PHENOMENON, WITH A MINIMUM OF THEORIZING. WHILE IN A VERY DEEP HYPNOTIC TRANCE, S WAS INDUCED TO HAVE BOTH POSITIVE AND NEGATIVE HALLUCINATIONS. ON THE FOLLOWING DAY, HE REPORTED SPONTANEOUSLY THAT HE HAD BEEN STRUCK BY THE CLARITY OF BOTH THE VISIONS AND THE PERCEPTIONS OF ACTUAL OBJECTS WHILE HYPNOTIZED; HE HAD NOT, HOWEVER, BEEN WEARING HIS GLASSES AT THE TIME, THOUGH, UNDER NORMAL CIRCUMSTANCES HE WORE HIS GLASSES AT ALL TIMES. NO SUGGESTIONS FOR IMPROVED VISION OR EXTRA EFFORT HAD BEEN GIVEN. 2 CAREFUL OPHTHALMOLOGICAL EXAMINATIONS WERE MADE DURING THE FOLLOWING 2 WK., CONFIRMING THE FACT THAT S'S EYESIGHT SHOWED A SIGNIFICANT IMPROVEMENT DURING HYPNOSIS AS OPPOSED TO THE WAKING STATE. (SPANISH + GERMAN SUMMARIES) (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Kramer, E.; Tucker, G. R. (1967). Hypnotically suggested deafness and delayed auditory feedback. International Journal of Clinical and Experimental Hypnosis, 37-43.

A PILOT STUDY INVESTIGATED HYPNOTICALLY INDUCED DEAFNESS USING DELAYED AUDITORY FEEDBACK (DAF). THE FOLLOWING TENTATIVE CONCLUSIONS ARE OFFERED: (1) INSTRUCTIONS TO PRETEND DEAFNESS DID DECREASE THE NUMBER OF SPEECH ERRORS PRODUCED IN THE DAF SITUATION WITH SOME SS, ALTHOUGH THE RESULTS WERE BY NO MEANS THOSE OF COMPLETE DEAFNESS; (2) HYPNOTICALLY INDUCED DEAFNESS ALSO PRODUCED A REDUCTION IN THE NUMBER OF ERRORS CAUSED BY DAF, THOUGH HERE, TOO, THE RESULTS DID NOT APPROACH THOSE OF COMPLETE DEAFNESS; AND (3) ADDITIONAL TRAINING OR EXPERIENCE IN HYPNOSIS SEEMED TO PRODUCE AN INCREASED ABILITY OF HYPNOTICALLY SUGGESTED

**DEAFNESS TO REDUCE SPEECH ERRORS UNDER THESE CONDITIONS. (GERMAN + SPANISH SUMMARIES) (PsycINFO Database Record (c) 2002 APA, all rights reserved)**

**Barber, Theodore Xenophon (1965). Physiological effects of 'hypnotic suggestions': A critical review of recent research (1960-64). Psychological Bulletin, 201-222.**

Recent studies are reviewed which were concerned with the effectiveness of suggestions given under "hypnosis" and "waking" experimental treatments in alleviating allergies, ichthyosis, myopia, and other conditions and in eliciting deafness, blindness, hallucinations, analgesia, cardiac acceleration and deceleration, emotional responses, urine secretion to sham water ingestion, narcotic-like drug effects, and other phenomena. The review indicates that a wide variety of physiological functions can be influenced by suggestions administered under either hypnosis or waking experimental treatments, and direct and indirect suggestions to show the particular physiological manifestations are crucial variables in producing the effects.

**Jackson, Bill (1965). The autoblink: A technique to explore nonveridical visual perception. International Journal of Clinical and Experimental Hypnosis, 13 (4), 250-260.**

The Autoblink technique was developed to allow objective, quantitative investigation of perceptual abnormalities found in psychiatric and normal populations under various experimental conditions. A pilot study demonstrated that spontaneous visual percepts could be elicited by this technique in a group of psychiatric patients and that wide individual differences were present. A 2nd study found significant differences in Autoblink rate between normal and hallucinating psychotic male Ss and also suggested that sensory deprivation and prestige suggestion are variables related to Autoblink rate. A 3rd study further explored differences between psychiatric patients and normal Ss as well as examining sex differences. The latter 2 studies are reported in detail. **Vasiliev, L. (1965). Mysterious phenomena of the human psyche. New York NY: University Books. (Reviewed by Leo Wollman in American Journal of Clinical Hypnosis, 1965, 8 (2), 146-147)**

**NOTES**

**1:**

**AJCH Abstract by Leo Wollman: Many interesting theories about hypnosis are aired in this book. The opinions Pavlov propounded many years ago, about cortical inhibition are assiduously asserted, yet some statements made bear investigation. The mere sight of the experimenter in B.N. Birman's experiments with dogs put the dog into a hypnotic state. The appearance in the room of other people, who had not participated in the experiments, had no sleep-inducing effect. For the experimental**

animal, therefore, the experimenter himself had been transformed into a conditioned hypnogenous stimulus. Similarly, in group hypnotherapy, the entrance of the physician-hypnotist into the room often effects a hypnotic state in some of the subjects. The doctor has become the stimulus for the conditioned response, that of hypnotic trance state induction.

An interesting and perhaps little known fact elicited from Chapter III (Hypnotism and Suggestion) is the high percentage (12%) of those replies to questionnaires during the First International Congress on Experimental Psychology held in Paris in 1899, which indicated that 3,000 respondents had hallucinations while in a normal state of health. The majority were visual; auditory and tactile hallucinations were less frequent.

Dr. P. P. Podyapolsky, in 1905, wrote 'I tried unsuccessfully to induce in a peasant a reddening of the skin from a mock mustard plaster not only was there no reddening, there wasn't even any appropriate sensation of burning or smarting. I surmised that this simple man had probably never experienced a mustard plaster; therefore, his mind lacked the corresponding images and the ability to reproduce them with all their consequences... And so it turned out--he had never experienced a mustard plaster. It happened that he later had occasion to put a mustard plaster on his chest, and when I hypnotized him thereafter, suggestion quickly created not only the appropriate burning sensation but also reddening of the skin where the mock mustard plaster was applied.' This phenomenon is explained by the fact that the connection between the skin and cerebral cortex by means of neural conductors may, under certain circumstances, alter the activity of different organs. The alteration operates, apparently, in the category of conditioned-reflex formation.

This book is interesting reading and from a historic point of view is worth having in one's library.

Brady, J. P.; Levitt, E. E. (1964). Hypnotically-induced 'anosmia' to ammonia. International Journal of Clinical and Experimental Hypnosis, 12, 18-20.

The procedure to demonstrate anosmia by the inhalation of ammonia is discussed. Deeply hypnotized Ss who are not knowledgeable of the relevant facts of physiology may fail to respond to ammonia fumes when it is suggested that they have no sense of smell (anosmia). However, persons who, in fact, are anosmic do respond to ammonia fumes because they are a powerful stimulus to the pain fibers in the nasal mucosa. This procedure illustrates that the crucial factor in the response of the hypnotized S is not the actual facts of anatomy and physiology, but the S's concept of them. Brady, J. P.; Levitt, E. E. (1964). Nystagmus as a criterion of hypnotically induced visual hallucinations. Science, 146, 85-86.

Hypnotized Ss who report hallucinating a visual situation which would ordinarily elicit optokinetic nystagmus demonstrate nystagmus under these conditions. They and control Ss are unable to feign nystagmus in the waking state, either by imagining the situation or by direct efforts to simulate the eye movements. Thus an

objective criterion is provided for the presence of visual hallucinations. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

Barber, Theodore Xenophon; Deeley, Douglas C. (1961). Experimental evidence for a theory of hypnotic behavior: 1. 'Hypnotic color-blindness' without 'hypnosis'. International Journal of Clinical and Experimental Hypnosis, 9 (2), 79-86.

Barber hypothesizes that a formal hypnotic induction procedure is unnecessary in eliciting alterations in sensory functioning ordinarily thought to characterize hypnotic behavior; similar performances can be elicited from normal persons by instructing them to remain inattentive to visual or auditory stimuli. Substantiating evidence is presented in the area of "hypnotic color-blindness." From Psyc Abstracts 36:02:2II79B. (PsycINFO:

### Conclusions

1. Normal persons who have been instructed to concentrate away from red and green give as many "color-blind" responses on the Ishihara as "deeply hypnotized" subjects who have been given elaborate suggestions to induce color-blindness.

1. Further experiments are necessary to determine if other behaviors which are considered as characteristic of "deeply hypnotized" subjects and which supposedly involve "sensory-perceptual alterations" -- e.g., "hypnotic deafness," "hypnotic blindness," "negative hallucinations" -- can be performed by persons who are simply asked to try to remain in-attentive to visual or auditory stimulation" (pp. 84-85).

Halpern, Seymour (1961). On the similarity between hypnotic and mescaline hallucinations. International Journal of Clinical and Experimental Hypnosis, 9, 139-149.

The hypnotically-induced visual percepts of one subject are presented and discussed. These percepts reputedly bore a close resemblance to mescaline hallucinations. It is argued that no essential qualitative difference exists between psychogenic and toxicogenic hallucinations. It was hypothesized that all perceptions including dreaming, hallucinating, imagining and hypnotic perceiving are explainable in terms of perceptual-conceptual reciprocity understood as a neuropsychological function of consciousness. Barber, Theodore Xenophon; Coules, John (1959). Electrical skin conductance and galvanic skin response during 'Hypnosis'. *International Journal of Clinical and Experimental Hypnosis*, 7 (2), 79-92.

#### Summary and Conclusions

"Six 'good' hypnotic Ss were given a ten-minute 'hypnotic induction' and a series of 'hypnotic tests.' Both basic skin conductance and momentary variations in skin conductance (GSR) were recorded during the experiment.

"The results were as follows:

1. There was no significant variation in skin conductance during the 'hypnotic induction procedure.'
2. Skin conductance generally increased throughout the remainder of the experiment, i.e., when the Ss were given suggestions of 'sensory hallucinations,' 'age-regression,' 'analgesia,' 'negative hallucinations,' and 'post'-hypnotic behavior.
3. The Ss usually showed a GSR when they were given 'hallucinatory' suggestions, i.e., when they were told that they were becoming 'itchy,' 'thirsty,' and 'very hot.'
4. The GSR to a pinprick was essentially the same before the experiment and during 'hypnotic analgesia.' Also, the GSR was essentially the same, during 'hypnotic analgesia,' (a) when three Ss were told they would receive a pinprick but did not receive the pinprick, (b) when they were told they would receive a pinprick and did receive the pinprick, and (c) when they received a pinprick without being told they would receive it.
5. Four Ss showed a GSR each time they were asked to look at a 'negatively hallucinated' object and person. Two Ss did not show a GSR when they were asked to look at the 'negatively hallucinated' object (or person). The four Ss who

showed a GSR stated, during or after the experiment, that they were by no means convinced that the person or object was no longer in the room. The two Ss who did not show GSR stated, after the experiment, that they had been 'certain' that the object (or person) was not present in the room.

6. Although the Ss stated that they did not 'remember' the 'post'-hypnotic suggestion (or anything else about the experiment), they usually showed a GSR when the E made the preliminary movements to give the signal for the 'post'-hypnotic behavior. (They also showed a GSR when E gave the signal for the 'post'-hypnotic behavior.)

"Since skin conductance is an index of the S's level of 'activation,' 'arousal,' or 'excitation,' these results indicate the following:

1. Ss do not necessarily become more 'passive' or 'relaxed' during the 'hypnotic induction procedure.'

2. Ss often become more and more 'excited' and 'aroused' when they are given a series of 'active' suggestions such as 'sensory hallucinations,' 'age-regression,' etc.

3. Ss often show momentary 'excitement' when they are 'hallucinating.'

4. A pinprick can 'arouse' a S to the same extent during 'hypnotic analgesia' as it can during 'normal waking.' In addition, 'hypnotic analgesic' Ss are often just as much 'aroused' by the threat of a pinprick as they are by an actual pinprick.

5. Many Ss become momentarily 'excited' when they are asked to look directly at an object (or person) which they have been told they will not be able to see. However, some Ss do not show this momentary 'excitement.'

6. Although Ss may state that they do not 'remember' the 'post'-hypnotic suggestion, they often become momentarily 'excited' when the E makes preliminary motions to give the signal for the 'post'-hypnotic act" (pp. 90-92).

Schneck, Jerome M. (1954). A hypnoanalytic investigation of psychogenic dyspnea with the use of induced auditory hallucinations and special additional hypnotic techniques. Journal of Clinical and Experimental Hypnosis, 2, 80-90.

" Summary. This paper describes in detail and with discussion the hypnoanalytic session which was instrumental in relieving a patient of severe dyspnea and fatigue based on intense, long standing psychological conflict. The conflict entailed the intermingling of past concerns and current pressing problems. These had to do with the patient's long repressed feelings about having been told that her birth had been unplanned. They related to current indecision about becoming pregnant. Attitudes toward her parents were significant and these involved mixed feelings with the significance of her conscious and unconscious images of them. Into this picture there were projected the patient's attitudes toward herself and her methods of functioning somatically as well as psychologically. The symbolic connotation of her symptoms as deterioration and dying in relation to needs for self-destruction were clarified. The symptoms of one and a half to two years duration were dissipated within a few hours and improvement had been maintained for more than a year at the time of writing.

"The use of induced music associations in order to make inroads into the core of the conflict is described. The dynamic significance of spontaneous choice of such theme [sic] is discussed. Other hypnotic techniques involve visual imagery with dream-like qualities and in the form of scene visualizations (8, 9). Attention is centered on

induced auditory hallucinations and interesting facets of such experiences are discussed in relation to subjective and objective qualities of such hallucinations and the issue of dynamic validity" (p. 90).

Schneck, Jerome M. (1954). An experimental study of hypnotically induced auditory hallucinations. Journal of Clinical and Experimental Hypnosis, 2, 163-170.

"Summary. An experimental study of hypnotically induced auditory hallucinations was incorporated into therapeutic contact with a patient at a time when an exploratory phase of treatment process seemed appropriate. The study was divided roughly into ten parts, nine of which involved attempts to induce hallucinations on an auditory level following an initial control procedure involving 'imagined' conversation. Choice of persons to be hallucinated was made at times by the therapist and at times this was left for spontaneous development by the patient. Some of the episodes involved marked emotional participation by the patient. Others were less intense. 'Imagined' conversations were distinct from hallucinated comments. Her own voice when hallucinated emanated from within herself. Other hallucinated voices had external origins. Some were far away. Her aunt's voice was in the same room. Spatial and temporal elements were divorced from their conventional relationships and distorted in keeping with psychodynamic needs. The patient was able to discuss her experiences and evaluate certain descriptive and dynamic qualities. Certain parts of the total experience served as controls in the evaluation of other parts. The beginning of hallucinatory behavior did not set a pattern for continuous similar activity. Responsive behavior varied from time to time. A hallucinatory episode might be followed by an 'imagined' conversation, although instructions remained the same. Deceased persons were hallucinated on an auditory level. This type of episode with her mother had considerable emotional impact. Her aunt died twenty years ago. Her husband was not hallucinated. Responses involving her daughter showed greater complexity.

"Further studies are in order in connection with the neuropsychological and neurophysiological elements in such hypnotic hallucinatory activity. Such elements as they play a role in visual imagery as described here and in visual hallucinations are also to be examined further. Aside from extensions of the type of investigation presented here, inroads may be made into an understanding of spontaneous hallucinatory activity among psychotic patients through the utilization of hypnotic exploratory methods. This would have to be preceded by more extensive studies of hypnosis in relation to psychotic patients than have been attempted thus far. The procedure discussed here and many potential ramifications makes possible a wide variety of investigations which can be planned for the future" (pp. 169-170).

1953

Naruse, Gosaku; Obonai, Torao (1953). Decomposition and fusion of mental images in the drowsy and post-hypnotic hallucinatory state. Journal of Clinical and Experimental Hypnosis, 1 (4), 23-41.

The following is the authors' summary.

Summary of Part I

"From the above we can conclude the following main facts.

- 1) When one sensory stimulus is given to a subject in a drowsy state, images of other objects associated with it often appear.
- 2) These images sometimes have forms, and sometimes are devoid of forms, only light and color being present. This phenomenon resembles the experience of color-hearing, and is called a new type of synaesthesia [sic] by Bachen.
- 3) These images are sure to disappear when they are observed attentively, a passive attitude being necessary for the image observation.
- 4) The remarkable character of these images are such that elements of forms and colors of various objects have been disjointed and connected with each other in different relationships which construct new images.
- 5) The longer and stronger persistence of stimulus, the more easily and clearly conditioned images appear. Conversely if the stimulus is momentary, the recalled images appear also momentarily.
- 6) Not only the visual images but also the sensory images can be elicited in a similar way" (p. 25).

#### Summary of Part II

"The chief results of Naruse's experiments with the various subjects are as follows:

1. When one stimulus (C.S.) is given in the normal waking state after a conditioning procedure in which a conditioned bond is formed between two sensory stimuli in deep hypnotic trance, a mental image corresponding to the other stimulus (U.C.S.) appears with amnesia for the conditioning situation. When the stimulus is removed, the image also disappears.
2. The images attained have various degrees of clearness which may be classified on a continuum from hallucinations to memory images.
3. Such images tend to disappear when subjects try to observe them attentively.
4. Images which are broken into elements of the original figure appear as distinct images.
5. Modifications of images may be made by distortion, vagueness of the image, and by decomposition of the image.
6. When two C.S.'s, which were already conditioned individually to two U.C.S.'s are presented at the same time, the images corresponding to each stimulus appear to overlap. This is the composed image.
7. In image composing, which involves the strong-weak stimulus relationship or the spatial positions of two C.S.'s, the clear-vague or positional relationships of the composed images are changed.
8. In the complex of meaningful images, there are two types, primarily. The one grasps the image as a whole, the other observes it in many mosaic elements. The latter can recall the original figure more correctly in an image form than the former.
9. Some positive and negative reports on sensory conditioning in the normal waking state are reviewed" (p. 36).

#### NOTES

1:

The investigators do not show that hypnosis enhances imagery, compared with the waking state. They studied sensory-sensory conditioning under hypnosis, with amnesia suggestions, followed by testing for the conditioning effect. This study is

relevant to studies of amnesia, "repression." In some studies they paired sound of a buzzer or metronome (the Conditioned Stimulus) with images (the Unconditioned Stimuli) as in [Oo, X]; other studies compared a color patch (CS) with an image (Oo, X). Some studies presented both CS's together, in different spatial arrangements (in the instance of the color patch CS).

Results (partial) included: "1. When one stimulus (CS.) Is given in the normal waking state after a conditioning procedure in which a conditioned bond is formed between two sensory stimuli in a deep hypnotic trance, a mental image corresponding to the other stimulus (UCS) appears with amnesia for the conditioning situation. When the stimulus is removed, the image also disappears. 2. The images attained have various degrees of clearness which may be classified on a continuum from hallucinations to memory images. 3. Such images tend to disappear when Ss try to observe them attentively. ... 5. Modifications of images may be made by distortion, vagueness of the image, and by decomposition of the image. 6. When two CS's, which are already conditioned individually to two UCS's, are presented at the same time, the images corresponding to each stimulus appear to overlap. ..." (P. 36).

Schneck, Jerome M. (1953). Hypnotic hallucinatory behavior. Journal of Clinical and Experimental Hypnosis, 1 (3), 4-11.

It would appear to be important to refer to experiences as hallucinatory only when the eyes of the percipient are open, in the case of visual hallucinations, or when he "hears" with the impression that the sound is of external origin rather than localized within (as an experience on the level of imagining) in the case of auditory hallucinations. In such hallucinatory occurrences, incidentally, the subject may in certain instances question the nature of his experience and evaluate it critically even though the stimulus retains its validity as an apparently externally centered event. Negative visual hallucinations involving avoidance reactions are apparently an order of experience different from negative hallucinations which do not involve such avoidance reactions. Although sensory end-organ functioning may be the same in both such occurrences, there are apparently as yet poorly understood differences in functioning on a neurophysiological and neuropsychological level wherein cortical integration is in operation.

Explicit description of hallucinatory activity in hypnosis enables the reader to know exactly what the writer is saying and thus avoids confusion in the literature. Hallucinatory experience and the more simple type of mental imagery may both be used in therapy, and comparisons may be attempted in relation to goal directed therapeutic efficacy. The issue of hallucinatory experiences and the mental imagery functioning, as described, have bearing on the study of perception where the exact nature of the events may affect considerably the plan of study, the description of events, the subjective evaluation of the events, and the final interpretation of the experimental situation. Examples of visual and auditory hypnotic hallucinations have been given and they have been discussed insofar as they relate to the current problem. The description of nocturnal dreams as hallucinations has probably fostered current confusion in terms.

## HEADACHE

**2000**

**Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)**

**This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; (3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.**

**1998**

**Eimer, Bruce; Freeman, Arthur (1998). Pain management psychotherapy: A practical guide. New York NY: John Wiley & Sons, Inc..**

**NOTES**

**1:**

**"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.**

**The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible**

to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

1994

Culbert, Timothy P.; Reany, Judson B.; Kohen, Daniel P. (1994). Cyberphysiologic strategies for children: The clinical hypnosis/biofeedback interface. International Journal of Clinical and Experimental Hypnosis, 42 (2), 97-117.

This article presents an in-depth discussion of the integrated use of self-hypnosis and biofeedback in the treatment of pediatric biobehavioral disorders. The rationale for integrating these techniques and their similarities and differences are discussed. The concepts of children's imaginative abilities, mastery, and self-regulation are examined as they pertain to these therapeutic strategies. Three case studies are presented that illustrate the integrated use of self-hypnosis and biofeedback in the treatment of children with psychophysiologic disorders. The authors speculate on the specific aspects of these self-regulation or "cyberphysiologic" techniques that appear particularly relevant to positive therapeutic outcomes.

Ter Kuile, Moniek M.; Spinhoven, Philip; Linsen, A. Corry G.; Zitman, Frans G.; et al. (1994). Autogenic training and cognitive self-hypnosis for the treatment of recurrent headaches in three different subject groups. Pain, 58 (3), 331-340.

The aims of this study were to (a) investigate the efficacy of autogenic training (AT) and cognitive self-hypnosis training (CSH) for the treatment of chronic headaches in comparison with a waiting-list control (WLC) condition, (b) investigate the influence of subject recruitment on treatment outcome and (c) explore whether the level of hypnotizability is related to therapy outcome. Three different subjects groups (group 1, patients (n = 58) who were referred by a neurological outpatient clinic; group 2, members (n = 48) of the community who responded to an advertisement in a newspaper; and group 3, students (n = 40) who responded to an advertisement in a university newspaper) were allocated at random to a therapy or WLC condition. During treatment, there was a significant reduction in the Headache Index scores of the subjects in contrast with the controls. At post-treatment and follow-up almost no significant differences were observed between the 2 treatment conditions or the 3 referral sources regarding the Headache Index, psychological distress (SCL-90) scores and medication use. Follow-up measurements indicated that therapeutic improvement was maintained. In both treatment conditions, the high-hypnotizable subjects achieved a greater reduction in headache

pain at post-treatment and follow-up than did the low-hypnotizable subjects. It is concluded that a relatively simple and highly structured relaxation technique for the treatment of chronic headache subjects may be preferable to more complex cognitive hypnotherapeutic procedures, irrespective of the source of recruitment. The level of hypnotic susceptibility seems to be a subject characteristic which is associated with a more favourable outcome in subjects treated with AT or CSH.

1992

Zitman, Frans G.; Van Dyck, Richard; Spinhoven, Philip; Linszen, A. Corrie G. (1992). Hypnosis and autogenic training in the treatment of tension headaches: A two-phase constructive design study with follow-up. Journal of Psychosomatic Research, 36, 219-228.

: Tension headaches can form a chronic (very long duration) condition. EMG biofeedback, relaxation training and analgesia by hypnotic suggestion can reduce the pain. So far, no differences have been demonstrated between the effects of various psychological treatments. In a constructively designed study, we firstly compared an abbreviated form of autogenic training to a form of hypnotherapy (future oriented hypnotic imagery) which was not presented as hypnosis and secondly we compared both treatments to the same future oriented hypnotic imagery, but this time explicitly presented as hypnosis. The three treatments were equally effective at post-treatment, but after a 6- month follow-up period, the future oriented hypnotic imagery which had been explicitly presented as hypnosis was superior to autogenic training. Contrary to common belief, it could be demonstrated that the therapists were as effective with the treatment modality they preferred as with the treatment modality they felt to be less remedial. NOTES 1:

#### NOTES

An earlier review by these authors found that EMG biofeedback and relaxation training were equally effective with headache [Zitman, 1983, Biofeedback and chronic pain, In *Advances in Pain Research and Therapy* (Edit by Bonica, Lindblom, Iggo) V. 5, pp 794-809. N. Y.: Raven Press]. Other authors also found that hypnotic suggestion, EMG biofeedback and EMG biofeedback plus progressive relaxation training were equally effective [Schlutter, Golden, Blume, 1980, A comparison of treatments for prefrontal muscle contraction headache. *Br J. Med Psychol*, 53, 47-52.]. The authors raise the question whether any treatment element or perhaps combination of elements can enhance a basic relaxation training procedure, with respect to chronic headache.

The first phase of this research compared autogenic training (AT) and future oriented hypnotic imagery (FI) which was not labeled as hypnosis. Results were the same for both groups, and were reported earlier [van Dyck, Zitman, Linszen et al. *International Journal of Clinical and Experimental Hypnosis*, 1991, 39, 6-23]. The current study added a third group which received future oriented hypnotic imagery but also was told that they were getting hypnosis (FI-H). Thus the AT and FI groups were 'historical' comparison groups for the FI-H group in this study.

Patients were described as having headache complaints of at least 6 months (76% had been suffering for >2 years), were over 18 years old, had no drug dependence

and no psychiatric disorder, and no previous therapy with autogenic training or hypnosis; no other treatment during the project; fluent in Dutch.

The autogenic training consisted of six exercises learned in a fixed order. The FI method, in which the hypnotized patient imagines himself in a future, pain-free, situation, had been described by Milton Erickson [1954, Pseudo-orientation in time as a hypnotherapeutic procedure. *JCEH*, 2, 261-283]. For that future situation the investigators used descriptions that the patients provided. Both kinds of intervention taught patients muscular and mental relaxation. Both methods required home practice of the technique, using audio cassettes.

In order to substantiate the labeling of the hypnotic procedure as hypnotic future oriented imagery (FI-H) "hand levitation induction was employed during session two with the purpose of inducing positive expectancies concerning hypnosis as a procedure capable of changing ordinary experiences in an unexpected way [17]. This hand levitation procedure, however, was not presented on tape. Except for the labeling as hypnosis and the hand levitation induction, the hypnotic future oriented imagery procedure was identical to the future oriented imagery procedure in the first phase" (p. 221).

Treatment lasted for 8 weeks and provided 2 12 hours of therapist and 24 1/2 hours of home training with taped instructions. The outcome measures included: 1. Budzinsky-type headache index (mean daily sum of intensity rating for each hour of headache activity recorded during 3 separate days of the week of an assessment session) 2. State Anxiety 3. Zung-type Self-rating Depression Scale 4. Perceived credibility of treatment (4 Question's developed by Borkovec & Nau using a visual analogue scale) 5. Neuroticism from the CPI

**RESULTS.** Of 96 patients who agreed to participate, 17 dropped out before the post-treatment assessment. Of the remaining 79, 28 completed AT treatment, 27 FI, and 24 FI-H. Sixty-six attended the follow-up assessment; there were no dropouts from the FI-H, and the drop-outs were equally divided between the AT and FI condition. The headache index scores were logarithmically transformed because the distribution was positively skewed.

Using ANOVA, in terms of post-treatment scores, there were no significant main effects for therapist or treatment, nor were there any significant interaction effects when analyzing headache index, state anxiety, and depression. There was a significant main effect for Time for three outcome measures: headache index score, state anxiety, and depression.

Post-treatment, neither amount of medication used nor subjective estimates of headaches differed by treatment or by therapist. However, over time there were beneficial results for both treatment groups. "Patients rated their headaches as significantly reduced compared to pre-treatment (a mean pain reduction of 40%). ...they had significantly reduced their use of analgesic medication (a mean decrease of 14%)" (p. 224).

Using ANOVA, in terms of follow-up scores, again there were no significant main effects for Treatment or Therapist on the outcome measures of headache index, state anxiety, or depression. There now were three time periods (pre-, post-, and follow-up), and once again there was significant main effect for Time for headache index (though not for state anxiety). That is, people benefitted over the time of the

treatment and follow-up. Moreover, there was a significant interaction effect between Therapy and Time on the headache index measure. "A posteriori contrasts revealed that the patients from the FI-H condition showed a greater reduction in their headaches between pre-treatment and follow-up than patients from the AT condition" (p. 225).

The authors write in their Discussion, "Our data indicate that at least in tension headache patients, defining a procedure explicitly as hypnotherapy may not lead to greater effects at post-treatment, but does lead to longer lasting effects" (p. 226).

"The paucity of differences between the three conditions may be a consequence of the study design: the small number of patients and the large SD may have prevented the detection of more differences in effect between the three conditions" (p. 226).

"Other critical remarks are related to the difference in headache reduction at follow-up between AT and FI-H. Firstly, the differences at follow-up were found only with respect to the headache index and not with respect to the subjective estimate of the pain. Secondly, in defining future oriented hypnotic imagery explicitly as hypnosis, we hoped to enhance the efficacy via increased credibility. We found increased efficacy, but we did not find enhanced credibility. Therefore, the differences in effect at follow-up must have another cause. The different effects at follow-up could be linked to the fact that the FI-H condition was the only one without drop-outs. This absence of drop-outs was due to a new research assistant who tried extraordinarily hard to make the patients return for follow-up. By doing so, she may have prevented the patients who gained much from the treatment from dropping out as well as those who gained little" (p. 226-227).

"In this study, despite the differences in therapists' preferences, both therapists were equally effective with all three treatments. This is an intriguing finding which goes against the belief commonly held by clinicians that therapists are more effective with the type of therapy they prefer" (p. 227).

"The effects were modest, but it must be kept in mind that most of our patients referred by a neurologist were chronic headache sufferers (76% had been suffering for > 2 yr). In such a group of patients even small effects are important, especially when these effects are long-lasting" (p. 227).

Madrid AD, Barnes SH. (1991, Oct). A hypnotic protocol for eliciting physical changes through suggestions [Abstract]. American Journal of Clinical Hypnosis, 34 (2), 122-128.

We employed brief hypnotherapy to effect physical changes in patients suffering from medical disorders including allergies, rectal bleeding, systemic lupus, hyperemesis, headache, asthma, and chronic pain. We present, in language appropriate to the individual patient, considerations and suggestions to effect the release of healing biochemicals. Ideomotor signals indicated the patient's awareness of the healing. We hypothesize that the technique triggered novel state-dependent memory, learning and behavior.

Madrid, Antonio D.; Barnes, Susan v.d.H. (1991). A hypnotic protocol for eliciting physical changes through suggestions of biochemical responses. American Journal of Clinical Hypnosis, 122-128.

We employed brief hypnotherapy to effect physical changes in patients suffering from medical disorders including allergies, rectal bleeding, systemic lupus, hyperemesis, headache, asthma, and chronic pain. We present, in language appropriate to the individual patient, considerations and suggestions to effect the release of healing biochemicals. Ideomotor signals indicated the patient's awareness of the healing. We hypothesize that the technique triggered novel state-dependent memory, learning, and behavior.

#### NOTES

They hypothesize that the technique they use triggers novel state-dependent memory, learning, and behavior (See for example Rossi, 1987, and Rossi & Cheek, 1988).

Hypnotic Protocol: "1. Tell the patient that he can heal himself by allowing his body to supply its own biochemicals needed to make him well. If a specific biochemical is known, such as cortisone or endorphins, name it. "2. Hypnotize the patient. Resistant or hard to hypnotize patients need not be deeply hypnotized because the patients, using this protocol, will automatically go into trance while accomplishing the next task of accessing and using ideomotor signals (Erickson, 1980; Rossi & Cheek, 1988). "3. Tell the patient that his index finger will automatically and involuntarily twitch and float when his body releases the biochemicals he needs. This ideomotor response (Rossi & Cheek, 1988) is the sole physical response required of the patient. Rossi hypothesizes that the ideomotor response correlates with biochemical changes (Rossi & Cheek, 1988). "4. Next, ask the patient to consider some things (as described below). Present the considerations one after another until one of them triggers the ideomotor response. "5. In some instances, ask the patient to practice on his own. Many patients who have dramatic emotional reactions during or at the completion of the task may not need to practice on their own" (p. 123).

They present several 'considerations' to the patient, one after the other, tailored to the patient's specific case, until his finger twitches or floats, indicating a biochemical response. For example, the following 'considerations' have been used: "1. Psychodynamic: 'Consider that you are not blamed for anything; that you are in fact perfect just the way you are; that you are loved by those you care about.' 'Consider that you can forgive whoever needs forgiving for hurting you.' 'Consider that there are no longer any threats; everything is better; everything is as it used to be.' "2. Autosuggestion: 'Tell your body to heal. It knows what to do; so ask it to do it.' 'Tell your adrenal glands to produce the steroids that your body needs.' 'Allow a glowing light to permeate that injured back, filling it with healing energy.' "3. Incompatible responses: 'Cover yourself with a cool breeze, cooling the injured leg.' 'Imagine your back getting slack and limp and relaxed.' 'Imagine your stomach lining becoming smooth and moving with easy, ocean-like waves.' "4. Emotion calling: 'Consider yourself feeling very happy with everything, for no reason at all.'

'Consider yourself getting angry at someone--your mother, your wife (husband), your boss, your lawyer.' "5. Bargaining: 'Tell yourself that you will heal if you agree to stay away from that job.' 'Tell yourself you will heal by allowing your right arm to begin to hurt when you are over- exerting yourself.' 'Tell yourself that you will heal in exchange for something else, not so serious, to replace this disease and to serve the same function'" (pp. 123-124).

They present seven cases involving, respectively, allergies, rectal bleeding, systemic lupus, hyperemesis of pregnancy, adult onset asthma, chronic pain, and cluster headaches. Two cases were particularly interesting because they represented patients who did not respond initially.

Their procedure involves reframing the state or emotion originally associated with the onset of disease using considerations, and then giving a suggestion that it is within the power of the person, rather than factors outside, to heal the body. First they instruct the patient that the body can heal itself; then they give the list of suggestions for the patient to consider, persisting with different considerations until they get an ideomotor response. Incorporation of the patient's psychodynamic issues appears to be very important.

The authors regard it as unimportant if the patient cannot be hypnotized; "As Cheek (Cheek & LeCron, 1968; Rossi & Cheek, 1988) points out, the patient's inability to be hypnotized may be synonymous with his disease. It is actually beneficial if the patient cannot achieve ideomotor responses at first because both he and the therapist then trust the validity of the response when it does occur after the appropriate consideration" (p. 127).

Van Dyck, Richard; Zitman, Frans G.; Linssen, A. Corry G.; Spinhoven, Philip (1991). Autogenic training and future oriented hypnotic imagery in the treatment of tension headache: Outcome and process. International Journal of Clinical and Experimental Hypnosis, 39, 6-23.

The aim of the present study was (a) to investigate the relative efficacy of autogenic training and future oriented hypnotic imagery in the treatment of tension headache and (b) to explore the extent to which therapy factors such as relaxation, imagery skills, and hypnotizability mediate therapy outcome. Patients were randomly assigned to the 2 therapy conditions and therapists. 55 patients (28 in autogenic therapy and 27 in future oriented hypnotic imagery condition) completed the 4 therapy sessions and 2 assessment sessions. Patients were to practice at home. No significant main effect or interaction effects for treatment condition or therapist was revealed. A significant effect for time in analyzing scores for headache pain, pain medication usage, depression, and state anxiety was found. In the self-hypnosis condition, pain reduction proved to be associated with depth of relaxation during home practice (as assessed with diaries) and capacity to involve in imagery (as assessed with the Dutch version of the Creative Imagination Scale). After statistically controlling for relaxation and imagery, hypnotizability scores (assessed by Stanford Hypnotic Clinical Scale) were significantly correlated with ratings of pain reduction. Results are discussed in the context of the neo- dissociation and

social-cognitive models of hypnoanalgesia. The clinical relevance and the methodological shortcomings of the present study are also critically assessed.  
NOTES 1:

#### NOTES

Unexpectedly, pain reduction occurring in AT [autogenic training] appears to be brought about by different means than in hypnotic treatment. Not only imagery skills and hypnotizability, but also level of relaxation were unrelated to pain reduction achieved during AT. Since the first two therapy sessions of AT and hypnosis were identical and in both treatment conditions patients are explicitly instructed to relax, the absence of a relationship between depth of relaxation and pain reduction in AT cannot be easily explained" (p. 19).

1988

Spinhoven, Philip (1988). Similarities and dissimilarities in hypnotic and nonhypnotic procedures for headache control: A review. American Journal of Clinical Hypnosis, 30 (3), 183-194.

Similarities and differences between hypnosis and similar psychological procedures in the treatment of headache are reviewed. A brief outline of various hypnotic and nonhypnotic interventions for headache reduction shows that none of these procedures has consistently proved to produce superior results. Possible common denominators such as control of physiological processes, placebo factors, and the alteration of cognitive factors are discussed. The positive relationship between hypnotic susceptibility and hypnotic pain reduction indicates that the value of hypnosis seems to be less a matter of therapeutic procedure per se than of which context activates a patient's hypnotic potential for pain reduction. NOTES 1: NOTES: The author summarizes literature on biofeedback and relaxation: "(a) biofeedback with home practice of relaxation is, at least in some cases, effective in reducing migraine and tension headache; (b) relaxation training alone has also produced some success in reducing migraine and tension headaches; and (c) there is not sufficient evidence that biofeedback in the treatment of these pain problems yields results superior to relaxation training" (p. 184). Hypnotherapy for headache is not reviewed in detail, but he provides a table showing various controlled studies and their results. "With the exception of the methodologically problematic study of Anderson, Basker, and Dalton (1975), no differences in effect are found between hypnosis and biofeedback (Andreychuck & Skriver, 1975; Schlutter, Golden, & Blume, 1980; Friedman & Taub, 1984) and hypnosis and relaxation (Friedman & Taub, 1984; Spinhoven, Van Dyck, Zitman, & Linnsen, 1985)" (p. 184). He notes that there are no studies that directly compare hypnosis and nonhypnotic relaxation interventions for headache.

"In all the studies in which hypnotizability was related to outcome, irrespective of patient selection method of measurement, and hypnotic procedure used, a significant positive relationship between hypnotizability and therapy results was found in more than 350 patients (Andreychuck & Skriver, 1975; Cedercreutz, Lahteenmaki, & Tulikoura, 1976; Cedercreutz, 1978; Friedman & Taub, 1984;

Spinhoven et al., 1985). If we consider the level of hypnotizability rather than the details of the hypnotic procedure, it seems that headache patients who are highly hypnotizable benefit more from hypnosis in the reduction of headache.

"However, little reliable information is available concerning the underlying dimensions of hypnotic susceptibility relevant for pain reduction. In the neodissociation theory of Hilgard it is suggested that highly hypnotizable patients register pain covertly outside conscious awareness (Hilgard, 1977, 1979). In the social learning model of Spanos and his coworkers (Spanos, Radtke-Bodorik, Ferguson, & Jones, 1979; Spanos, Kennedy, & Gwynn, 1984), it is assumed that high susceptibles show a relatively greater preference for focusing attention on internal thoughts and images as a way of attenuating pain than low susceptibles.

"A recent experimental study of Miller and Bowers (1986), which directly compared hypnotic analgesia, cognitive-behavior therapy, and cognitive-behavior therapy defined as hypnosis in high and low susceptibles, suggests that pain reduction achieved by highly hypnotizable subjects during hypnosis is not mediated by the deliberate use of cognitive strategies (such as imaginative inattention). Cognitive strategy use resulted in pain reduction only during behavior therapy. Clinical studies about the experiential aspects of high and low susceptible headache patients during hypnosis, biofeedback, relaxation training, and cognitive-behavior therapy are urgently needed. If process research in a clinical setting validates that hypnotic analgesia involves the activation of a subsystem of pain control temporarily dissociated from conscious executive control, a therapy component specific for hypnosis will have been identified" (pp. 189-190).

1987

Olness, Karen N.; Libbey, Patricia (1987). Unrecognized biologic bases of behavioral symptoms in patients referred for hypnotherapy. American Journal of Clinical Hypnosis, 30, 1-8.

Twenty patients referred for hypnotherapy had organic conditions which explained their symptoms. Each had been evaluated previously by physicians. Eleven had also been in psychotherapy; two of these had been hospitalized on child psychiatry inpatient units. Presenting symptoms included five with nocturnal enuresis, four each with headaches and recurrent abdominal pain, three with recurrent headaches, two with anxiety, and one each with sleep problems and tics. Diagnoses included hyperthyroidism, diabetes, diastometamyelia, partial oxalotranscarbamylase deficiency, sinusitis, carbon monoxide poisoning, vitamin overdose, food allergy, amebiasis, constipation, urinary tract infection, paroxysmal atrial tachycardia, and seizures. Each child had complete remission of symptoms with treatment of his/her underlying disease. Morbidity related to delayed diagnoses included parental anxiety and guilt, child anxiety, growth delays, family financial difficulties, loss of parental work time, loss of school days, and loss of confidence in child health professionals by families.

Miller, Mary E.; Bowers, Kenneth S. (1986). Hypnotic analgesia and stress inoculation in the reduction of pain. Journal of Abnormal Psychology, 95, 6-14.

Investigated the influence of hypnotic ability on 3 methods of reducing cold-pressor pain. Following a baseline immersion, 30 high- and 30 low-hypnotizable undergraduates were randomly assigned to 1 of 3 treatment groups: stress inoculation training, stress inoculation training defined as hypnosis, or hypnotic analgesia. Analysis of pain reports indicated a significant hypnotic ability x treatment interaction. Among Ss receiving hypnotic analgesia, high-hypnotizables reported significantly less intense pain than lows. There was no differential response for high- and low-hypnotizable Ss receiving stress inoculation training, whether or not it was defined as hypnotic. Moreover, Ss in the stress inoculation condition (whether or not defined as hypnosis) reported using cognitive strategies to reduce pain, whereas this was not the case for Ss in the hypnotic analgesia condition. The present findings seem inconsistent with the social psychological account of hypnosis and are discussed from a dissociation perspective, which views hypnosis as involving changes in the way information is processed.

Sargent, Joseph; Solbach, Patricia; Coyne, Lolafaye; Spohn, Herbert; Segerson, John (1986). Results of a controlled, experimental, outcome study of nondrug treatments for the control of migraine headaches. Journal of Behavioral Medicine, 9, 291-323.

Headache variables were examined for 136 subjects who participated for 36 weeks in one of four groups: No Treatment, Autogenic Phrases, EMG Biofeedback, Thermal Biofeedback. All subjects kept daily records of headache activity and medication usage and participated in 22 laboratory sessions during which frontalis EMG and hand temperature measurements were taken; those in the 3 treatment groups practiced at home. There was a substantial reduction in headache variables in all groups. The No- Treatment Group differed significantly from the treatment groups combined, with the least reduction in headache variables. The thermal biofeedback group vs EMG biofeedback and autogenic phrases groups showed a suggestive trend toward improvement in the frequency and intensity of total headache.

1984

Fogel, Barry S. (1984). The 'sympathetic ear': Case reports of a self-hypnotic approach to chronic pain. American Journal of Clinical Hypnosis, 27 (2), 103-106.

Secondary gain issues may limit the success of hypnotherapeutic approaches to chronic pain. A self-hypnotic suggestion that promotes patients' awareness of the interpersonal aspects of their pain complaints was used in the treatment of two patients with chronic headache. Hypnotic suggestions that help make secondary gains conscious may be a useful addition to hypnotic techniques of pain management.

1983

Bassman, S. (1983). The effects of indirect hypnosis, relaxation and homework on the primary and secondary psychological symptoms of women with muscle contraction headache (Dissertation). Dissertation Abstracts International, 44, 1950-B.

Compared the effects of indirect hypnosis (e.g., metaphors, stories, vague suggestions, and implied directives) on muscle contraction headaches with a relaxation and a no-treatment control condition. Both hypnosis and relaxation conditions reduced symptoms more than did the no-treatment condition. Unlike relaxation, indirect hypnosis did not reduce the intensity and duration of headaches, although it did reduce the amount of medication and also benefitted sleep.

Classen, Wilhelm; Feingold, Ernest; Netter, Petra (1983). Influence of sensory suggestibility on treatment outcome in headache patients. Neuropsychobiology, 10, 44-47.

In 45 headache patients the relationship between sensory suggestibility and three measures of treatment effect-ratings on (1) intensity of headaches; (2) efficacy of drugs, and (3) physician's competence - was investigated in a double-blind long-term crossover study. Subjects scoring high on sensory suggestibility clearly showed more relief of headaches upon the analgesic as well as upon the placebo. The physician's competence was rated higher by high-suggestible patients, whereas ratings on drug efficacy were low in all patients. The seemingly controversial behavior of high-suggestible patients was interpreted as a call for continuation of the physician's efforts in spite of the relief the patients already achieved.

1982

Howard, L.; Reardon, J. P.; Tosi, D. (1982). Modifying migraine headache through rational stage directed hypnotherapy: A cognitive-experiential perspective. International Journal of Clinical and Experimental Hypnosis, 30 (3), 257-269.

Recent techniques designed to modify migraine headache have emphasized physiological modification via hypnosis only or biofeedback. Psychological factors, however, have been identified as causal in many psychophysiological disorders such as migraine. The present case study describes the results of utilizing Rational Stage Directed Hypnotherapy (RSDH) of Tosi (1974), Tosi and Marzella (1975), and Tosi (1980a) in the treatment of an individual suffering from severe migraine headaches. RSDH, designed to attend to both physiological and psychological factors, is a cognitive-experientially based, stage directed, systematic psychotherapeutic regimen which utilizes hypnosis and hypnotic imagery to enhance the rational restructuring of negative cognitive/emotional/physiological/behavioral states.

In the present case study, RSDH demonstrated superior effects over the hypnosis only treatment and baseline in reducing migraine headaches. The client demonstrated improvement on both self-report measurement (frequency of migraine headaches) and objective test results (MPI, Hathaway & McKinley, 1951; Tennessee Self-Concept Scale, Fitts, 1979). In describing this case, particular

attention was given to analyzing cognitive distortions via hypnotic imagery in a temporal framework. Analysis and restructuring of past traumatic events which were symbolically affecting the client's current behavior were particularly significant aspects of the treatment process.

1981

Claghorn, James L.; Mathew, Roy J.; Largen, John W.; Meyer, John S. (1981). Directional effects of skin temperature self-regulation on regional cerebral blood flow in normal subjects and migraine patients. *American Journal of Psychiatry*, **138**, 1182-1187.

Vascular headache of the migraine type is associated with vasomotor changes in cerebral arteries. The authors studied whether skin temperature training (biofeedback) reduced the frequency, severity, and duration of these headaches by measuring the regional cerebral blood flow (CBF) in 11 female migraine patients (27-52 years) and 9 female volunteers (22-37 years), using the noninvasive <sup>133</sup>Xe inhalation technique. Half of each group was randomly assigned to a hand-warming or a hand-cooling group. CBF increased in several regions of the left hemisphere to a significant degree only for the migraineurs who were in the hand-warming group. The pattern of vasomotor regulation apparently differed between migraine and normal Ss. The migraineurs' headache symptoms were affected by both warming and cooling, but warming produced more salutary effects.

Cott, A.; et al. (1981). The long-term therapeutic significance of the addition of electromyographic biofeedback to relaxation training in the treatment of tension headaches. *Behavior Therapy*, **12**, 556-559.

Eight tension headache sufferers seeking traditional medical treatment from a neurologist participated in either a therapist-delivered relaxation training (RT) condition or an RT plus EMG feedback condition. Mean hours of pain/day, headache severity, and medication ingestion were significantly lower in both groups following treatment. Results were maintained at a 1-year follow-up for hours of pain/day and medication ingestion. Findings thus indicate no benefit of adding EMG feedback to relaxation training.

1980

Adams, Henry E.; Feuerstein, Michael; Fowler, Joanne L. (1980). Migraine headache: Review of parameters, etiology, and intervention. *Psychological Bulletin*, **87** (2), 217-237.

The migraine headache is a disorder of much interest to clinicians and researchers in the areas of psychology and medicine. Research that has investigated various characteristics of this disorder and the factors contributing to its etiology and a variety of treatment techniques have appeared in both the medical and the psychological literature. The present article provides a comprehensive critical appraisal of this literature, with particular emphasis on psychological intervention. Theoretical issues involving biological and psychological factors in migraine etiology are discussed, and a psychobiological model for the migraine disorder is proposed. Areas requiring further basic and clinical research are identified. Major conclusions

include (a) that etiological factors of migraine remain unclear; (b) that pharmacological intervention does not constitute an adequate treatment method in terms of headache elimination; (c) that although a number of psychological treatment approaches have been reported in the literature, there are few well-controlled evaluations, and definitive conclusions regarding differential effectiveness of the various techniques are difficult; and (d) that a biofeedback approach directed at modifying the peripheral pain mechanism in migraine appears to be a promising treatment technique for this disorder.

1979

Di Piano, Frank A.; Salzberg, H. C. (1979). Clinical applications of hypnosis to three psychosomatic disorders. Psychological Bulletin, 86, 1223-1235.

Studies of hypnosis in the treatment of skin disorders, headaches, and asthma were reviewed in terms of outcomes and methodological soundness. Some studies focused on changing physiological functions, others on increasing insight in their patients, and still others on altering patients' perceptions of their symptoms. Methodological weaknesses included lack of control groups, nonrandom assignment of patients to treatment conditions, and confounding of treatment effects or lack of control for placebo effects. Additional weaknesses centered around the use of single outcome measures and the failure to assess the specific roles of mediating variables. Most of the studies reviewed showed positive treatment effects. However, there is equivocal evidence that hypnosis can directly influence autonomic functioning. Hypnosis may be valuable in facilitating one's capacity to gain insight into how one's symptoms developed and are maintained. In addition, hypnotic procedures have resulted in some success when used to indirectly alleviate symptoms by altering how individuals perceive their disorders and how these disorders affect their lives.

Turk, Dennis C.; Meichenbaum, Donald H.; Berman, William H. (1979). Application of biofeedback for the regulation of pain: A critical review. Psychological Bulletin, 86 (6), 1322-1338.

The biofeedback literature for the regulation of pain is reviewed and found wanting on both conceptual and methodological grounds. In particular, studies on the use of biofeedback for the treatment of tension and migraine headaches and chronic pain indicate that biofeedback was not found to be superior to less expensive, less instrument-oriented treatments such as relaxation and coping skills training. The relative absence of needed control comparisons was noted, and the need for caution in promoting biofeedback was stressed. Suggestions for future research are offered.

1978

Acosta, Frank X.; Yamamoto, Joe; Wilcox, Stuart A. (1978). Application of electromyographic biofeedback to the relaxation training of schizophrenic, neurotic, and tension headache patients. Journal of Consulting and Clinical Psychology, 46 (2), 383-384.

This study examined the effects of electromyographic (EMG) biofeedback on tension reduction by schizophrenic, neurotic, and tension headache patients. Fourteen patients participated voluntarily in at least 10 weekly EMG biofeedback sessions at a public outpatient clinic. All had complained of chronic tension. Patients showed significant decreases in their muscle tension levels with successive biofeedback training sessions. No significant differences were found between the schizophrenic, neurotic, and tension headache groups. A further contribution was the finding that patients with diverse socioeconomic and educational levels benefitted similarly from EMG biofeedback training.

1977

Ansel, Edward Leslie (1977). A simple exercise to enhance response to hypnotherapy for migraine headache. International Journal of Clinical and Experimental Hypnosis, 25 (2), 68-71.

A common method of hypnotherapy for migraine headache utilizes suggestions of warmth for the hands and coldness for the head. This procedure reverses the abnormal pattern of vasodilation and excess supply of blood in the head and decreased supply in the extremities associated with this type of headache, thereby relieving the pain. A simple exercise, utilizing centrifugal force to dramatically increase blood flow to the hands, is described. It promotes relief in itself and provides a vivid background experience to enhance productivity of this effect in hypnosis. It appears to be especially useful in patients exhibiting lesser degrees of trance capacity.

Wickramasekera, Ian (1977). The placebo effect and biofeedback for headache pain. [Paper]

NOTES

1:

"The strength of the placebo response is hypothesized to be primarily a function of the following variables:

1. Credibility of the therapist.
2. The credibility of the placebo per se.
3. The credibility of the setting in which the placebo is administered.
4. The credibility of the administration ritual.
5. The level of emotional arousal of the patient.
6. The patient's level of attention to the placebo elements.
7. The baseline suggestibility of the patient" (P. 197).

"I suggest that more careful attention to the placebo and hypnosis literatures and to the isolation of the conditions which potentiate the context of treatment, the rituals of treatment, the instructions that accompany treatment, and the relationship within the therapeutic unit, will significantly increase the reliability and the power of biofeedback effects. It will do this by a more systematic arrangement of conditions for motivated patient behavior" (p. 198).

1976

Cedercrentz, C.; Lahteenmaki, R.; Tulikoura, J. (1976). Hypnotic treatment of headache and vertigo in skull injured patients. International Journal of Clinical and Experimental Hypnosis, 24, 195-201.

Symptoms of headache and vertigo were treated using direct hypnotic suggestions of symptom relief in 155 consecutive skull injured patients. Posttraumatic headache and vertigo were completely relieved after an average observation period of 1 year 10 months in 50% and 58% of the patients, and partially relieved in 20% and 16% respectively. Most of the relief was achieved after about 4 weekly sessions and, particularly with the headaches, only if treatment began within a few weeks of the injury. Therapeutic outcome was correlated with depth of hypnosis achieved for both headache ( $r = .44$ ,  $p < .0001$ ) and vertigo ( $r = .47$ ,  $p < .0001$ ) symptoms. Patients who could not even achieve light hypnosis obtained no therapeutic improvement, but patients who experienced only light hypnosis were as clinically responsive as those achieving deep hypnosis.

NOTES

Outcome of hypnosis treatment was studied in relationship to hypnotizability

1975

Anderson, J. A. D.; Basker, M. A.; Dalton, R. (1975). Migraine and hypnotherapy. International Journal of Clinical and Experimental Hypnosis, 23 (1), 48-58.

Therapeutic measures for migraine are largely ineffective. Prophylaxis by hypnosis (including autohypnosis) and prochlorperazine is difficult to assess because of the intermittency of the disease and the subjective nature of the disabling symptoms. A method of studying this problem is described in this article. Random allocation of 47 patients was made to one or other prophylactic measure. This was followed by monthly assessments and independent evaluation of 1 year of continuous care. Criteria of improvement were the number of attacks per month, number who had Grade 4 attacks, and complete remission. Results showed that the number of attacks and the number who suffered blinding attacks were significantly lower for the group receiving hypnotherapy than for the group receiving prochlorperazine. For the group on hypnotherapy, these 2 measures were significantly lower when on hypnotherapy than when on previous treatment. Prochlorperazine seemed about as effective as previous treatment. 10 out of 23 patients on hypnotherapy achieved "complete remission" during the last 3 months of the trial as opposed to only 3 out of 24 on prochlorperazine. It is concluded that further trials of hypnotherapy are justified against some other treatment not solely associated with the ingestion of tablets.

Andreychuk, Theodore; Skriver, Christian (1975). Hypnosis and biofeedback in the treatment of migraine headache. International Journal of Clinical and Experimental Hypnosis, 23 (3), 172-183.

A study was made to explore the effects of subject hypnotizability in response to 3 treatment procedures applied to 33 migraine headache sufferers. These treatment procedures included biofeedback training for hand-warming, biofeedback training for alpha enhancement and training for self-hypnosis. The Hypnotic Induction Profile (HIP) of Spiegel & Bridger (1970) was given to each S to determine degree of hypnotizability and the MMPI was administered to all Ss. All 3 treatment groups showed significant reductions in headache rates and there were no significant differences between groups. Cutting across treatment groups, high hypnotizable Ss (N - 15) showed significant reductions in headache rates when compared with low hypnotizable Ss (N - 13). There was no correlation between HIP scores and the hysteria scale of the MMPI. NOTES 1:

#### NOTES

This research investigated the relationship between hypnotizability and treatment outcome.

**Graham, George W. (1975). Hypnotic treatment for migraine headaches. International Journal of Clinical and Experimental Hypnosis, 23, 165-171.**

2 patients with a long clinical history of migraine headaches were treated with hypnosis coupled with the hand-warming technique of Sargent, Green, and Walters (1973). Both patients were followed up (1 for 12 months and 1 for 9), and the treatment was extremely effective in reducing the intensity, frequency, and duration of their migraine headaches.

1972

**Cedercrentz, C. (1972). The big mistakes: A note. International Journal of Clinical and Experimental Hypnosis, 20, 15-16.**

In his book, *A System of Medical Hypnosis*, Ainslie Meares writes, "Most books on hypnosis, from Bernheim to the present time, devote a great deal of space to the description of successful and dramatic cures. These accounts may be of prestige value to the author, and may do something to inform the profession of the potential value of hypnosis in medicine, but these success stories are really of little help to those who would learn the technique of hypnotherapy because the emphasis is always on the success of the treatment rather than on analysis of the psychodynamic mechanisms which brought it about. As in everything else, we learn most from a study of our failures [p. 3]." These comments remain as true today as they were ten years ago. With the notable exception of Meares, few colleagues have been willing to share their errors, allowing us to profit from their experience. Thus, when Dr. Cedercreutz sent along a note describing his experience with one of his patients, I was struck by his generosity, and it seemed most appropriate for all of us to share his experience by way of the Journal. Hopefully, this may encourage other colleagues to share their failures as well as their successes so that all of us may learn to be more effective therapists and better scientists. M.T.O. [Martin Orne] NOTES 1:

The case reported involves a patient who had migraine headache removed with hypnosis, but later developed gastrointestinal symptoms that were operated surgically with absence of positive (physical) pathology noted. Subsequent investigation of the psychological component of the problem with hypnosis revealed an early trauma (seeing a soldier killed with a bayonette) that led to migraine-like pain in the head and vomiting.

Meares, Ainslie (1972). Group relaxing hypnosis. Journal of the American Society of Psychosomatic Dentistry and Medicine, 19, 137-141.

#### NOTES

1:

The paper is reprinted from *Med. J. Aust.*, 1971, 2, 675-676 with permission of Editor. The author discusses theoretical concepts, techniques and patient selection for this method. "I avoid all logical communication, as this would only keep the patient alert, and so prevent the atavistic regression which is the essential factor in hypnosis" (p. 139). He moves from patient to patient, saying little except "Good--easy--natural" etc. and he uses touch to reinforce their development of hypnotic state. To ratify the trance and make sure they are hypnotized, not just relaxed, he places a clip on forearm skin for a few moments. "This potentially painful stimulus has the effect of further deepening hypnosis" (p. 139). After about 35-40 minutes he alerts the group. Patients are taught self hypnosis to extend the results into daily life.

#### NOTES

1:

This article mentions only three papers dealing with hypnotherapy used with migraine headache and none used with tension headache or headaches of other etiologies. The papers are:

Hanley, F. W. (1964). Hypnotherapy of migraine, *Canad. Psychiat. Ass. J.*, 9, 254 (June).

Krogen, W. S. [Kroger?] (1963). Hypnotherapeutic management of headache, *Headache*, 3, 50.

Blumenthal, L. S. (1963). Hypnotherapy of headache, *Headache*, 2, 197.

1953

Erickson, Milton H. (1953). The therapy of a psychosomatic headache. Journal of Clinical and Experimental Hypnosis, 1 (4), 2-6.

The author presents a case in which the patient complained of headaches to illustrate a theoretical position, described as follows in the Introduction: "For example, many psychotherapists regard as almost axiomatic that therapy is contingent upon making the unconscious conscious. When thought is given to the unmeasurable role that the unconscious plays in the total experiential life of a

person from infancy on, whether awake or asleep, there can be little expectation of doing more than making some small parts of it conscious. Furthermore, the unconscious as such, not as transformed into the conscious, constitutes an essential part of psychological functioning. Hence, it seems more reasonable to assume that a legitimate goal in therapy lies in promoting an integrated functioning, both singly and together, and in complementary and supplementary relationships, as occurs daily in well-adjusted living in contrast to the inadequate, disordered and contradictory manifestations in neurotic behavior" (p. 2).

Horan, John S. (1953). Hypnosis and recorded suggestions in the treatment of migraine: Case report. Journal of Clinical and Experimental Hypnosis, 1 (4), 7-10. (Abstracted in Psychological Abstracts 54: 6399)

## NOTES

1:

Author's Discussion: "The case above is presented because of its rather bizarre features. It is notable in that in the hypnotic sessions no attempt was made to explore the dynamics of the patient's resentment or her illness, no insight was given into psychic mechanisms connected with the migraine. This had been done before, in conventional psychiatric interviewing, without much result. Under hypnosis, the only suggestions given were concerned with direct symptomatic relief of headache, insomnia and anorexia. For the patient's purposes, these were sufficient. Just how the pathological physiological state causing the migraine attacks was altered by direct and recorded suggestion is a mystery to this writer. It may be that hypnotic states can cause a dissociation of the subject from the emotional stress related to the attacks. Or perhaps the strangeness and the mystery of hypnosis was sufficient. It would be absurd to make any claims about the efficacy of hypnosis in migraine patients in general on the basis of this one case. In a disease which causes as much disability and suffering as migraine, however, it is profitable to report any safe means that gives a satisfactory result" (pp. 9-10).

## HEADACHE

Haddock CK. Rowan AB. Andrasik F. Wilson PG. Talcott GW. Stein RJ. Home-based behavioral treatments for chronic benign headache: a meta-analysis of controlled trials. *Cephalalgia* 1997;17(2):113-8 Controlled clinical trials have consistently demonstrated that behavioral treatments for chronic benign headache produce clinically beneficial outcomes both post-treatment and at follow-up. Given these results there is interest in cost-reduction and redesign of these treatments to improve their accessibility. One promising approach in this regard is home-based headache treatment. These treatments seek to provide the same amount of treatment as clinic-based treatments; however, some of the material typically presented to the patient by a clinician is presented through home-study materials (e.g., manuals, audiotapes). To date, the published literature contains 20 controlled clinical trials which have examined the outcomes produced by home-based treatments. This article presents the first comprehensive meta-analysis of these clinical outcome studies. Results of the quantitative analyses suggest that home-based treatments produce comparable, or with certain outcome measures, superior results to clinic-based treatments. Moreover, costeffectiveness scores of home-based

treatments were found to be more than five times larger than those of clinic-based therapies. Methodological analyses are also presented along with suggestions for future research.

Johnson PR. Thorn BE. Cognitive behavioral treatment of chronic headache: group versus individual treatment format. *Headache* 1989;29(6):358-65 Two hypotheses were tested in this study: (1) that a short course of cognitive behavioral therapy (CBT) is effective in the treatment of chronic headache; and (2) that group CT is as effective as individually administered CBT. Twenty-two chronic headache sufferers were randomly assigned to one of three treatment conditions: group administered CBT, individually administered CBT, or no treatment (wait list) control. Wait list subjects ultimately received treatment identical to that offered to subjects in the group treatment condition. Treatment outcome measures included the Brief Symptom Inventory, the McGill Pain Questionnaire, and several measures calculated from self-monitoring data. Tentative support was found for the hypothesis that CBT as provided in this study is effective in the treatment of chronic headache. There was no evidence that group versus individually treated subjects differed significantly on any of the measures used, although the small N and large variance among subjects limit us to preliminary conclusions for our findings. Clinical implications and suggestions for future research are discussed.

Llaneza-Ramos ML. Hypnotherapy in the treatment of chronic headaches. *Philippine Journal of Psychology* 1989;22:17-25. 35 chronic headache patients were assessed on frequency, duration, intensity, amount of medication, and number of difficulties associated with headaches. 25 Subjects were randomly assigned to 2 psychotherapists who administered Ericksonian hypnotherapy; 10 Subjects became the comparison group. Prior to treatment, all 25 Subjects were nonsignificantly different on their baseline measures. Posttreatment measures showed all Subjects with complete relief from headaches. Two months later, 20 Subjects experienced complete recovery while 5 had a single attack of headache. For the 2 experimental groups, there were no significant differences in symptomatic manifestations before and after treatment. At the delayed posttreatment period, post hoc test analysis evidenced a shared pattern of significant differences between each of the 2 treatment groups and the comparison group.

Melis PM. Roomans W. Spierings EL. Hoogduin CA. Treatment of chronic tension-type headache with hypnotherapy: a single-blind time controlled study. *Headache* 1991;31(10):686-9 We investigated the effectiveness of a special hypnotherapy technique in the treatment of chronic tension-type headache. A waitinglist control group was used to control for the changes in headache activity due to the passage of time. The results showed significant reductions in the number of headache days (p less than 0.05), the number of headache hours (p less than 0.05) and headache intensity (p less than 0.05). The improvement was confirmed by the subjective evaluation data gathered with the use of a questionnaire and by a significant reduction in anxiety scores (p less than 0.01).

Passchier J. Hunfeld JA. Jelacic M. Verhage F. Suggestibility and headache reports in schoolchildren: a problem in epidemiology. *Headache* 1993;33(2):73-5 In a sample from the general population of school children of 15 years of age, we studied whether receiving information about the prevalence of headaches had any effect on

their subsequent headache report. Sixty children in the fourth year at four secondary schools were allocated at random to two conditions: a biased condition emphasizing the high prevalence of headaches and a neutral condition. Subjects in the biased condition reported more headaches but they did not report more other physical symptoms than the subjects in the neutral condition. The results are discussed.

Reich BA. Non-invasive treatment of vascular and muscle contraction headache: a comparative longitudinal clinical study. *Headache* 1989;29(1):34-41 The purpose of this investigation was to evaluate the long-term course of non-invasively treated chronic headache. A total of 1015 adult patients with primary diagnosis of vascular/migraine or muscle contraction headache participated in the study investigating symptom frequency and severity over a 36 month period after receiving treatment. Treatment consisted of either: relaxation training (stepwise relaxation/hypnosis/autogenic training/cognitive behavior therapy); biofeedback (thermal/photoplethysmograph/EMG); micro-electrical therapy (TENS/Neurotransmitter Modulation) or multimodal treatment (combination of any of the above two treatments). Seven hundred and ninety-three patients returned sufficient data to be included in the analysis. Patients were randomly assigned to treatment groups and received either short term intervention (15 or less treatments) or long term intervention (greater than 15 treatments). Results indicate that all treatment conditions significantly reduced frequency and intensity of cephalalgia. Repeated measure analysis of variance indicated that grouping variables of Biofeedback treatment, symptoms being evidenced less than 2 years and receiving over 15 treatment sessions best predicted successful intervention.

Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40.

This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; (3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

1999

McConkey, Kevin M.; Wende, Vanessa; Barnier, Amanda J. (1999). Measuring change in the subjective experience of hypnosis. International Journal of Clinical and Experimental Hypnosis, 47 (1), 23-39.

The authors indexed the subjective experience of hypnosis through the use of a continuous behavioral measure of the strength of the participant's experience at the time of the suggestion. Specifically, subjects turned a dial to indicate changes in their experience of the suggested effect during that experience. Thirty-three high, 47 medium, and 28 low hypnotizable subjects were asked to use the dial during the suggestion, test, and cancellation phases of three hypnotic items: arm levitation, arm rigidity, and anosmia. The pattern of ratings differed according to the nature of the suggestion. Also, across the items, subjects who passed according to behavioral criteria experienced the suggested effect to a greater degree than those who failed. Notably, whereas the ratings of highs and mediums did not differ for any item, they differed from lows on all three items. The authors discuss the implications of these findings in terms of the potential for this method to provide insight into the experience of hypnosis.

## NOTES

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-be patient/client that he or she has something to offer that can help take away pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

1995

Green, J. P.; Lynn, Steven J. (1995, August). Dissociation, hypnotic amnesia and automatic writing: Is there an association?. [Paper] Presented at the annual meeting of the American Psychological Association, New York.

This study examined whether differences in self-reported dissociative experiences (DES, Bernstein & Putnam, 1986) and past performance on hypnotic amnesia (HGSHS: A, Shor & Orne, 1962) influence the frequency of passing an automatic

writing suggestion. Participants (N = 112) were divided into high hypnotizable ('real') and simulating groups. Results from a log linear analysis indicated that automatic writing was independent of both dissociation status and past performance on an ostensibly dissociative hypnotic suggestion (i.e., amnesia). Simulators were more than six times as likely to pass the automatic writing suggestion than reals. Findings were discussed in light of other research regarding the relation between the DES and hypnotizability. (ABSTRACT from Bulletin of Division 30, Psychological Hypnosis, Fall, 1995, Vol. 4, No. 3.)

1994

Lynn, Steven Jay (1994, October). Toward an integrative theory of hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Francisco.

#### NOTES

This is a re-evaluation of neodissociation and cognitive models of hypnosis, and an attempt to be integrative. This paper focuses more on ideomotor behaviors but we will extend the model to other hypnotic behaviors in the future.

Automaticity of behavior in hypnosis can be accounted for without using a concept of divided consciousness or weakened consciousness. Parapraxes (doing one behavior while intending another) are not instances of decreased control of behavior, but relate to where attention is drawn. This requires a different use of the hierarchy concept from Hilgard's model (which in turn comes from Hull's concept of habit hierarchy).

Here hierarchy is a concept drawn from Miller, Galanter, & Pribram: acts are comprised of molecular units, that are comprised of even more molecular units. Behavior only needs to be processed at an executive level when unusual events occur. But one or more hierarchies may be set into motion at the same time. Dissociation is not an infrequent event. Behavior is controlled by subroutines rather than by an executive control structure; subroutines operate in parallel rather than in a hierarchy. Parapraxes are due to an overlap between two subfunctions.

Parapraxes are different from ideomotor responses, where we pay close attention and involuntariness is reported not just post facto but as part of the experience.

1992

Somerville, Wayne R.; Jupp, James J. (1992). Experimental evaluation of a brief 'ideodynamic' hypnotherapy applied to phobias. Contemporary Hypnosis, 9, 85-96.

This study used a test-retest design to investigate the effectiveness of a brief 'ideodynamic' hypnotherapy which notionally located and reformulated memories in the treatment of simple phobia disorder. Subjects were 19 phobics randomly assigned to treatment (n = 10) and waiting control groups (n = 9). Rapid, significant, and sustained relief from phobic fear and avoidance was reported by 50% of treatment subjects. A number of symptoms and therapy process variables were correlated with treatment outcome. These included a negative association with hypnotizability and a positive association with hypnotic depth estimates. The

ramifications of these and other associations are discussed and it is concluded that the 'ideodynamic approach' investigated may have contributed a therapeutic effect beyond the operation of treatment non-specific factors. NOTES 1:

## NOTES

Treatment consisted of: 1. Hypnotic induction. 2. Establishment of ideomotor signals described to clients as a means of communicating with the 'inner unconscious mind'. 3. Beyond the first therapy session, a review of work done in previous sessions. 4. Gaining signaled permission from clients to work on their problem and for the 'inner mind' to review relevant memories. 5. Location of the 'earliest critical event' by the 'inner mind'. 6. Review of the located memory by the 'inner mind'. 7. Establishing age at the occurrence of the 'critical' event. 8. Ideomotor signaling indicating suitability of a visual imagoic processing of the event.

If visual processing was chosen, the dissociated viewing procedure (step 9A) was used next, otherwise the ego-state procedure (step 9B) was employed.

The authors describe each treatment step in detail. Each subject received at least two sessions of therapy, or a maximum of three sessions if signaling indicated the presence of further unresolved memories after two sessions.

They present a case illustrating that the approach is possible with minimally hypnotizable subjects, in the apparent absence of imagoic experience, 'desensitization', catharsis, unpleasant affect, talking through or 'insight'.

"There was a positive correlation between changes in phobic fear and capacity for mental imagery which suggests that this may be one relevant variable in predicting response to memory reformulating therapy.

"There was a negative correlation between changes in fear and hypnotic responsiveness. So, successful therapeutic outcome was obviously not limited to highly hypnotizable subjects. Hypnotizability was assessed in a careful and standardized manner but testing was conducted 10 weeks following therapy. This meant that subjects had a substantial experience in hypnotherapy at assessment. Furthermore, at the time of assessment subjects were aware of the outcome of therapy and of the kinds of memories located during therapy. It has been suggested that an association between level of hypnotizedness achieved during treatment and outcome rather than an association between degree of hypnotizability possible during therapy and outcome, taps an hypnotic effect (Spiegel & Spiegel, 1978).

"All therapy sessions were of equal duration and, as the inductions were standardized, all subjects had an approximately equal opportunity to engage in memory reformulation. However, there were individual differences in the number of memories located and a strong significant association was found between reduced fear and the number of these critical memories that were dealt with. This result suggests that the therapeutic effect may have derived either from factors specific to the therapy cycle or from differing levels of motivation among subjects to undertake the necessary 'work'.

"Maximum discomfort experienced during session two of treatment was negatively correlated with relief from phobic fears. This relationship may again reflect the influence of unresolved problematic memories on subjects who had not achieved

relief by that time. It is clearly consistent with relief not being associated with painful abreaction.

"The therapy permitted a pervading privacy through the options of non-imaginative processing of recalled material (which was used by a substantial minority of subjects) and conscious withholding of the content of memories from the therapist (which was employed to a large extent by all subjects). Their reports indicated that this 'privacy' was seen as attractive by both successfully and unsuccessfully treated subjects. Taken with other results mentioned above these process findings suggest that the treatment studied stood up quite well against other brief but highly stressful exposure treatments for phobia currently in use (e.g. Ost, 1989).

"Further research needs to address the complex question as to what are the necessary and sufficient features of this procedure in producing therapeutic change. Unsolicited comments by subjects about their experience during treatment suggested that some of them were surprised by the 'involuntary' nature of their ideomotor signaling while others said that signaling was under their voluntary control. Some expressed surprise at the nature of the memories that came to them 'suddenly' during therapy. Some memories were of traumatic childhood experiences that were unexpected and considered to have 'nothing to do with my phobia'" (pp 93-94).

**1991**

**Madrid, Antonio D.; Barnes, Susan v.d.H. (1991). A hypnotic protocol for eliciting physical changes through suggestions of biochemical responses. American Journal of Clinical Hypnosis, 122-128.**

We employed brief hypnotherapy to effect physical changes in patients suffering from medical disorders including allergies, rectal bleeding, systemic lupus, hyperemesis, headache, asthma, and chronic pain. We present, in language appropriate to the individual patient, considerations and suggestions to effect the release of healing biochemicals. Ideomotor signals indicated the patient's awareness of the healing. We hypothesize that the technique triggered novel state-dependent memory, learning, and behavior. NOTES 1: NOTES: They hypothesize that the technique they use triggers novel state-dependent memory, learning, and behavior (See for example Rossi, 1987, and Rossi & Cheek, 1988).

Hypnotic Protocol: "1. Tell the patient that he can heal himself by allowing his body to supply its own biochemicals needed to make him well. If a specific biochemical is known, such as cortisone or endorphins, name it. "2. Hypnotize the patient. Resistant or hard to hypnotize patients need not be deeply hypnotized because the patients, using this protocol, will automatically go into trance while accomplishing the next task of accessing and using ideomotor signals (Erickson, 1980; Rossi & Cheek, 1988). "3. Tell the patient that his index finger will automatically and involuntarily twitch and float when his body releases the biochemicals he needs. This ideomotor response (Rossi & Cheek, 1988) is the sole physical response required of the patient. Rossi hypothesizes that the ideomotor response correlates

with biochemical changes (Rossi & Cheek, 1988). "4. Next, ask the patient to consider some things (as described below). Present the considerations one after another until one of them triggers the ideomotor response. "5. In some instances, ask the patient to practice on his own. Many patients who have dramatic emotional reactions during or at the completion of the task may not need to practice on their own" (p. 123).

They present several 'considerations' to the patient, one after the other, tailored to the patient's specific case, until his finger twitches or floats, indicating a biochemical response. For example, the following 'considerations' have been used: "1. Psychodynamic: 'Consider that you are not blamed for anything; that you are in fact perfect just the way you are; that you are loved by those you care about.' 'Consider that you can forgive whoever needs forgiving for hurting you.' 'Consider that there are no longer any threats; everything is better; everything is as it used to be.' "2. Autosuggestion: 'Tell your body to heal. It knows what to do; so ask it to do it.' 'Tell your adrenal glands to produce the steroids that your body needs.' 'Allow a glowing light to permeate that injured back, filling it with healing energy.' "3. Incompatible responses: 'Cover yourself with a cool breeze, cooling the injured leg.' 'Imagine your back getting slack and limp and relaxed.' 'Imagine your stomach lining becoming smooth and moving with easy, ocean-like waves.' "4. Emotion calling: 'Consider yourself feeling very happy with everything, for no reason at all.' 'Consider yourself getting angry at someone--your mother, your wife (husband), your boss, your lawyer.' "5. Bargaining: 'Tell yourself that you will heal if you agree to stay away from that job.' 'Tell yourself you will heal by allowing your right arm to begin to hurt when you are over- exerting yourself.' 'Tell yourself that you will heal in exchange for something else, not so serious, to replace this disease and to serve the same function'" (pp. 123-124).

They present seven cases involving, respectively, allergies, rectal bleeding, systemic lupus, hyperemesis of pregnancy, adult onset asthma, chronic pain, and cluster headaches. Two cases were particularly interesting because they represented patients who did not respond initially.

Their procedure involves reframing the state or emotion originally associated with the onset of disease using considerations, and then giving a suggestion that it is within the power of the person, rather than factors outside, to heal the body. First they instruct the patient that the body can heal itself; then they give the list of suggestions for the patient to consider, persisting with different considerations until they get an ideomotor response. Incorporation of the patient's psychodynamic issues appears to be very important.

The authors regard it as unimportant if the patient cannot be hypnotized; "As Cheek (Cheek & LeCron, 1968; Rossi & Cheek, 1988) points out, the patient's inability to be hypnotized may be synonymous with his disease. It is actually beneficial if the patient cannot achieve ideomotor responses at first because both he and the therapist then trust the validity of the response when it does occur after the appropriate consideration" (p. 127).

Meyer, H. K.; Diehl, B. J.; Ulrich, P. T.; Meinig, G. (1989). Changes in regional cortical blood flow in hypnosis. Zeitschrift für Psychosomatische Medizin und Psychoanalyse, 35, 48-58.

#### NOTES

Regional cerebral blood flow (rCBF) was measured by means of the 133-Xenon inhalation method in 12 healthy male volunteers who had several months of experience in doing self-hypnosis (autogenic training). During hypnotically suggested right arm levitation, as compared to resting conditions, they found an increase in cortical blood flow and an activation of temporal areas; the latter finding was considered to reflect acoustical attention. In addition, a so-far-unexplained deactivation of inferior temporal areas was observed during successful self hypnosis and hypnosis. While there was a global absolute increase of cortical blood flow bilaterally, they could not observe a relative increase of the right as compared to the left hemisphere during hypnosis. Several subjects successfully performed the levitation of the right arm, despite a relative left hemispheric activation, provided the absolute right hemispheric activation remained dominant.

Jupp, James J.; Collins, John K. (1985). Hypnotic responsiveness and depth in a clinical population. Australian Journal of Clinical and Experimental Hypnosis, 13 (1), 37-47.

Two samples of clinical subjects estimated depth during procedures which allowed their estimates to be related to aspects of responsivity. In Sample 1, subjects estimated depth after they scored their responsivities and tested their post-hypnotic recall. In Sample 2 subjects estimated depth before they had completed these tasks. Results suggested that subjects use the range of available information in making depth estimates and that they may be more influenced by the more obvious ideomotor challenge performances than by the cognitive distortion responses, aspects of amnesia, or impressions of involuntariness.

Crabtree, Adam (1984, October/1986). Explanations of dissociation in the first half of the twentieth century. In Quen, Jacques M. (Ed.), Split minds/split brains (pp. 85-108). New York: New York University Press. (Based on symposium in Bear Mt., N.Y., by Section on the History of Psychiatry of Cornell University Medical Center)

#### NOTES

In 1907 Morton Prince, Editor of Journal of Abnormal Psychology, introduced a symposium by listing 6 meanings of subconscious: 1. that portion of our field of consciousness which is outside the focus of attention 2. (Janet's idea) - split off ideas which may be isolated sensations like the lost tactile sensation of anesthesia, or maybe aggregated into groups or systems. The author quotes Janet as stating that "they form a consciousness coexisting with the primary consciousness and thereby a doubling of consciousness results" (p. 87). The primary consciousness is usually dominant, but sometimes is reduced under exceptional conditions (e.g. automatic writing). 3. the subconscious \_self\_ or hidden self -- a part of every human, not just

seen in psychopathology; this is a personalized entity; every mind has a double, with the unconscious self having powerful effects on feelings, thoughts, and reactions of the conscious self 4. extends #3 to include not only ideas that remain active below surface but also those which are inactive -- forgotten or out of mind 5. Frederic Myers' concept of the 'subliminal self' which had 3 functions:

a) inferior - seen in processes of dissociation

b) superior - seen in works of genius, arising from 'subliminal rush' of information, feelings, and thoughts which lie below consciousness

c) mythopoeic - the unconscious tendency to create fantasies 6. physiological meaning, e.g. William Carpenter's 'unconscious cerebration' in which unconscious phenomena are interpreted in terms of pure neural processes unaccompanied by mental activity.

Prince suggested some redefinitions to clarify unconscious and subconscious. He would replace Janet's subconscious with co-conscious and reserve unconscious for physiological processes that lack the attributes of consciousness. Prince noted that co-conscious ideas have been called unconscious (e.g. by Freud) but said that is confusing and to be avoided.

"Coconscious ideas include states we are not aware of because they are not the focus of our attention, and also pathologically split-off and independently active ideas or systems of ideas, such as occur in hysteria and reach their most striking form in co-conscious personalities and automatic writing.

"Prince prefers the term coconscious to Janet's subconscious for two reasons. First, because it expresses the simultaneous coactivity of a second consciousness. And second, because the coactive ideas or idea systems may not be outside the awareness of the personal consciousness at all. They may be recognized by the personal consciousness as a distinct consciousness existing alongside it.

"Thus, through his redefinition of terms, Prince makes simultaneous activity of two or more systems of consciousness in one individual the key element in dissociation. He thereby moves the issue of amnesia or lack of awareness by one system of another into the background, making it a secondary, nonessential element. Prince was one of the few to provide a theoretical framework for dissociation in which any combination of interawareness among the coconscious systems was possible" (p. 91). Two researchers at the turn of the century came to opposite conclusions about the nature of the Subconscious Self that every human has. Morris Sidis saw it as "a brutelike consciousness with a tendency toward personalization. Frederic Myers held that it included those functions and much more, being the source of all that is human, including the highest intuitive powers" p. 96.

Bernard Hart, in 1910, did an analysis of Janet and Freud. Janet's work is essentially descriptive: "he is always talking about a consciousness which manifests itself in a way we can \_perceive\_, whether by listening to it talk, reading its written communications, or watching its movements" (p. 97). However Janet's spatial model of dissociation cannot explain the presence of the same material (e.g. memories) in two or more dissociated systems. According to Hart, Freud offered the conceptualization that Janet lacked, in his idea of the Unconscious .

Freud's Unconscious is not in competition with Janet's subconscious. "Janet's subconscious is the arena of dissociated phenomena which manifest in observable

form as elements coactive with the personal self. Freud's unconscious is a conceptual, nonobservable construction put forward to explain certain facts of human experience. In this way Hart equates the unconscious with the atomic theory in physics or the theory of heredity in biology" p. 99. But Hart also thought Freud's theory did not do justice to dissociative phenomena. Not only do psychoanalysts show little interest in double personality or multiple personality, they also neglected dissociation on the phenomenal level.

In 1915 Freud denied the existence of a second consciousness and wrote, "there is no choice for us but to assert that mental processes are in themselves unconscious, and to liken the perception of them by means of consciousness to the perception of the external world by means of the sense organs" (p. 101). Janet claimed that Freud had simply taken over his own system and given it a new terminology, and in 1924 Freud wrote an angry rebuttal. For him, "dissociated systems are simply separate groups of mental but unconscious elements. As our consciousness turns now to one group, now to another, as a searchlight shines now on one object and now on another, the dissociated groups manifest in conscious life. ... There exists no doubling of consciousness" p. 102.

Jung's ideas were closer to those of Janet, and like Janet he made dissociation a key concept in his theory. The complex is unconscious, has an archetypal core clothed in personal experience, is like a self-contained psyche within the big psyche, sometimes called a fragmentary personality dwelling inside us. Dissociation for him meant being cut off from the Ego, which is the center of an individual's field of consciousness. "Dissociated or autonomous complexes are those which have no direct association with the ego" (p. 103). If complexes are charged with enough energy they will become manifest--as a neurotic symptom, as projected into idea of a god or demon, or perhaps as an alternate personality. Therefore Jungian treatment aims at assimilating dissociated complexes into the ego.

## NOTES

Dissociative disorders might be at times very difficult to diagnose and treat, especially since they are very similar to epilepsy in general and to temporal lobe epilepsy in particular. Amnesia, fugue, changing personality and depersonalization are part of both disorders. Patients who suffer from dissociative disorders might be diagnosed and treated for epilepsy with anticonvulsive medications without any beneficial results. These patients are labeled as epileptics and have to face the social stigmata associated with being epileptic. The wrong label could even reinforce the sick role and make it become fixed and chronic.

Hypnosis was used to diagnose the dissociative disorder by using the hand levitation technique for the differential diagnosis. It was found by the author that patients who suffer from dissociative disorders would get into spontaneous hypnotic trance

during the hand levitation. Hypnosis was used also for successful therapy of these patients.

Seven cases are presented in which the hand levitation technique was used to diagnose the dissociative disorder. They were also treated by hypnotherapy. Their treatment by hypnosis is discussed. The purpose of this paper is to introduce the hand levitation technique for the differential diagnosis of dissociative disorder and to emphasize the effectiveness of hypnotherapy in the treatment of this disorder. Sorting out the cases of dissociative disorders from the epileptics is very important clinically, since it can save many patients from the anguish of having to take anti-convulsants unnecessarily and having to face the social stigmata of being labeled as epileptic.

**(Author's Summary) "Unrecognized subconscious fears can be uncovered while using ideomotor questioning with a Chevreul pendulum or with finger signals. The technique described by LeCron for evaluating knowledge regarding the sex of an unborn child is a most helpful way of approaching subconscious fears. The frightened patient refuses to indicate knowledge of the sex of her unborn child. Uncovered fears can be resolved by appealing to conscious-level understanding with adroit questioning" (p. 258).**

## **ILLUSION**

**1995**

**Dywan, Jane (1995). The illusion of familiarity: An alternative to the report-criterion account of hypnotic recall. International Journal of Clinical and Experimental Hypnosis, 43 (2), 194-211.**

**Hypnosis increases the likelihood that participants will report incorrect material at higher levels of confidence. One interpretation of such data is that hypnosis induces individuals to lower the criterion they use to make memory reports. A lowered report criterion could account for the increase in items that participants are willing to report as memories but not for the increase in confidence that typically**

accompanies hypnotic retrieval. Although some participants may indeed lower their report criterion, this alone should not result in the highly confident confabulation so often observed. An alternative perspective is that for some participants, hypnosis alters the experience of retrieval such that items generated during retrieval attempts are more likely to have the qualities (e.g., perceptual fluency, vividness) usually associated with remembering. This illusion of familiarity would account for the higher levels of confidence that are so frequently observed in hypnotic recall, and adopting this perspective should lead to even greater caution in the use of hypnosis as an aid to retrieval.

1994

Lynn, Steven Jay; Pezzo, Mark (1994, August). Close encounters with aliens? Simulated accounts following a hypnotic interview. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

#### NOTES

1:

A survey of 5900 adults regarding unusual experiences concluded that 1 of 50 Americans may have had UFO experiences.

This study resembles that of Lawson (1977), in which Ss were asked to imagine UFO experiences; their descriptions were difficult to distinguish from real reports. One problem with Lawson's research is that he provided the Ss with information (e.g. to imagine they were abducted by aliens).

Our study differs from Lawson's in that we didn't actually hypnotize subjects. Our Ss' task was to 'simulate hypnosis, in recovered memory research.' We manipulated cues provided to the Ss.

Ss were told their purpose was to role play an excellent hypnotic subject. Standard simulation instructions were given. Then they were told that hypnosis frequently is used to recover experiences that the Ss cannot remember.

Ss were given a description of a Scene: driving on a road in the country, no traffic, etc. They were told that they couldn't remember 2 hours of what happened. Then a second Experimenter used a pseudo hypnotic induction, and told them they were going to recall material regarding events that had happened.

Ss completed an Omni Magazine questionnaire developed by Hopkins, who is an advocate of UFO sightings. They received the questionnaire either after the experiment, before the experiment, or with specific cues.

4 of 21 (19%) of the minimal cue condition Ss identified lights in the sky as a UFO; at the end, 52% saw a UFO. Thus, even with minimal information, subjects report interactive behavior. Almost all medium cue Ss reported the UFO. 17% felt a loss of control, being floated or transported to the spaceship. Only one S said the aliens were cruel. Only one of the role players picked up the word "trondant," a word used by Hopkins to pick up simulators who are hypnotized.

Our findings present a conservative picture. When Ss thought they would be thrown out of the experiment if detected as simulators, they avoided talking about bizarre events. 15% who were told to role play a close encounter failed to do so!

Our findings do not imply that persons who report contacts are simulating; but the basis for such reports are widely available to college students.

Newman, Leonard S.; Baumeister, Roy F. (1994, August). Who would wish for the trauma? Explaining UFO abductions. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

## NOTES

1:

UFO abduction reports are more frequent than ever before. 1979 200 1984 500 1988 5000 letters [to a magazine?] 1993 55,000 letters, with 200/wk still being sent Hopkins, Jacobs, & Westrum (1992) took a poll: 3.7 million abductees in U.S. were estimated.

These, I maintain, are motivated in attempt to accept the self; the phenomenon relates to masochism on a psychological level. I think we need a more psychological explanation than other arguments being presented. The other arguments being made are: 1. People are actually being abducted. 2. Abductees are publicity seeking liars. 3. These people cannot distinguish between fantasy and reality (but there is no evidence for that).

The two key questions we should attempt to answer are: 1. Why would people claim to remember things that did not actually happen to them? Most of these reports emerge under hypnosis. They may be creating memories rather than retrieving memories. 2. Why would people claim to remember this in particular?

Maybe abductees are people with knowledge about reports of UFO experiences, with therapists who believe in paranormal experiences? Probably this is not the explanation.

In the '50's there were reports of space aliens who abducted people, taught them about peace, love, etc. and the need for intergalactic harmony. But stories today are very different.

They want to escape the self because the self is "me." They may have done something that makes them feel stupid, unlovable; or it is just because of constantly having to maintain a positive self image. This kind of anxiety pertains to people who have an over-inflated presentation of the self. If you can avoid thinking about the implications of your behavior (e.g. through drinking, vigorous exercise, or masochism) you don't have the anxiety.

Masochism is a bizarre way to obtain pleasure, but it underlines both of these things. It cancels out meaningful aspects of the self (thought, self reflection); and needs of control are denied (bondage); it negates esteem and dignity. People higher paid, in more responsible jobs, are more likely to engage in masochistic activity.

The main features of masochism also apply to abduction stories: 1. Pain 2. Loss of control 3. Humiliation 4. Demographics (abductees seem to come from higher socio-economic classes) 5. International pattern - mostly an American & British phenomenon 6. Concern with "selfhood" 7. Sexual differences. (There are male and female masochists, but the contents are different: females more often talked about humiliation involving display than men did. Abduction cases are the same: alien examination episode (display) are in 50% of male stories but 80% of female stories.)

1993

Atkinson, Richard P. (1993, October). Shifts in Muller-Lyer Illusion difference thresholds: Are high hypnotizables more sensitive than lows in hypnosis?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

#### NOTES

1:

Refers to Wallace (1979) finding that hypnotizability correlates with afterimage persistence. Atkinson showed highs perform better than lows in perceptual tasks in hypnosis only. Also studies indicate highs are more susceptible to illusions. Our study showed difference in threshold and point of subjective equality for highs and lows.

32 undergraduates had Harvard and Group Stanford Form C, were 9-12 or 0-3 on both scales. Counterbalanced conditions of waking and hypnosis. Used computer monitor to compare length of lines. Waking condition Ss had to close eyes for 15 minutes before the trials, same length of time as for hypnosis condition.

Significant interaction between hypnotizability and sessions was observed: highs had significantly decreased difference thresholds in hypnosis compared to waking, and significantly decreased difference thresholds compared to lows in hypnosis. Thus they had greater sensitivity than lows.

The point of subjective equality ANOVA did not yield significant effects.

Highs show higher sensitivity to illusion in hypnosis than in waking, and more than the lows.

1992

Atkinson, Richard P.; Crawford, Helen J. (1992). Individual differences in afterimage persistence: Relationships to hypnotic susceptibility and visuospatial skills. American Journal of Psychology, 105 (4), 527-539.

To investigate the moderating role of individual differences in hypnotic susceptibility and visuospatial skills on afterimage persistence, we presented a codable (cross) flash of light to 40 men and 46 women who had been dark adapted for 20 minutes. In an unrelated classroom setting, subjects had previously been given two standardized scales of hypnotic susceptibility (Harvard Group Scale of Hypnotic Susceptibility, Shor & Orne, 1962; Group Stanford Hypnotic Susceptibility Scale, Form C, Crawford & Allen, 1982) and the Mental Rotations Test (Vandenberg & Kuse, 1978). The first afterimage interval and the afterimage duration correlated significantly with hypnotic responsiveness, supporting Wallace (1979), but did not show the anticipated relationships with mental rotation visuospatial skills. Individuals in the high hypnotizable group had (a) significantly longer afterimage intervals between its first appearance and first disappearance than did those in low groups, but those in medium groups did not differ significantly from the other groups. Discriminant analysis using the afterimage persistence measures classified correctly 65.2% of high hypnotizables, 37.5% of medium hypnotizables, and 54.8% of low hypnotizables. Hypothesized cognitive skills that assist in the maintenance of afterimages and underlie hypnotic susceptibility include abilities to maintain focused attention and resist distractions over time and to

maintain vivid visual images.

#### NOTES: DISCUSSION

"Because there is no apparent evidence for physiological differences of the visual system between low and high hypnotizables (e.g., Wallace, 1979), cognitive factors are suggested as possible moderators of afterimage persistence.

"Hypnotic susceptibility per se is not the moderator of afterimage duration. Rather, we argue that hypnotic susceptibility represents a constellation of underlying cognitive skills (e.g., for reviews, see Crawford, 1989; Kihlstrom, 1985) that assist an individual to respond to hypnotic suggestions as well as assist in the persistence of afterimages by interacting with more primary causal mechanisms that are physiological in origin. These cognitive skills are thought to include the abilities to focus attention selectively upon both external stimuli and internally generated images, to maintain vivid visual images, to sustain attention over time and remain absorbed in the experience at hand, and to resist distractions. The relationships between these cognitive skills and hypnotic susceptibility are reported in a large body of literature (e.g., Crawford, 1982, 1989; Crawford et al., 1991; Crawford & Grumbles, 1988; Finke & Macdonald, 1978; Grumbles & Crawford, 1981; Mitchell, 1970; Tellegen & Atkinson, 1974)....

"Sustained and selective attention without interference from extraneous stimuli plays an important role in hypnosis. Individuals who are responsive to hypnosis demonstrate greater skills in extremely focused and sustained attention (e.g., Crawford et al., 1991; Tellegen & Atkinson, 1974). Electrophysiological research had found that high hypnotizables often generate substantially more theta electroencephalogram (EEG) power than do low hypnotizables (e.g., Crawford 1990, 1991; Crawford & Gruzelier, 1992; Sabourin, Cutcomb, Crawford, & Pribam, 1990). Such a relationship may be interpreted as further evidence of greater attentional skills in highs, because certain theta waves have been correlated with enhanced problem solving and attentional task performance (e.g., Crawford & Gruzelier, 1992; Schacter, 1977)....

"Hypnosis is seen often as a condition of amplified attention, where attention can be either more focused or diffuse dependent upon set (e.g., Krippner & Binder, 1974). Increases in vigilant performance during hypnosis have been reported, albeit inconsistently (e.g., Barabasz, 1980; Fehr & Stern, 1967; Kissen, Reifler, & Thaler, 1964; Smyth & Lowy, 1983). Fehr and Stern's results suggest that hypnotized subjects devote more attention to a primary task with less available attentional resources for a secondary task. Hypnosis has been found to have an enhancing effect on the imaginal processing of information-to-be-remembered that consists of literal or untransformed representations of pictorial or nonverbal information for high but not low hypnotizables (Crawford & Allen, 1983; Crawford, Nomura, & Slater, 1983; Crawford, Wallace, Nomura, & Slater, 1986). This may possibly be the result of increased attention and/or shifts in cognitive strategies. Supportive of the hypothesis that sustained attention can be enhanced during hypnosis, Atkinson (1991) recently found that high but not low hypnotizables report significantly more persistent afterimages in hypnosis than in waking.

"Although we have argued for a cognitive explanation for individual differences in afterimage persistence and their possible relationship to hypnotic susceptibility and sustained attentional abilities, as has Wallace (1979, 1990), we must point out the possibility that high hypnotizables may be more suggestible to imagery instructions or more willing to discuss or experience imagery than low hypnotizables, particularly in the context of hypnosis and hypnotic susceptibility testing (e.g., Zamansky, Scharf, & Brightbill, 1964). A contextual account of the longstanding relationship between hypnotic susceptibility and absorption was raised by Council, Kirsch, and Hafner (1986), but was not supported by two independent, and more methodologically sound, studies reported by Nadon, Hoyt, Register, and Kihlstrom (1991). The context of hypnosis was not an issue in the present study, because none of the subjects was aware of the investigated relationship between afterimage persistence and hypnotic susceptibility at the time of recruitment or participation" (pp. 533-535).

Perry, Campbell (1992, October). J. Phillip Sutcliff's contributions to the field of hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

1:

Sutcliff did research that led him to conclude that the high hypnotizable was deluded rather than truly perceiving things, and he said the high is simply strongly emotionally invested in the suggested belief.

Wallace, Benjamin; Kokoszka, Andrzej (1992). Experience of peripheral temperature change during hypnotic analgesia. International Journal of Clinical and Experimental Hypnosis, 40, 180-193.

Many Subjects who experience hypnotic analgesia in a portion of their body often report that it is accompanied by sensations of coldness in the affected area. Experiments were conducted to determine if such reports are the result of a physical change in peripheral temperature or are due to psychological factors. When analgesia was induced in a limb or in the back of the neck, a concomitant physical change in temperature was not observed. Subjects did report experiencing coldness, however, in the affected body part. Such experiences were attributed to associations that Subjects developed between numbness or analgesia and a drop in peripheral temperature. As a result, coldness as an associate of hypnotic analgesia is suggested as a manipulation check for the presence of such sensation reduction. NOTES 1:

#### NOTES

When a limb feels numb, there also appears to be degradation of proprioceptive abilities (Wallace & Garrett, 1973, 1975; Wallace & Hoyenga, 1980). When Ss are asked to touch their nose with finger, either subjects miss the nose or they take longer to do the task. This kind of proprioceptive decrement has also been reported by Spanos, Gorassini, and Petrusic (1981) and Welch (1978, p. 27).

This study used highly hypnotizable Ss (10-12 on Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) and low hypnotizables (0-2) in Experiment 1 which established temperature variability in an arm and sites for measuring temperature during hypnotic analgesia.

In Experiment 2, 40 subjects (20 highs and 20 lows by above standards, with group assignment confirmed by Stanford Hypnotic Susceptibility Scale, Form C, on which highs  $M = 10.4$ , lows  $M = 1.2$ ) were given relaxation imagery (e.g. to imagine a white, fluffy cloud gently moving across a deep, blue sky during a count of 20, while at the same time, listening only to the voice of E describing the scene to them.

The analgesia suggestion was that "their right arm had been injected with massive doses of Novocain, that Novocain had been injected in their shoulder, in their elbow, in their forearm, in their hand, and in their fingers ... their arm would become progressively more and more numb as E counted backward from 20 to 1" (p. 185; for more details see Wallace & Hoyenga, 1981). They were asked to perform the nose touch test as confirmation of the analgesia suggestion response.

Highs and lows who served as control subjects had the same treatment except instead of analgesia instructions they were told their arm would become progressively more and more relaxed as E counted backwards from 20 to 1.

The peripheral skin temperature was monitored during the procedures, and following the experimental manipulation Ss completed a questionnaire on their experience of numbness, heaviness, changes in limb temperature (very warm to very cold), and changes in mobility.

Analyses of variance were used to analyze the results. Although there were no objective skin temperature changes, there was a significant interaction effect for pointing error. Highs who received analgesia suggestions were off 4.35 cm; the other 3 groups had mean error of .45 cm or less. There was also an interaction effect for latency of response: highs with analgesia instructions took 3.05 seconds longer than in relaxation condition, while other three groups only took .27 sec longer, on average. Additionally, there was a correlation between receiving analgesia instructions and feeling limb heaviness for the high hypnotizables ( $r = .68$ ) but not for lows or for any Ss asked to relax their arm during the procedures.

The sensation of coldness was reported by the majority of highs receiving analgesia suggestions (7 of 10), but 2 Ss scoring 12 on the SHSS:C did not report coldness. Cold sensation was not reported by any S in any of the three other groups. The correlations between cold sensation and heaviness ( $r = .65$ ,  $p < .05$ ) and cold sensation and immobility ( $r = .79$ ,  $p < .05$ ) were found only in the High hypnotizable, analgesia suggestion group.

The authors performed a third experiment to determine whether temperature change could be used to confirm analgesia. This would be useful when one cannot confirm with inability to move the body part, e.g. when the analgesia is being developed in a part of the body that usually doesn't move. The design for Experiment 3 was the same as for Experiment 2.

Analgesia rated on a 7-point scale was reported as 6.1 by high hypnotizables and 1.2 by low hypnotizables. "Reports of a temperature change during the induction were also related to hypnotic analgesia and being classified as high in hypnotizability. Such a relationship was only significant, however, for a feeling of coldness ( $r = .63$ ,  $p$

<.05), and 7 of the 10 high hypnotizable Subjects assigned to the analgesia group reported the aforementioned sensation. A significant experiencing of a temperature change (cold or warm) was not reported by the other three groups of Subjects" (p. 189).

In their Discussion, the authors suggest that expectancy might account for the results, since during post-experiment interviews many Ss said that they expected their arm would become cold when it was numb. That was based on their previous experience, e.g. in placing ice on the skin. Notable, people did not exhibit this association if they were not able to develop the analgesia in response to suggestion.

The authors also take note of the fact that none of the Subjects reported associating cold with pain, though cold and pain often are concurrently experienced. This might be because only extreme cold is painful, and coolness might actually be perceived as pleasant.

### 1991

von Kirchenheim, Clement; Persinger, Michael A. (1991). Time distortion: A comparison of hypnotic induction and progressive relaxation procedures. International Journal of Clinical and Experimental Hypnosis, 39 (2), 63-66.

Hypnotic experiences are frequently associated with alteration in temporal perception. 24 male and 24 female Ss were asked to estimate the interval associated with hypnotic, relaxation, or control procedures. Only the group that received the hypnotic condition displayed significant distortions in time estimations. These were primarily underestimations (temporal constriction or "time loss") compared to the more normal distributions of estimations for the other 2 groups of Ss. The hypnotic treatment explained about 35% of the variance in the absolute distortion of time estimates. The present study demonstrates that subjective distortions of time experience during a hypnotic procedure are more than an artifact of deep relaxation or instruction.

### 1990

Wallace, Benjamin (1990). Imagery vividness, hypnotic susceptibility, and the perception of fragmented stimuli. Journal of Personality and Social Psychology, 58, 354-359.

Two experiments were conducted to determine the role of hypnotic susceptibility level (high or low) and imaging ability (vivid or poor) in the performance of gestalt closure tasks. In Experiment 1, subjects were required to identify fragmented stimuli in the Closure Speed Test and in the Street Test. In Experiment 2, subjects reported on fragmented stimuli that were projected to the right eye and subsequently produced an afterimage. Individuals were asked to identify the composite if possible and to report on the duration of the afterimage. In both experiments, hypnotic susceptibility level and imaging ability affected reports of gestalt closure. The greatest number of correct closures was reported by those who were both high in hypnotic susceptibility and vivid in imaging ability. In addition, in the second experiment, this group also reported the longest enduring afterimage.

These results are discussed in terms of the processes required to perform in a gestalt closure task.

1989

Heap, Michael (1989). Antecedent imagery in a case of Gilles de la Tourette syndrome. British Journal of Experimental and Clinical Hypnosis, 6 (1), 55-56

NOTES

1:

Author presents a male teenager diagnosed with Gilles de la Tourette syndrome, who was treated without noticeable success using a variety of techniques (relaxation, suggestion, hypnoanalysis, video-feedback, paradoxical injunction).

Kunzendorf, Robert G. (1989-90). Posthypnotic amnesia: Dissociation of self-concept or self-consciousness?. Imagination, Cognition and Personality, 9, 321-334.

Two studies of posthypnotic amnesia tested predictions derived from the 'source' monitoring theory of self-consciousness. Experiment 1 tested the prediction that posthypnotic source amnesia is irreversible, because hypnosis attenuates self-consciousness of whether one's sensations have an imaginal source or a perceptual source. In this initial study, recall amnesia was reversed by posthypnotic cueing with a prearranged signal, but source amnesia was not reversed by such cueing. Experiment 2 examined whether the cued reversal of recall amnesia is attributable, in part, to the hypnotic attenuation of self-conscious 'source monitoring' and, in part, to the reversal of recall criteria: from a criterion rejecting 'seemingly imaginary' or 'sourceless' memories, to a criterion accepting 'sourceless but familiar' memories. In this latter study, posthypnotic recall amnesia was breached when subjects were instructed to trust their seemingly imaginary memories, but not when they were instructed to try harder to remember [emphasis removed from quoted text].

1988

Jones, Lynette A. (1988). Motor illusions: What do they reveal about proprioception. Psychological Bulletin, 103 (1), 72-86.

Five illusions involving distortions in the perception of limb position, movement, and weight are described in the context of their contribution to understanding the sensory processes involved in proprioception. In particular, these illusions demonstrate that the position sense representation of the body and the awareness of limb movement results from the cross-calibration of visual and proprioceptive signals. Studies of the vibration illusion and phantom-limb phenomenon indicate that the perception of limb movement and position are encoded independently and can be dissociated. Postural aftereffects and the illusions of movement induced by vibration highlight the remarkable lability of this sense of limb position, which is a necessary feature for congruence between the spatial senses. Finally, I discuss the role of corollary discharges in the central processing of afferent information with respect to the size-weight and vibration illusions.

Wallace, Benjamin (1988). Hypnotic susceptibility, visual distraction, and reports of Necker cube apparent reversals. Journal of General Psychology, 115, 389-396.

Subjects, either susceptible (n = 50) or resistant (n = 50) to hypnotic suggestion, were asked to report on frequency of apparent reversals (ARs) to the Necker cube illusion. Such reports were made in the presence or absence of various types of visual, geometric surrounds (squares, triangles, crosses, or parallelograms). In agreement with a number of previous experiments, susceptible subjects reported perceiving more ARs than did resistant subjects. This difference held whether visual surrounds were present or absent. The presence of surrounds did serve to reduce AR reports regardless of hypnotic susceptibility level. The results are examined in terms of the ability of subjects to selectively attend when confronted with potential visual distractors.

1986

Wallace, Benjamin (1986). Latency and frequency reports to the Necker cube illusion: Effects of hypnotic susceptibility and mental arithmetic. Journal of General Psychology, 113 (2), 187-194.

An experiment (N = 32) was conducted to assess latency of first apparent reversal (AR) and AR frequency while observing the Necker cube illusion. Subjects who were either high in hypnotic susceptibility (susceptibles) or low in hypnotic susceptibility (resistant subjects) observed the cube either while performing or not performing mental addition problems. Susceptibles reported perceiving the first AR more quickly and a greater frequency of ARs than did resistant subjects. Also, latency of the first AR was negatively correlated with AR frequency. These results were interpreted in terms of the ability of susceptibles to allocate concentrative or selective attention in a manner that was conducive to faster performance when faced with competing tasks.

1983

Nash, John (1983). Negative visual hallucination and concomitant changes in cortical event-related potentials (Dissertation, University of California, Santa Barbara). Dissertation Abstracts International, 45 (2), 716-B. (Order No. DA 8411224)

"The purpose of this investigation was to examine the effects of negative visual hallucination (NVH) on cortical event-related potentials (ERPs), and to compare these effects with those of selectively attending to and ignoring stimuli. Five highly hypnotically susceptible subjects, four female and one male, were trained to block from subjective experience, i.e., negatively hallucinate, a ring of strobe-illuminated circles surrounding a central, independently strobe-illuminated circle. This stimulus array was modeled after part of the Titchener-Ebbinghaus circle illusion, since previous research had shown that subjects could attenuate the effects of the optical illusion via NVH of the outer, illusion-producing circles." Analysis of the ERP data

revealed amplitude and latency changes in various ERP components across the three experimental conditions (Attend, Ignore, NVH) for the four female subjects, a negative result which is explained in motivational terms. "The most noteworthy finding was the selection of the P3 amplitude variable at C2 by stepwise discriminant analysis for the four females, and the fact that this amplitude systematically decreased across conditions from largest in Attend to smallest in NVH. A variety of individual patterns were observed in terms of other ERP components which allowed discrimination (successful classification) among the three conditions. The results suggest that both Ignoring and NVH of a stimulus result in a decrease in the subjective certainty of perception of the stimulus. Individual differences in patterns of ERP changes are interpreted in terms of differing strategies for execution of the experimental instructions. The results support the view that NVH instructions produce distinctive ERP effects and that NVH generally can be viewed as an extreme level of ignoring" (p. 716).

1981

Blum, Gerald S.; Nash, John; Jansen, Robert D.; Barbour, John S. (1981, June). Posthypnotic attenuation of a visual illusion as reflected in perceptual reports and cortical event-related potentials. Academic Psychology Bulletin, 3, 251-271.

Highly selected and trained hypnotic subjects, capable of ablating portions of visual stimuli from conscious awareness, showed varying degrees of ability to attenuate the Titchener-Ebbinghaus circles illusion post-hypnotically under a negative visual hallucination instruction. The presence or absence of such inhibitory skill, inferred from perceptual reports, was differentially reflected in changes in cortical event-related potentials not typically associated with shifts in selective attention. These findings point to the cognitive operation of a distinctive mechanism of selective inattention.

#### NOTES

Blum et al. postulate an inhibitory mechanism of the central nervous system with stages of amplification and attenuation. They suggest that individual differences in inhibitory skill may be improved with practice even for very skilled Subjects. They studied this type of inhibition using a visual illusion (the Titchener-Ebbinghaus circles) because the neural locus of such illusions is thought to be more central in the nervous system rather than at the level of the retina.

Experiment 1. Three Ss trained in using hypnosis viewed stimuli in waking and posthypnotic negative visual hallucination (NVH) conditions. All three had previously passed a negative hallucination item (not seeing a playing card of three such cards placed on a table). Training included practice sessions applying NVH to the experimental stimuli. S1 reported immediate success; S2 experienced some initial difficulty ("I have a feeling something's there") but then reported success; S3 required a couple of long practice sessions.

The classic Titchener-Ebbinghaus illusion stimuli were used. Stimuli were ten slides with drawings of a standard 17-mm-diameter black circle on the left and a comparison black circle on the right. The black circle on the right was either 14, 15,

16, 17, or 18 mm in diameter, skewed intentionally around 17, to compensate for the proportion of smaller and larger judgments applied to the comparison figure in relation to the standard. One black comparison figure was surrounded by seven 15-mm diameter white circles; the other by seven 10 mm diameter white circles. The key drawings were both black circles of 17 mm. The second set of five drawings, used as a control, contained the same black circles but lacked outer rings of white circles.

The Subject was to state whether the black circle on the right appeared larger, smaller, or the same as the standard black circle on the left. Slides were shown for 4 seconds each, with 6 seconds in between slides.

Alternating blocks of trials were given under baseline (B) condition and a posthypnotically programmed negative hallucination condition (NVH). In the NVH condition, "the rings of white circles surrounding the standard and comparison black inner circles were 'ablated' from consciousness. The observers were amnesic in the waking state for their prior hypnotic instructions and were cued in advance of a block of trials simply by the phrases 'This will be a mixed series' (referring to B, in which the stimuli appeared as they really were, some with outer rings of white circles present and others not), or 'This will be a black only series' (referring to NVH, in which all stimuli appeared to the observer as black circles only, whether the outer rings were physically present or not)" (pp. 254- 255). Sessions were spread out over 8-12 months for each observer, interspersed with a variety of other experiments.

In one session the Experimenters used a selective attention instruction, with Ss given posthypnotic suggestions to regulate their cognitive arousal to a peak of mental alertness and concentration (+AA) and focus on the inner black circles but not to negatively hallucinate the outer white circles.

Although all three Ss showed the illusion effect, they varied in ability to attenuate the illusion when negative visual hallucination suggestions were given. "S1 showed a very greatly reduced frequency of reports in the illusory direction under the NVH condition, a less marked reduction under +AA concentration, and no reduction at all under a waking instruction to ignore the outer circles; S2 revealed a moderate but significant reduction under NVH but not under +AA; S3 gave no evidence of attenuation in either condition" (p. 258). The response times for the two more successful Ss (1 and 2) with the 17 mm stimuli under NVH conditions were not different when the outer circles were either present or absent.

Experiment 2. The next year S1 and S2 returned but S3 was no longer available as a Subject; S4 and S5 were added and trained in hypnosis skills. EEG evoked response potentials (ERPs) were recorded while Ss made size judgments as in Experiment 1. Averaged ERPs for each block of 100 stimulus presentations were obtained for the first 500 milliseconds following stimulus onset. Judges blind to the experimental conditions evaluated the ERP records.

All Subjects experienced the Titchener-Ebbinghaus illusion, but again there were individual differences in ability to attenuate the illusion: S1 was the most successful; S2 gave significantly fewer responses in the larger category under NVH than B conditions; and both S1 and S2 improved attenuation performance over the

previous year. S4 fell between S1 and S2 in ability; S5 was unable to attenuate the illusion in the NVH condition.

**Results.** "All three observers whose perceptual reports indicated some attenuation of the visual illusion during the NVH condition also showed a consistent reduction of the P2-N2 amplitude during NVH" (p. 262) at the Occipital sites. Median amplitude reduction was 36%, 40%, and 36% for S1, S2, and S4; only 7% for S5. There were no similar reductions for the other electrode sites, though "enhancement of P2-N2 amplitudes occurred in the lateral prefrontal and frontal areas in the two most successful individuals, S1 and S4" (p. 263). There was also a lag in N2 peak latencies for the three best subjects. The Experimenters noted that the N2 peak occurred 50 msec later in the frontal and prefrontal areas than in the occipital area.

In their Discussion, the authors express the view that it is not likely that faking could have occurred, for several reasons: 1. The Subjects were trained to report honestly, and they often had reported failures to experience hypnotic phenomena suggested during training sessions. 2. The task elicited rapid responses, usually in less than 2 seconds, to 10 different slides in randomized blocks of 100 trials, which would make self monitoring of responses extremely difficult. 3. Subjects exhibited a consistency of responses over experimental sessions that were widely separated in time, making conscious or unconscious deception unlikely. 4. The finding of no difference in latency between 17 mm stimuli with and without outer rings of white circles supports an interpretation of reliable reporting. 5. Differences in ERP data between the B and NVH conditions were obtained only for those Ss who successfully attenuated the illusion.

The authors also state, "In terms of our conceptual model of the mind, inhibitory skill is attributable to the capacity for invoking inhibitory action earlier in the sequence as signals are processed through stages of amplification and attenuation en route to consciousness (Blum & Barbour, 1979). In the NVH condition of the present task, first- stage attenuation ... [Subject 1] ... occurs in time to negate the illusion as well as preventing conscious awareness of the outer white circles, second-stage attenuation takes place too late to disrupt the illusion but still in time to keep the outer circles from consciousness" (p. 265). Note that the unsuccessful Subject 5 had the highest score on the screening hypnotizability tests. The variation among very high hypnotizables casts doubt on the practice of grouping Ss who score between 9 and 12 on the SHSS. "It is perhaps not surprising that many previous hypnotic studies involving alterations in such subtle phenomena as visual illusions have yielded negative results." p. 266.

**N.B.** None of the Ss was able to eliminate the illusion under a strong waking instruction to ignore the outer circles while judging the inner black ones. "These different results for AA and NVH instructions pinpoint the contrast between selective attention (+AA) and selective inattention (NVH)" (p. 266).

The ERP changes seen in occipital and frontal areas were in opposite directions. Thus "the data suggest an effect which seems to parallel both investment of attention (increases in late components over frontal cortex) and withdrawal of attention (relative decreases in late components over occipital cortex). This parallel leads us to speculate that our occipital decreases may have been due to active inhibition of information-processing in the occipital regions, and that the late

component enhancement over frontal areas may have been due to the mobilization of resources in these areas necessary to accomplish the tonic inhibition of visual input. ... Activity in the frontal cortex apparently 'programs' inhibition on the specific sensory nuclei of the thalamus, in a modality specific and topographical way, accomplishing gating of sensory information to primary sensory cortex" (p. 268).

Ryan, M. L.; Sheehan, Peter W. (1977). Reality testing in hypnosis - subjective versus objective effects. International Journal of Clinical and Experimental Hypnosis, 25, 27-51.

90 unselected Ss were assigned to a 2 x 3 (Request for Honesty x Suggestibility Instruction) factorial design to test the hypothesis that hypnotic Ss would show pronounced impairment of reality testing by expressing a degree of conviction substantially out of phase with their objective performance. Barber's operational model of hypnosis was adopted to test the prediction on an unusually distinctive auditory comprehension task. The 2 interdependent measures, confidence and accuracy, were highly positively related indicating that, generally speaking, hypnotic Ss performed adaptively, as did task motivated and control Ss. Results for the difficult aspects of the task were most distinctive. Here, degree of confidence about behavior as expressed by Ss who performed well on the suggestibility tests was relatively greater than the confidence expressed by those who performed poorly; further, hypnotic Ss were distinctively willing to respond on the least intelligible parts of the task. The inconsistent nature of certain features of hypnotic behavior was discussed in some detail.

Schneck, Jerome M. (1977). Sleep paralysis and microsomatognosia with special reference to hypnotherapy. International Journal of Clinical and Experimental Hypnosis, 25, 72-77.

Sleep paralysis is described in connection with a patient whose episodes incorporated the experience of her entire body feeling extremely small. The psychological implications of the paralysis and her microsomatognosia are discussed. Comparisons are made with other perceptual distortions involving the sense of change in body size. The characteristics of sleep paralysis and associated personality patterns are delineated. This material is discussed with special reference to experiences of patients in hypnosis, especially hypnotherapy and hypnoanalysis.

1970

Sarbin, Theodore R.; Juhasz, Joseph B. (1970). Toward a theory of imagination. Journal of Personality, 38 (1), 52-76.

NOTES

1:

Imagination refers to (1) forming mental pictures (imaging) and creative innovating. The authors focus on "the more literal meaning of imagining, that is, 'having mental

pictures,' for [they] believe that a clarification of that concept is basic to any further discussion of the psychology of the imagination.

"Before continuing, let us establish some reference cases for what a psychologist would call instances of imaging or imagining.

1. In a psychophysical experiment, a subject declares that he hears an auditory signal when no signal is presented. The experimenter scores the response as a 'false alarm.'
2. A patient in a mental hospital reports seeing the Mother of God. The psychiatrist classifies the report as a hallucination.
3. A novelist describes his work habits as involving conversations with imaginary characters. The critic calls this creative work.
4. A three-year-old child engages in play with a fictitious invisible rabbit. She is said to have an imaginary playmate" (p. 54).

1969

Graham, Kenneth (1969). Brightness contrast by hypnotic hallucination. International Journal of Clinical and Experimental Hypnosis, 17, 62-73.

Tested the veridicality of a hypnotic hallucination elicited by a buzzer through a conditioning procedure. The stimulus to be hallucinated consisted of 2 gray circles, 3 in. in diameter, mounted on a white card. 11 highly susceptible Ss were able to produce this hallucination upon hearing the buzzer during a series of test trials following the training. Following a 2nd training series, a black and white background was provided for the hallucination and Ss tended to report the hallucinated circles as a brightness contrast. A 2nd group of highly susceptible Ss was not hypnotized, but was asked to respond as if hypnotized. These Ss tended not to report the contrast. 1965

Jackson, Bill (1965). The autoblink: A technique to explore nonveridical visual perception. International Journal of Clinical and Experimental Hypnosis, 13 (4), 250-260.

The Autoblink technique was developed to allow objective, quantitative investigation of perceptual abnormalities found in psychiatric and normal populations under various experimental conditions. A pilot study demonstrated that spontaneous visual percepts could be elicited by this technique in a group of psychiatric patients and that wide individual differences were present. A 2nd study found significant differences in Autoblink rate between normal and hallucinating psychotic male Ss and also suggested that sensory deprivation and prestige suggestion are variables related to Autoblink rate. A 3rd study further explored differences between psychiatric patients and normal Ss as well as examining sex differences. The latter 2 studies are reported in detail. 1964

Furneau, W. D. (1964). The heat-illusion test and the structure of suggestibility. International Journal of Clinical and Experimental Hypnosis, 12 (3), 169-180.

2 similar forms of the heat-illusion test are shown to correlate to a smaller degree than would be expected if they measure the same attribute. The 2 versions also differ in the way in which they correlate with other suggestibility tests. It is shown that linear regression techniques are not appropriate for analyzing the data concerned. The interaction of various nonlinear relationships with a difference in "difficulty," as between the 2 forms of the illusion, seems to provide an adequate explanation for the results. It is suggested that these nonlinear relationships may indicate the existence of an attribute which prevents some Ss from responding to any suggestibility test, irrespective of what the specific mechanisms of response may be. 1961

Skemp, Richard R. (1961). Note on an hypnotic induction device. International Journal of Clinical and Experimental Hypnosis, 9 (4), 303-304.

Author describes a technique for increasing suggestibility by causing the person to experience effects that he believes are caused by the hypnotist. "If one fixates the edge of a coloured strip on a white background, a narrow line of deeper colour will be seen close to the edge. This is because small movements of the fixation point bring this strip, for part of the time, on to an area of the retina which has been fatigued by the white. (The effect is best obtained if the colour is unsaturated). At the same time a narrow strip of brighter white will appear along the other side of the edge. If fixation is continued, this band of brighter white gradually takes on the colour complementary to that of the coloured band. These effects are unexpected to a naive subject, and therefore satisfy the requirements for a feed-back process" (p. 303). Thus, if the color is red, then the hypnotist suggests that a green line will appear, that the green band will continue to become greener, the red part redder; then suggests that the eyes will blink faster and faster, eventually closing, etc. After the eyes are closed, the suggestion that one will continue to see the green line is given.

## IMAGERY

Gibbons, Don E.; Sanchez, George P. (undated). Hyperempiria, a new 'altered state of consciousness'. [Unpublished manuscript]

## NOTES

The authors suggest that any induction procedure legitimizes acceptance of primary-type suggestions that are at variance with everyday experience. Such primary (i.e. "waking") suggestions are actually accepted at a higher rate than most people think (Barber & Calverley, 1962), and passing those suggestions convinces the subject he must be "hypnotized." However, inductions with the word "sleep" tend to retard subject's response to suggestions. An induction that is more oriented to alert states would be very useful for many people and situations. "Hyperempiria"

in Greek means hyper-experience or enhanced quality of experience. The hyperempiric induction contains suggestions of increased alertness, mind expansion, enhanced awareness, and enhanced sensitivity.

**Comey, Gail; Kirsch, Irving (1995, November). Intentional and spontaneous imagery in hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.**

**Students were given one of two versions of the Carleton University Responsiveness to Suggestion Scale (CURSS): a) the original version, which contains instructions to intentionally imagine goal-directed fantasies, and b) a modified version, in which instructions for suggestion-related imagery was deleted. Participants were asked to report their goal-directed fantasies and to indicate whether these occurred spontaneously or were generated intentionally. They were also asked whether they had tried intentionally to generate the suggested experience and to indicate whether they had believed that the suggested states of affairs were real (e.g., whether they thought a hallucinated cat really existed). The deletion of instructions for goal-related imagery significantly increased responsiveness to CURSS suggestions. Spontaneous goal-directed imagery was significantly correlated with behavioral response, but intentional imagery was not. Most successful responders tried to generate suggested experiences intentionally, indicated that they could have resisted challenge suggestions if they really wanted to, and reported believing in the reality of suggested ideomotor and challenge experiences, but not of cognitive suggestions. Voluntary attempts to generate suggested experiences were correlated with subjective responding.**

**Jasiukaitis, Paul; Spiegel, David (1995, November). Relateralizing hypnosis, or have we been barking up the wrong hemisphere?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.**

#### **NOTES**

**The association between the right hemisphere and hypnotizability dates to the Gurs and Bakan; and to Hilgard and Morgan who developed a measure based on EEG power spectrum. Results from the body of research using alpha are conflicting. De Pascalis, 1988, also couldn't show a large alpha difference between hemispheres.**

**Research on hypnotic hallucination with Pribram found Highs in a visual obstruction condition reduced P200 and P300; there was a slightly greater response at O2 than O1 EEG leads, leading us to think it was maybe a Right hemisphere task. But it was a foveal stimulus.**

**We tested with hemifield stimuli, blocking perception of 1/2 of the visual monitor; had them do the obstruction hallucination. P200 had the greatest reduction, with stimuli presented on the left. With obstruction of left visual field, we got little response. So ERP results were greater in right visual field (left hemisphere). This suggests the earlier observation was predominantly due to left, not right, hemisphere influence.**

Martha Farah's work on imagery is instructive. Also Steve Kosslyn. The Right hemisphere answers "Where" do you see something. The Left answers "What is it you see?" The left hemisphere generates image patterns that match what you see. When you ask people to generate an image, the activity is in O1 area. Also, patients with left hemisphere damage can't generate images; callosotomy patient also gave evidence. Many inductions use generation of images (left occipital and temporal regions). So when asking subjects to generate a hallucinated image blocking the screen, they are using that area.

The cortex can serve as an amplifier or a suppressor of response. In earlier study of somatosensory potential we observed bigger response when asking person to be more aware of pain. The cortex has an arousal system. There are two relevant systems in the brain (see Posner)--posterior and anterior. Hypnotizability is correlated with a metabolite of dopamine, which is associated with the anterior system which is dopaminergic.

Tucker & Williamson, in article in Psychological Review, 1984, write that activation is "the determination of information control by previous, stored internal representations" as opposed to arousal which is the "determination by novel [missed words....]"

Kinsbourne, in Consciousness and Contemporary Science, 1988. wrote that if at any time a hemisphere works like an automaton, it is the left hemisphere. With R. Davidson, he has shown the left hemisphere elevates affect, the right depresses it. Many people report that hypnosis is a pleasurable thing to do, maybe because it elevates mood.

One obstacle to this formulation is the idea that the left hemisphere governs logical thought.

We may disturb the relationship between words and images in hypnosis; you start to manipulate images and passively receive words, so that language is now a passive, receptive experience and images are active (instead of the usual pattern of actively using words and passively using images).

1994

Krippner, Stanley (1994, August). Improvement of academic skills for children and adolescents with hypnosis. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.

## NOTES

Literature and research in this area are sparse, though there is clinical evidence that hypnosis is useful. My definition of hypnosis is a procedure facilitating a variety of structured goals or procedures in which a suggestion or motivation is enhanced by a mechanical device, another person, or oneself.

There are 3 areas of application in academics:

study habits

test taking

strengthening academic motivation

The hypnotist should know the specifics of academic achievement, because specific suggestions (e.g. "Imagine you are at desk focusing well for 20 minutes,") are better.

Emphasis on the positive is better than negative. Use the words "imagination," "concentration," or "imagining pictures," rather than "hypnosis." I try to determine what they expect, based in part on what words they use.

In elementary school I focus on attitude and self esteem. I have them imagine reading a story, then how well they feel; that when they notice mistakes they won't be bothered because everyone makes mistakes.

For high school, I help them develop good habits for time motivation (e.g. suggestions to "make an outline to follow while you study"). At college level, I introduce self hypnosis. I make frequent use of mental imagery, at all levels--especially imagery rehearsal, in which the person is engaged in a particular activity.

In the NSF report on accelerated learning techniques (a project sponsored by the Army), Lozonov's "suggestopedia" techniques were studied. This review indicated it might enhance training effectiveness and reduce training time.

I have observed the suggestopedia classes in Bulgaria and Hungary. Classes had a relaxed comfortable learning environment. Rather than individual learning, it was group learning. It included preliminary exercises, new material, and a review of what was learned. The first stage used 2/3 of the time. Then suggestions were given by the teacher to promote learning. The presentation phase took one third of the time. The method encourages students to make mental images of the material. In foreign language classes, people take on new roles.

**Malinoski, Peter; Aronoff, Jodi; Lynn, Steven J.; Moretsky, Michael (1994, August). Hypnosis and early memories. [Paper] Presented at the annual meeting of the American Psychological Association, Los Angeles.**

## NOTES

We studied autobiographical memory in the college population, as manifested in the therapy situation, as a way of investigating an individual difference variable. Most people do not have recall before age 3 or 4 (and probably infantile amnesia begins before age 2).

Administered Autobiographical Memory Scale (AMS), and later in context of a hypnosis scale. 247 students were in phase 1, conducted as two separate experiments so that Ss wouldn't link the AMS to measures used in the second study.

First study was presented as a study of personal memories. Asked Ss to distinguish first five birthdays, circumstances around loss of first tooth, first day of high school. Also, they were asked about their earliest memory events, rated according to 3 scales (detail, vividness, accuracy of recall). Authors summed Ss' responses on these 3 ratings for the 8 item scale.

Part II. Administered various scales: Life Experiences, Fantasy Proneness, Wilson & Barber's scale, Imagery Control Scale, Global Psychopathology, 25 item scale of physical and sexual abuse, Brier's list of symptoms of abuse, and DES (Dissociative Experiences Scale). Imbedded were 12 items to test carelessness in responding (e.g. "I have never said Hello to anyone who wore eyeglasses.")

## RESULTS

Phase 1. Two people indicated they had memories dating to before their first birthday; an additional 5% of Ss gave memories between 12-24 months. This would probably be impossible. Another 14.4% described events between 24-36 months; 37.4% said their earliest memory was at age 3. Mean age for earliest memory was 3.4 years (which agrees with other surveys.) Only 1 subject stated his earliest memory was as late as the tenth year of life.

High intercorrelation was obtained, ranging .79 to .89, between ratings on any of the memory event ratings (as detailed, vivid, or accurate). There was a negative correlation of these ratings with age of recall. Ss who report more detail, vividness, and competence, were also likely to report earlier first memories.

Authors divided Ss into three groups based on age of first memory: 12 with first memory earlier than first year; those whose first memory was between 1-7 years; and those with a later first memory. The earlier memory group were more fantasy prone; and rated their memories as more reliable, vivid. This suggests there are persons who report memories that are covered by infantile amnesia, report them with greater detail, and are more fantasy prone than those who report memory events beginning later in life. This is consistent with Wilson & Barber's finding that fantasy prone people have vivid recall of early childhood events.

None of the memory reports correlated with psychopathology or dissociation. Dissociation (DES) was correlated with abuse indicators, however. Compared top and lowest 10% and middle range on DES on their memory scores and found no relationship. There was no support for the idea that report of early life events in dissociative people is compromised. Failure to recall early memories shouldn't suggest that people are dissociative (which some therapists tend to do).

All three memory measures were associated with Harvard Scale scores. The AMS was administered at the same time as the Harvard. Objective responding on the Harvard correlated with detail, vividness, and accuracy of recall. Also, involuntariness of response correlated with all 3 measures of the AMS. Finally, subjective involvement correlated with all three measures of AMS. At least when hypnosis is measured first, and explicit connection is suggested, there is a connection. Further research is needed to see if the relationship holds when measured in independent contexts. This may explain why High Hypnotizables are more prone to pseudo memories and leading questions. They may come to confuse them with historical reality.

The results suggest caution for early memory reports. They may be vulnerable to confusing fantasy and reality, as well as to biasing effects.

1993

Elter-Nodvin, Sabette; Lynch, Gregory; Nash, Michael R. (1993, October). Is primary process mentation a feature of hypnotic responding?. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

NOTES

It is difficult to measure primary process; usually measures from Rorschach are used. Recently Steven Lynn and Ken Bowers have done interesting work.

From literary criticism, we took the newer method of lexical pattern analysis--like a fingerprint (e.g. of Shakespeare's language). Wanted to determine whether there are differences between High and Low hypnotizables; or a difference in waking and hypnotic state. Martindale has a measure based on a lexical dictionary.

In Martindale's method, you take a long verbal sample, transcribe it into computer text file (response to TAT cards, and 3 tasks like--"Imagine you are ascending a spiral staircase and see someone at the top; describe what you see"); then do word count.

Gruzelier, John; Warren, Kristen (1993). Neuropsychological evidence of reductions on left frontal tests with hypnosis. Psychological Medicine, 23, 93-101.

Individuals with high and low susceptibility to hypnosis were compared in a baseline condition and after instructions of hypnosis on tests of anterior left and right hemispheric functions of word fluency to letter categories, word fluency to semantic categories, design fluency and bilateral finger tapping dexterity. With hypnosis high susceptibles showed a reduction in word generation to letter categories, no significant change in word generation to semantic categories, an improvement in design fluency, and bilateral reductions in finger tapping dexterity. Low susceptibles showed the opposite changes except for the improvement in design fluency. These results, together with correlational results, were interpreted as evidence of central inhibitory processes, particularly of the left hemisphere, in response to instructions of hypnosis in high susceptibles. NOTES 1:

#### NOTES

The authors discussion of their study includes the following statements. "The main result of the study was the differential influence of instructions of hypnosis on high and low susceptibles for word fluency to letter designated categories, as distinct from semantic categories, and design fluency" (p. 98).

"The absence of effects of hypnosis on word generation to semantic categories (left fronto-temporoparietal) versus letter categories (left frontal) has a bearing on evoked potential evidence (Gruzelier et al. 1987). Bilateral comparisons at temporal lobe and central locations showed that high susceptibles were characterized by asymmetric changes in evoked potential amplitude (N116 component) with hypnosis. Activity at the central electrodes was compatible with a left-to-right hemispheric shift of function, but this was not the case at the temporal electrodes. Instead of an inhibition of left temporal activity with hypnosis activation was maintained. Maintenance of activity in the left temporal lobe follows consideration of the fact that hypnosis requires sustained attention to the voice of the hypnotist, which is predominantly a left temporal function" (p. 99).

"The absence of differences in the pre-hypnotic condition between high and low susceptibles indicates that hemisphericity per se may not be a factor that characterizes susceptibility. The fact that lateral differences were found in some experiments (e.g. Gruzelier et al. 1984; Gruzelier & Brow, 1985) but not others (e.g. Cikurel & Gruzelier, 1990; McCormack & Gruzelier, 1993) may indicate that such

effects, when apparent, were secondary to another factor such as cognitive flexibility as conceptualized by Crawford (1989)" (p. 99).

Hall, Howard R.; Papas, Angela; Tosi, Michael; Olness, Karen (1993, October). Bi-directional changes in neutrophil adherence following hypnosis. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington Heights, IL.

## NOTES

At the last time that I presented a paper, I talked about the neutrophil. The neutrophil is a model of convenience because it responds quickly to psychological interventions, it is important in upper respiratory infections, and it can be measured reliably in vitro.

We had found that Ss with two weeks of relaxation/imagery training showed an increase in stickiness of neutrophils. We wanted to replicate and extend that study. We wanted one group to increase, another group to decrease, stickiness in neutrophils. There were a total of three groups, including a resting control group. The model of investigation involves two weeks of training in self hypnosis or simply resting.

### Session 1

1 week of practice

### Session 2

Results. The Control group increased adherence in neutrophils. The imagery-increase group and imagery-decrease group both decreased adherence. (In the first study the controls had no previous experience in relaxation. Also, the experimental group that was tested showed a decrease in first week and increased in the second week.)

Imagery is work, and that may result in less adherence. Pulse rate increased for the group trying to increase stickiness, in Session 1--implying less relaxation for them. Hypnotizability (measured with the Pennsylvania State University Scale) was not correlated with increase in neutrophil adherence.

Kraft, Tom (1993). Using hypnosis with cancer patients: Six case studies. Contemporary HypnHypnosis can be used in a number of different ways for helping patients suffering from cancer. As well as pain relief, hypnosis may be used to correct insomnia that does not respond to sleeping tablets; for the reduction in skin irritation and dyspnoea when these are due to organic causes, and for treatment-related over-eating. Some patients will use hypnosis in a symbolic way. When this occurs, just as in dream interpretation, it is important to ask the patient for associations, so that these symbols can be understood. Hypnosis can be an extremely useful addition to the medical armamentarium, and should be employed as an adjunct to standard forms of cancer treatment. This paper reports six case studies in which hypnosis was used to help cancer patients.

## 1992

Appel, Philip R. (1992). Performance enhancement in physical medicine and rehabilitation. American Journal of Clinical Hypnosis, 35, 11-19.

Performance enhancement or mental practice is the "symbolic rehearsal of a physical activity without any gross muscular movements" to facilitate skill acquisition and to increase performance in the production of that physical activity. Performance- enhancement interventions have been well known in the area of sports psychology and medicine. However, clinical applications in physical medicine and rehabilitation have not flourished to the same extent, though the demand for improved physical performance and the acquisition of various motor skills are as important. In this paper I will describe how hypnosis can potentiate mental practice, present a model of mental practice to enhance performance, and describe how to help patients access an ideal performance state of consciousness.

Hall, Howard R.; Mumma, Gregory H.; Longo, Santo; Dixon, Richard (1992). Voluntary immunomodulation: A preliminary study. International Journal of Neuroscience, 63 (3-4), 275-285.

This study explored the effects of relaxation and imagery procedures on the voluntary self-regulation of immune responses. Immune studies of 19 adults were made before and after a 45 minute intervention consisting of relaxation with imagery aimed at enhancing immune activity. A self-report measure of psychological distress was completed before each blood sample. Results indicate that the seven blood measures of immune functioning were measured with adequate reliability and consisted of two sets of immune parameters. A statistically significant increase in one of the mitogen measures and a marginally significant increase in one of the blood count measures was found following the relaxation/imagery procedure. Age, hypnotizability, and their interaction significantly predicted change on the set of blood count measures but not on the set of mitogen measures. As expected, level of subjective psychological distress generally decreased following the intervention. The methodological limitations of this study included limited sample size and absence of a control group.

Hargadon, Robin M.; Bowers, Kenneth S. (1992, October). High hypnotizables and hypnotic analgesia: An examination of underlying mechanisms. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, Arlington, VA.

#### NOTES

Bowers' dissociated control adaptation of Hilgard's neodissociation theory of hypnosis posits that higher control systems are not used if lower systems are activated.

Imagery may be less important for achieving hypnotic effects. It also may contribute differently than previously thought, an uncorrelated factor. If imaginal involvement and imagery is integral to the production of analgesia using hypnosis, one would get results different than if not integral.

Research: 65 Ss rated as high on two hypnotizability tests participated.

Session 1:

Procedure entailed finger pressure pain: baseline, followed by 2 hypnosis treatment trials. Ss were not informed of the second trial before they did the first.

Standard suggestions: imagery congruent with the suggestion (hand like block of wood, protected by a glove)

Imageless condition: your hand will remain comfortably nonresponsive to the pressure; you will not allow other things to come into your mind.

Outcome Measures

Analogue scale for pain 0-10

Nonvoluntary experience rated 0-4

Session 2:

Administered Tellegen Scale, Woody & Oakman Scale, Marks Vividness of Imagery, Bowers' Effortless Experiencing, and Duality of Experience during age regression.

## RESULTS

No difference was found between the standard and imageless conditions in amount of pain reduced. So in high hypnotizables, use of imagery or not doesn't matter for controlling pain. Some Ss had a clear preference however, for one or the other method (even counter to their own expectations).

Feelings of nonvolition did not differ as a function of imagery use.

Multiple regression showed effects of hypnotizability and effortless experiencing. Ss who have an effortless experiencing of imagery benefit from using it to reduce pain; those who find it more effortful do better without imagery when attempting to reduce pain.

Contrary to last year's results reported by Bowers, high imagery was related to duality of experiencing in age regression.

Dissociated control theory is consistent with the results but not necessarily demonstrated. It is important to discriminate between imagery as a mediator rather than as a co-occurrence. This research suggests, as did Zamansky's work on counter suggestions, that imagery is not as critical for hypnotic response as we previously thought.

Holroyd, Jean (1992). Hypnosis as a methodology in psychological research. In Contemporary hypnosis research (pp. 201-226). New York: Guilford Press.

## NOTES

This chapter deals with how the changes brought about by hypnosis (in cognition, behavior, motivation, etc.) may be used in research in other areas of psychology. "The distinction between experimental effects attributable to a personality trait (i.e. hypnotizability), hypnosis context (i.e. an induction), and interaction between the two is particularly important in using hypnosis as a research strategy.

The author discusses suggestibility, imagery enhancement, and changes in the mind-body relationship (immunology, pain, cognitive neuropsychology, attention, learning and memory, and awareness) as they might be employed in social psychology or psychophysiology research. She reviews problems inherent in using hypnosis as part of the research methodology, while noting that hypnosis nevertheless offers new

information when introduced into traditional content areas. "For example, in cognitive psychology it has re-introduced the importance of studying experiential aspects of cognition, i.e. I think, I remember, or self reference (Kihlstrom, 1987)" (p. 223).

She concludes, "Hypnosis as a research method will continue to benefit from contributions of radically different theoretical views of hypnotic phenomena. Social-cognitive psychologists have contributed significantly toward unifying the fields of hypnosis research and general experimental psychology. At the same time, advances in neurophysiology and psychosomatic medicine employing hypnosis indicate that there is a role for hypnosis as a research strategy, solely because of its altered-state characteristics. If theoretical physics can reconcile both wave and particle theories of light, it is conceivable that psychology can accommodate both behavioral and state theories of hypnosis" (p. 224).

**Kraft, Tom (1992). Counteracting pain in malignant disease by hypnotic techniques: Five case studies. Contemporary Hypnosis, 9, 123-129.**

Five cases of patients suffering from cancer are described in which hypnotic visualization techniques were successfully employed to relieve pain and anxiety. This study supports the view that hypnosis can be an effective tool for pain relief in malignant disease, particularly when traditional methods have been exhausted.

**Grossarth-Maticek, R.; Eysenck, H. J. (1991). Creative novation behaviour therapy as a prophylactic treatment for cancer and coronary heart disease: Part II - Effects of treatment. Behaviour Research and Therapy, 29, 17-31.**

#### **NOTES**

Reports on what they call creative novation behavior therapy or "autonomy training" to prevent cancer and coronary heart disease in prone individuals. This individually tailored cognitive-behavioral program includes the use of hypnosis and of imagery. When administered individually (20-30 hours) in a group (6-15 sessions of up to several hours) or via bibliotherapy with 4-6 hours of individual therapy, the outcome was better than that of control subjects. After 13 years, 45 of 50 cancer-prone subjects in individual treatment were still alive (and none of the 5 deaths were from cancer), while among 50 control subjects, 31 died, 16 from cancer. This study along with Spiegel et al. (1989) article in Lancet have important implications for health care.

**Hinshaw, Karin E. (1991). The effects of mental practice on motor skill performance: Critical evaluation and meta-analysis. Imagination, Cognition and Personality, 11, 3-35.**

21 studies that met the criteria of having both an adequate control and a mental practice alone group were included. The 44 separate effect sizes resulted in an overall average effect size of .68 (SD = .11) indicating that there is a significant benefit to performance of using mental practice over no practice. A series of General Linear Models revealed that the use of "internal" imagery produced a

larger average effect size than the use of "external" imagery, and that mental practice sessions of less than one minute or between ten and fifteen minutes in length produced a larger average effect size than sessions of three to five minutes in length. These findings suggest the complexity of the relationship between variables that influence mental practice.

1990

Avants, S. Kelly; Margolin, Arthur; Salovey, Peter (1990-91). Stress management techniques: Anxiety reduction, appeal, and individual differences. Imagination, Cognition and Personality, 10, 3-23.

#### NOTES

Four stress management techniques were evaluated for their general appeal, their immediate benefits, and the subjective experiences they evoke. One hundred undergraduates were randomly assigned to one of five treatment groups: (1) progressive muscle relaxation (PMR); (2) distraction imagery; (3) focused imagery; (4) listening to music; (5) sitting quietly (control). Distraction imagery and listening to music were the only techniques found to reduce anxiety to a greater extent than simply sitting quietly. The techniques differed in the way they made subjects feel, but not in their general appeal. Individuals with a 'blunting' coping style were more likely to find all five techniques appealing.

Tests used included the Miller Behavioral Style Scale, Cognitive-Somatic Anxiety Questionnaire of Schwartz, Davidson & Golman, Life Orientation Test of Scheier & Carver, Somatic Perception Questionnaire of Landy and Stern, Body Consciousness Questionnaire of L. C. Miller, Murphy, & Buss, Betts' Questionnaire Upon Mental Imagery, Shortened Form, State-Trait Anxiety Inventory, and Technique Evaluation Questionnaire of the authors.

Progressive muscle relaxation was according to Bernstein & Borkovec. Distraction imagery involved successively imagining a walk along a beach, a stroll across a flower filled meadow, sitting by a stream, a walk into the woods, sitting in a cabin in the woods listening to the rain against the windowpane, all including images in a variety of sense modalities. Focused imagery involved creating an image of a stressor, then through symbolic imagery experiences Ss were guided through a typical day's events that might lead up to the stressor, reinterpreting cues associated with the stressor as signals that they are in control, visualizing encountering the stressor feeling strong and determined, and any physical sensations reinterpreted as 'energy' that would help them to cope, visualizing enjoying their success (from Crits-Cristoph & Singer. Music was a 20-min tape (10 min of music used in the distraction imagery tape--Natural Light by Steve Halpern & David Smith) and 10 min of music used in background of the focused imagery tape (Structures of Silence by Michael Lanz). A 5th group, Control, was instructed to sit quietly with eyes closed.

This data can be used in support of imagery-suggestion types of hypnosis (as in surgery study) reducing anxiety. It shows particularly strong effects for people high in cognitive anxiety or low in optimism, pre-treatment.

**Discussion: "... we feel confident that our distraction techniques were more effective for the immediate relief of anxiety than was PMR. This conclusion is consistent with the Suls and Fletcher meta-analysis (29) that suggested that 'avoidance' is an effective short-term coping strategy. That distraction (positive) imagery may be a more useful clinical technique than focused (active involvement) imagery was concluded in a study comparing these two techniques in the treatment of phobias (24)" (p. 19. [Ref #24 is Crits-Cristoph & Singer (1983) in *Imagination, Cognition, and Personality*.])**

**"Pessimism and cognitive anxiety emerged as the only individual difference variables to influence anxiety reduction. Pessimism as measured by the LOT is cognitive in nature, with most of the items relating to expectations of negative outcomes; similarly, cognitive anxiety is characterized by worry and an inability to control negative thoughts and images. That individuals who perceive their world somewhat negatively should have entered the study more anxious than individuals who do not is hardly surprising. What is surprising is that despite an inverse relation between cognitive anxiety and the ability to relax, these individuals were able to benefit from whatever technique they performed to a greater extent than were individuals with a more positive outlook. In fact, after performing the technique, pessimists had reduced their anxiety to the level of optimists" (p. 19).**

**"The stress management techniques used in the current study did not differ in their appeal" (p. 20). "Our finding that PMR produced more somatic effects than did focused imagery and less cognitive effects than did distraction imagery, listening to music, or sitting quietly is consistent with the model of anxiety proposed by Davidson and Schwartz (17). Our findings are also generally consistent with a conclusion reached by Woolfolk and Lehrer (4): that although various techniques are generally stress reducing, they seem to have highly specific effects. However, we found no support for the hypothesis that individuals who express anxiety cognitively (or somatically) prefer and benefit most from techniques that produce cognitive (or somatic) effects. In fact, the extremely high correlation found between the cognitive and somatic anxiety subscales of the Schwartz et al. measure (5) casts some doubt on the usefulness of a cognitive-somatic distinction, as does the corr between the experience of physical symptoms under stress (the Somatic Perception Questionnaire) with the cognitive, as well as the somatic, anxiety subscale.**

**"The finding that blunters experiences more 'somatic effects' regardless of the technique they were assigned may have been the result of a single response--'how much did mind-wandering interfere with performing the technique'--which was the only Factor 2 item that was highly inversely related to blunting. Since blunters are more likely to perceive mind wandering as the essence of stress management rather than as 'interference,' we do not view this main effect as particularly illuminating" (p. 20). "However, our finding that blunters experienced all techniques as appealing is consistent with the results of Martelli et al. (1) who found that individuals with low information-preference benefitted from what the authors labeled an 'emotion-focused' intervention, but which, in fact, included many of the quite diverse stress management techniques that we compared in the current study. That 'avoiders' failed to benefit from any intervention in the Scott and Clum study (11) may be due to the nature of the stressor [postsurgical pain]. Our undergraduates may have been**

more like the Martelli dental patients in terms of their level of distress than were the Scott and Clum subjects who were patients undergoing major surgery (hysterectomy or cholecystectomy). Future research needs to examine possible three-way, technique by patient by stressor-type, interactions (cf. 19)" pp 20-21.

Heyneman, Nicholas E. (1990). The role of imagery in hypnosis: An information processing approach. International Journal of Clinical and Experimental Hypnosis, 38 (1), 39-59.

Imagery is widely agreed to be an important component of hypnosis. The theoretical framework from which to conceptualize the role of imagery in hypnosis, however, has remained controversial. A model is presented which attempts to reconceptualize hypnotic imaginal processing in terms of current theory and research in cognitive psychology and psychophysiology. This model draws from a propositional approach to imagery (e.g. Pylyshyn, 1973), particularly as adapted by Lang's (1979) bioinformational theory. It is argued that the hypnotic image is fundamentally more complex than simple iconic mental representation, containing instead both stimulus and response components. It is proposed that the critical properties of the hypnotic image are not the stimulus components or propositions which give rise to the experience of the image but instead are response propositions which are associated with overt behavior. Processing of these response propositions is conceptualized as a negative feedback system between the brain and effector site. Some preliminary sources of support as well as implications and research suggested by this model are discussed.

#### NOTES

The author notes that the brain does not store a kind of "photograph," but rather stores "meanings" (Anderson, 1978); and that images actually represent response processes, as observable in physiological concomitants (Lang, 1977).

The hypnotic suggestion that a Subject's arm is being pulled up into the air by a large helium balloon is represented by two separate propositions: "There is a helium balloon tied to your arm" (a stimulus proposition) and "Your arm is moving up into the air" (a response proposition). According to Peter Lang (1979), an image is not a mental stimulus to which a response is made, but is in itself an active response process, accompanied by physiological activity. Verbal instructions to a Subject determine whether they will access stimulus propositions or response propositions. "Lang et al. (1980) found that only those Ss given response training coupled with response proposition scripts showed significant physiological arousal. These Ss were presumably better able to access and process that portion of the propositional network which controls visceral and motoric responding" (p. 46).

This author proposes that cognitive processing of a hypnotic image involves (internal) responding, and that 'responsive propositions' provide the basis for understanding the function of imagery in hypnosis, and are more important to hypnotic imagery than stimulus propositions. "In other words, the experience of a visual image and thus the vividness or controllability of that image is not critical for hypnosis. What is important to note is that the hypnotic behavior is not a response

to a visual image but is instead a function of the processing of the image itself (cf. Lang, 1979)" (pp. 47-48).

In explaining how an image might facilitate amplification of a subtle response (such as in arm levitation), the author suggests that physiological and external feedback systems are involved--principally a neural feedback loop between brain and target organ (in this case, arm muscles). "Efferent signals, which are activated by processing response propositions, initiate the overt behavior while afferent signals feed back to the brain and modulate further input to the effector system. The process progressively reduces the mismatch between the image instructions and behavior until the hypnotic task is completed" (p. 48). The feedback loop "provides information on the discrepancy between desired behavior and actual behavior:  $e = B_d - B_a$ , where  $e$  = error,  $B_d$  = desired behavior, and  $B_a$  = actual behavior (Arbib, 1972). The error signal generated by this discrepancy modifies the efferent output so as to eventually approximate  $e = 0$ " (p. 49). The author notes that this complex process of physiological feedback may be "augmented by external feedback such as modified verbal instructions or vocal intonations of the hypnotist and self-observation by S" (p. 49).

The author's model is summarized as: "1. The context, setting, and expectations implied by being hypnotized as well as the wording of the hypnotic suggestions provides S with: (a) explicit or implicit instructions to use imagery, (b) repetitious wording which may increase the probability of fully accessing the relevant propositions, and (c) instructions that task completion is expected. This may function to increase the probability that the deep structure of the response propositions will be processed. 2. The hypnotic suggestion proper is composed of stimulus and response propositions embedded within a propositional network. 3. Stimulus propositions give rise to the phenomenological characteristics or the percept-like experience of the image but may be unimportant in determining hypnotic behavior. 4. Processing of the response propositions includes an active response. This response process is facilitated by S's expectation to become actively involved in the imagined scene. Response propositions are the critical features of hypnotic imagery. 5. During hypnosis, the propositional network may be systematically modified by physiological or external feedback regarding the relative progress of the behavior toward task completion. This processing of response propositions is conceptualized as a negative feedback system. Efferent signals are delivered to the appropriate effector site while afferent signals feed back to the brain in order to modify further neural input, functioning to reduce the error between image and behavior. While the initial feedback is probably physiological, additional feedback may be obtained from the hypnotist's instructions and S's self-observations. 6. If stimulus propositions are simultaneously accessed, S experiences an image" (p. 51).

Holroyd, Jean (1990). How hypnosis may potentiate psychotherapy. In Fass, Margot L.; Brown, Daniel (Ed.), Creative mastery in hypnosis and hypnoanalysis (pp. 125-130). Hillsdale, NJ: Lawrence Erlbaum Associates.

NOTES

This chapter is a reprint of an article published in the American Journal of Clinical Hypnosis in 1987. It provides a conceptual framework for understanding psychotherapy processes in the context of a hypnotic state. Based on empirical and theoretical considerations, the author identified nine changes occurring with hypnosis: changes in attention and awareness, imagery, dissociation, reality orientation, suggestibility, mind-body interactions, initiative or volition, availability of affect, and relationship. "This chapter proposes that hypnotherapy exploits hypnotic phenomena-- takes advantage of them--in the service of standard therapy endeavors" (p. 125).

Lombard, Lisa S.; Kahn, Stephen P.; Fromm, Erika (1990). The role of imagery in self-hypnosis: Its relationship to personality characteristics and gender. International Journal of Clinical and Experimental Hypnosis, 38 (1), 25-38.

30 volunteer Ss practiced self-hypnosis for approximately 4 weeks and wrote a record of their experiences in a diary following each session. Imagery produced during self-hypnosis was coded in 2 ways: the imagery was either reality oriented or it was fantastic and had primary process qualities. Levels of imagery production remained virtually the same over a 4-week period. Self-hypnotic imagery was significantly greater for the female Ss than for the male Ss, particularly primary process imagery. Verbal expressivity (measured as the average number of words per page of each S diary) was calculated to control for the effects of verbal production on Ss' imagery scores. When imagery scores were standardized based on verbal expressivity, female Ss still produced significantly more primary process imagery than male Ss. Personality characteristics (assessed by standardized personality inventories) were examined in relation to self-hypnotic imagery. "Impulse Expression" was positively related to primary process imagery for the female Ss. "Outgoingness" was positively related to primary process imagery for the entire sample, but especially for the female Ss.

McAleney, Patrick J.; Barabasz, Arreed; Barabasz, Marianne (1990). Effects of flotation restricted environmental stimulation on intercollegiate tennis performance. Perceptual and Motor Skills, 72, 1023-1028.

The study investigated the effects of flotation Restricted Environmental Stimulation (REST) with an imagery message on the competitive performance of intercollegiate tennis players (10 men, 10 women). Pre- and posttreatment athletic performance was measured during intercollegiate competition. Posttreatment results indicated that subjects exposed to flotation REST with an imagery message performed significantly better than subjects exposed to imagery only on a measure of first service accuracy. Findings suggest that flotation REST can be used to enhance the performance of a well learned skill by athletes of high ability.

Newshan, Gayle; Balamuth, Ron (1990-91). Use of imagery in a chronic pain outpatient group. Imagination, Cognition and Personality, 10, 25-38.

Reports treatment of chronic pain, integrating relaxation, cognitive therapy, and imagery techniques for 3 groups of chronic pain patients. Imagery and visualization were the most important components of the treatment. NOTES 1:

## NOTES

Chronic nonmalignant pain is defined as pain that exists beyond the normal and expected healing time, usually six months or more after the initial injury or trauma. Patients used daily journal to monitor level of pain using a color scale 4 times/day (blue - little or no pain, green mild pain, yellow moderate, orange severe, and red pain so intense it could kill or render the patient unconscious.

Used two types of imagery: mental rehearsal of actually doing and reaching a goal, or symbolic representation of the pain as a creature, alive, within their bodies. They dialog with the creature, asking Why are you here? What do you need from me? What can I do to live with you? What is the message you have for me? patients are asked to listen very closely for the response.

Cognitive restructuring is introduced later to identify dysfunctional thought patterns and correct them. They are taught, 1) thoughts influence behavior and emotions, 2) thoughts can be changed, and therefore 3) behavior can be changed. However, not all patients benefit from cognitive restructuring (because resistant to self monitoring or frightened or critical of own negative thoughts.

Relaxation is especially beneficial in breaking the pain/anxiety cycle, reducing fear associated with pain, improving sleep patterns, promoting a general feeling of well-being and facilitating mental imagery. Mental imagery, on the other hand, provides a means of self-discovery. It is defined by Achterberg and Lawlis (1980) as the internal experience of a perceptual event in the absence of the actual external stimuli; although usually thought of as visual, it may well involve any other sensory modality associated with the image.

Imagery is a proverbial process, eliciting the rich symbolism of knowledge of a person's unconscious and providing powerful insights indirectly. It provides an opportunity for one to reorganize a problem or experience, such as pain, towards a more positive resolution. Imagery can increase the patient's self-esteem and self-control and seems to facilitate well behavior. It is also a vivid method of communication from the patient to the therapist and the rest of the group. The group members had a healthy respect for these images and were able to appreciate the impact they had in their recovery, even if the process is not completely understood.

In each of their cases, "it is important to emphasize that the pain was never 'cured,' the pain persisted throughout treatment. Again, the program does not take away the patients' pain but changes the pain experience and enables patients to participate more fully in their lives despite the pain. As suggested by the 'big person, small person' concept, the pain would probably always be part of their lives, but through the program it could be a smaller, more manageable part. Imagery proved to be a valuable tool in helping clients achieve this goal.

Nilsson, Kayla Mae (1990). The effect of subject expectations of 'hypnosis' upon vividness of visual imagery. International Journal of Clinical and Experimental Hypnosis, 38, 17-24.

This study explored how the expectation of hypnosis and the expectation of relaxation affected the vividness of visual imagery. 63 Ss who volunteered for a visual imagination study were randomly assigned to 4 groups. Ss were administered the vividness subscale (VS) of the Vividness and Control of Imagery Scale twice. In the 3 experimental groups, expectations were varied during the 2 VS administrations. All 3 groups were presented with a relaxation exercise between VS administrations. In 2 groups, it was labeled "hypnosis," and in the third group it was correctly labeled "relaxation." A control group listened to a neutral tape between their VSs. All groups were administered the Harvard Group Scale of Hypnotic Susceptibility, Form A (Shor & E. C. Orne, 1962) after the 2 imagery tests. The results indicated that the vividness of visual imagery was significantly enhanced (equally) in the experimental groups but not in the control group.

1989

Cooper, Nancy A.; Clum, George A. (1989). Imaginal flooding as a supplementary treatment for PTSD in combat veterans: A controlled study. Behavior Therapy, 20 (3), 381-391.

14 Vietnam veterans suffering from posttraumatic stress disorder (PTSD) were assigned either to standard treatment (control group), or standard treatment plus imaginal flooding (experimental group). The 2 groups were closely matched on medications and combat roles and tours of duty were comparable. Experimental Ss received up to 14 sessions of flooding for a maximum of one and one-half hours per session. Self-report measures were administered at pre-treatment, post-treatment, and at 3-mo follow-up. These measures included the Behavioral Avoidance Test, the Beck Depression Inventory, and a Modified Vietnam Experiences Questionnaire. Results indicate that flooding increased the effectiveness of usual treatment, particularly in such areas as re-experiencing symptoms and sleep disturbances. However, flooding had no effect on level of depression, trait anxiety, and violence-proneness.

Grant, Guy (1989, June). An investigation of hypnotic susceptibility in self-hypnosis and imagery (Dissertation, University of Utah). Dissertation Abstracts International, 49 (12), 5517-5518-B.

## NOTES

"There were two phases in the study. In Phase One hypnotic susceptibility scores were assessed for 43 graduate student subjects by the Harvard Group Scale of Hypnotic Susceptibility: Form A (HGSHS:A). In addition, the Self-Hypnosis Research Questionnaire (an experimental scale) provided performance scores for subjects under three hypnosis conditions: heterohypnosis, self-directed self-hypnosis, and tape-assisted self-hypnosis. The first purpose in Phase One was to

calculate correlations between hypnotic susceptibility and each of the hypnosis conditions. The second purpose was to determine if there were significant differences across the three types of hypnosis. The third purpose was to discover if any existing differences were dependent on level (e.g., low, medium, or high) of hypnotic susceptibility. Analysis of the data yielded significant correlations between hypnotic susceptibility and (a) heterohypnosis, (b) self-directed self-hypnosis, and (c) tape-assisted self-hypnosis. There were significant performance differences across the three hypnosis conditions with heterohypnosis being somewhat superior to tape-assisted self-hypnosis, and tape-assisted self-hypnosis being slightly superior to self-directed self-hypnosis. This relationship held true regardless of level of hypnotic susceptibility (e.g., low, medium, and high).

"In Phase Two, 49 graduate student subjects were administered the shortened form of the Betts' Questionnaire Upon Mental Imagery (QMI) as well as the HGSHS:A, and to determine if mental imagery is an important component of hypnotic susceptibility. Analysis yielded a significant correlation between the two measures.

"Based on the current data, it was concluded that the HGSHS:A had some utility for predicting performance in hypnosis. It was noted that, as compared with self-hypnosis, heterohypnosis provided the greatest chance of eliciting a positive hypnotic response from subjects not trained or experienced in hypnosis. It was also concluded that the QMI was correlated with and had some utility for predicting performance on the HGSHS:A. It had difficulty, however, differentiating between low and medium hypnotizability" (pp. 5517- 5518).

Hall, H.; Minnes, L. (1989). Psychological modulation of auditory responses. International Journal of Psychosomatics, 36 (1-4), 59-63.

Psychological modulation of auditory response, the effects of imagery and suggestion on auditory thresholds were examined in naive subjects. After a hypnosis-like induction, the subjects, who were not aware of the purpose of the study, were asked to generate and maintain a specific set of images before, during, and after which their auditory thresholds were tested. Following the imagery, which represented cooling and vasoconstriction in the cochlea, audiograms revealed a temporary auditory threshold shift (TTS) in the experimental group only. This TTS pattern was similar to that produced by exposure to loud noise. Information carried in the image is suggested as the basis for the observed auditory changes. Although a hypnosis-like induction was employed, the subjects' level of hypnotizability did not appear to be related to the findings.

Jirout, J. (1989). Reaction of the cerebral vertebrae in imagined changes in the shape of the cervical spine. Ceskoslovenska Neurologie a Neurochirurgie, 52, 75-77.

Postural reaction of the cervical vertebrae on imagined, but actually not performed, changes in the shape of the cervical spine in the sagittal plane are described. The percentage of reacting vertebrae is relatively high. The findings seem to indicate that, (1) the described phenomena belong to the constant features of the spinal dynamics, (2) that there probably exist residual traces of preceding activities, and

(3) that these changes are due to the activation of the polymetameric system of the intrasegmental muscles. Abstracted in *American Journal of Clinical Hypnosis*, 1990, v. 32, p. 213.

Kahn, Stephen P.; Fromm, Erika; Lombard, Lisa S.; Sossi, Michael (1989). The relation of self-reports of hypnotic depth in self-hypnosis to hypnotizability and imagery production. *International Journal of Clinical and Experimental Hypnosis*, 37, 290-304.

Studied multidimensional nature of self-hypnotic depth in 22 high hypnotizables who volunteered for self hypnosis research. On personality scales, they were distinguished from the population at large by: strong theoretical orientation, high level of curiosity, disregard for opinions of others, and high Mf scale on the MMPI. Used the Stanford Profile Scale, SHSS:C and HGSHS:A, which measure the entire range of phenomena ordinarily used in experimental studies of hypnosis, including ideomotor phenomena, hypnotic fantasy and dreams, hypermnesias and age regressions, analgesias, negative and positive hallucinations, amnesias, posthypnotic phenomena, and cognitive and affective distortions. They asked Subjects to experience self hypnosis for 60 minutes/day for 4 weeks. Journals were coded for imagery production by scoring for both reality-oriented and primary process imagery. Subject had been taught to monitor their hypnotic depth using a slightly revised version of the Extended North Carolina Scale (ENCS) of Tart (1979). Previously, ENCS has been used only with hetero-hypnotic Subjects. The self-reports of depth using ENCS correlated highly with hypnotizability as measured by the Revised Stanford Profile Scale of Hypnotic Susceptibility... and with imagery production. Results demonstrate that ENCS scores are also a valid indicator of self-hypnotic depth among highly hypnotizable Subjects. Furthermore, they indicate that both hetero- hypnotizability and imagery production are related to self-hypnotic depth, but that the association between imagery and hypnotizability is due to their individual relationships to self-hypnotic depth.

Kihlstrom, John F.; Register, Patricia A.; Hoyt, Irene P.; Albright, Jeanne Sumi; Grigorian, Ellen M.; Heindel, William C.; Morrison, Charles R. (1989). Dispositional correlates of hypnosis: A phenomenological approach. *International Journal of Clinical and Experimental Hypnosis*, 37, 249-263.

Attempted to construct and validate a questionnaire measure of hypnotic- like experiences based on Shor's (1979) 8-dimension phenomenological analysis of hypnosis. Separate item pools were developed to measure each disposition: Trance, Nonconscious Involvement, Archaic Involvement, Drowsiness, Relaxation, Vividness of Imagery, Absorption, and Access to the Unconscious. Based on preliminary testing (total Number - 856), a final questionnaire was produced containing 5 items measuring normal, everyday experiences in each domain. Results from a standardization sample (Number - 468) showed that each of the subscales, except for Archaic Involvement, possessed satisfactory levels of internal consistency and test-retest reliability. Factor analysis indicated that 6 subscales loaded highly on a

common factor similar to the absorption construct (Tellegen & Atkinson, 1974), while items pertaining to Relaxation and Archaic Involvement formed separate factors. Validation testing on 4 samples receiving the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A) of Shor and E. Orne (1962) (total Number = 1855) showed that the Absorption and Trance dimensions correlated most strongly with HGSHS:A; the correlations with Drowsiness, Relaxation, and Nonconscious Involvement approached 0. The scales derived from Shor's analysis, however, did not improve the prediction of hypnotizability over that obtained with the absorption scale (Tellegen & Atkinson, 1974).

Kunzendorf, Robert G. (1989-90). Posthypnotic amnesia: Dissociation of self-concept or self-consciousness?. Imagination, Cognition and Personality, 9, 321-334.

Two studies of posthypnotic amnesia tested predictions derived from the 'source' monitoring theory of self-consciousness. Experiment 1 tested the prediction that posthypnotic source amnesia is irreversible, because hypnosis attenuates self-consciousness of whether one's sensations have an imaginal source or a perceptual source. In this initial study, recall amnesia was reversed by posthypnotic cueing with a prearranged signal, but source amnesia was not reversed by such cueing. Experiment 2 examined whether the cued reversal of recall amnesia is attributable, in part, to the hypnotic attenuation of self-conscious 'source monitoring' and, in part, to the reversal of recall criteria: from a criterion rejecting 'seemingly imaginary' or 'sourceless' memories, to a criterion accepting 'sourceless but familiar' memories. In this latter study, posthypnotic recall amnesia was breached when subjects were instructed to trust their seemingly imaginary memories, but not when they were instructed to try harder to remember [emphasis removed from quoted text].

Matheson, George; Shu, Karen L.; Bart, Catherine (1989). A validation study of a short-form hypnotic-experience questionnaire and its relationship to hypnotizability. American Journal of Clinical Hypnosis, 32, 17-26.

#### NOTES

Investigated the validity of a 16-item scale inquiring about hypnotic experience, drawn from the Hypnotic Experience Questionnaire developed by Kelly (1985) to measure components of hypnotic experience. We administered the HEQ-S and the Harvard Group Scale of Hypnotic Susceptibility: Form A (HGSHS:A) to 198 students. Factor analysis of the scale produced three stable principal components accounting for 70% of the data variance: Dissociation/Altered State (DAS), Rapport (RAP), and Relaxation (REL). Subscales representing these three factors and a composite measure, "General Depth," were constructed. Subscale correlations with HGSHS:A scores were highest for the DAS subscale (.69) and lowest for REL (.41). Applications of the HEQ-S in clinical and research use are considered.

Using the phenomenological studies and theories of J. R. Hilgard (1979) and Shor (1962), Kelly (1985) constructed the Hypnotic Experience Questionnaire (HEQ), a 47- item scale designed to demonstrate the existence of five factors of the hypnotic

experience. These factors included dissociation/altered state, relaxation, rapport, visual imagery, and a negatively correlated factor of cognitive rumination measuring the amount of anxious self-reflective, and interfering thought. A composite scale, General Depth, was also derived to provide a summary measure of the subjective quality of the hypnotic experience. The HEQ was developed as a research instrument.

The HEQ-S was administered immediately after Ss completed the Harvard response record. Items were responded to on a 5-point Likert scale ranging from one (No, none or not at all) to 5 (Yes, a great deal, or almost completely).

Groh, Margaret (1989). Correlates of hypnotic susceptibility. In Spanos, Nicholas P.; Chaves, John F. (Ed.), Hypnosis: The cognitive-behavioral perspective (pp. 32-63). Buffalo

#### NOTES

The author describes a non-linear relationship between imagery and hypnotizability and between absorption and hypnotizability. People good at imagery may be high or low on hypnotizability scales; the same is true for people high on absorption trait. However, people low on those traits generally are low on measured hypnotizability.

#### 1988

Borgeat, Francois; Rezanowicz, Thaddeus; Chaloult, Louis (1988). La stimulation preconsciente et consciente de l'imaginaire erotique. Revue Canadienne de Psychiatrie, 33, 394-398.

The stimulation of erotic fantasies through the association of relaxation and erotic conscious or preconscious suggestions has been evaluated. This study was attempted following positive results in the stimulation of fantasmatic activity in alexithymic subjects with a similar procedure. Thirty female subjects, allocated into three groups practiced relaxation daily for two weeks including three sessions with psychological measures. During the second week, erotic suggestions, preconscious for one group and conscious for another one were added. The third group (control) received only relaxation throughout. Results have shown an increase of sexual arousal and erotic imagery during the sessions with erotic suggestions. Sexual activities and desire increased in the two experimental groups. There was no difference between the effects of the preconscious and conscious suggestions. Possible clinical applications of such a procedure are discussed.

Brink, Nicholas E. (1988-89). Using imagery as a planning and treatment guide in therapy. Imagination, Cognition and Personality, 8, 187-200.

Procedures and case studies of how imagery can provide a means to redefine the problem, an agenda for therapy, information for determining the appropriate interventions, a criteria for evaluating progress, and the appropriate time for termination are presented. Images are evoked using one of several imagery situations. These images may converge on the common dynamic pattern clarifying

the problem, represent different aspects of the problem, or represent different problems, depending upon the hypnotic suggestion used in evoking the images. The emerging pattern(s) provide the agenda for therapy. Emotional energy in imagery work is used to determine the appropriate timing and content for the therapeutic interventions. Emotional release provides a means of evaluating progress. When each of the items on the agenda are resolved with an emotional release the time for termination is near at hand. Therapy begins by evoking a minimum of three images using one of several situations, including time regression, seeing behind doors on a hallway, or going down in an elevator. These images may represent different aspects of the problem, different problems, or, by using the affect bridge, may converge on a common dynamic pattern clarifying the nature of a single problem.

Cross, W. P.; Spanos, Nicholas P. (1988-89). The effects of imagery vividness and receptivity on skill training induced enhancements in hypnotic susceptibility. Imagination, Cognition and Personality, 8, 89-103.

#### NOTES

This article is cited by Spanos & Flynn (1989) as indicating that high hypnotizability requires imaginative skills that some people do not possess in sufficient degrees.

1988

Dougherty, John E.; Payne, Paul A. (1988). The use of breathing rhythm to enhance the vividness of mental imagery. Imagination, Cognition and Personality, 8 (2), 175-179.

The study assessed Jencks' claim that responses to certain suggestions are enhanced by being paced with different phases of the breathing cycle. Following hypnotic induction, twenty-four subjects were given four treatments in counterbalanced order: 1) exhalation-enhanced suggestions paced to exhalation, 2) inhalation-enhanced suggestions paced to inhalation, 3) inhalation-enhanced suggestions counterpaced to exhalation, and 4) exhalation-enhanced suggestions counterpaced to inhalation. Subjects' reports of imagery vividness provided marginal support ( $p < .06$ ) for Jencks' hypothesis. Post-experimental inquiry indicated subjects were unaware of the breathing contingency. Results suggest that appropriate pacing may make a greater difference for the energy-confidence group of suggestions (inhalation-paced) than for the calm-relaxation group (exhalation-paced).

Dywan, Jane (1988). The imagery factor in hypnotic hypermnesia. International Journal of Clinical and Experimental Hypnosis, 36, 312-326.

Week-long repeated recall attempts were used as baseline against which to assess the effects of hypnosis on the recall of pictures. Hypnosis increased errors for all Ss but especially for high hypnotizables. In Experiment 1, dividing Ss on the basis of imagery ability had the same effect on recall as dividing them on the basis of hypnotic ability. In Experiment 2, imagery ability was found to interact with hypnosis in mediating the level of error during waking trials. Results do not support

the claim that hypnosis enhances recall, but they do suggest that further study is needed to clarify the role that imagery ability plays in recall patterns over time.

NOTES

1:

NOTES

Author reviews research indicating that introduction of confident errors is a reliable finding in hypnosis-memory research, and notes that the role of imagery ability has not as yet been examined even though imagery is viewed as important to memory functioning. She also reviews the imagery- hypnotizability correlation literature.

### EXPERIMENT 1

Involved 54 Ss screened by Harvard Scale and SHSS:C, divided into highs (7-12) and lows (1-6) by SHSS:C. Stimuli were 60 black and white line drawings. There were 3 baseline trials in the lab; Ss were then given 6 envelopes, each containing a 60 blank item recall sheet, and asked to complete one each day and return it via campus mail. (When unable to recall more items, they were asked to draw a line under the last item recalled and then use "educated guesses." ) After a week of repeated recalls, Ss in the hypnosis condition were told they would be able to 'see' the slides appear before them; in the task motivating condition Ss were informed about such things as context dependent recall, the importance of focused attention, and the importance of good recall for forensic investigations.

Results were analyzed for increase in recall over the cumulative number of correct items recalled. Neither hypnotizability nor visual imagery ability influenced the cumulative baseline measures. High hypnotizable Ss produced a small but significantly greater increase in new, correct information during hypnosis than other Ss, but also made 3 times as many errors.

Dividing Ss by imagery score produced similar results. That is, people with very good imaging ability reacted in the same manner as the highly hypnotizable Ss: in hypnosis they increased the number of items they were willing to call a memory but also increased the number of errors.

### EXPERIMENT 2

Differed from Experiment 1 in that Ss were selected for hypnotic ability and imagery ability so that both would be adequately represented. (The high hypnotizable - low visual imagery group is a group that hasn't been represented much in earlier research, and the author notes that those Ss are rather difficult to locate. ) The task motivation condition was not used, based on results of Experiment 1. Ss who were low on hypnotizability and imagery ability served as the controls.

Ss were told that they could be either in a hypnosis condition or a control condition but actually all Ss received a hypnotic induction. (This is like the London- Fuhrer, 1961, research design, which goes on the assumption that low hypnotizables do not enter into hypnosis even though they are exposed to an induction. Thus, hypnotic effects are not assumed for lows in the hypnotic condition and they become "controls.")

Results of correct and error recall over the baseline week were analyzed. There was no difference in correct recall as a function of hypnotic ability or visual imagery

ability. However, there was a main effect for visual imagery ability and for hypnotizability, and a significant interaction between trials, for cumulative errors over the baseline week.

Effects of hypnosis were weaker than in Experiment 1 but followed same pattern. Those Ss most likely to have been hypnotized (highs) produced slightly more correct information than lows, and showed a greater increase in errors than lows. However high and low visualizers did not differ in response to hypnosis for correct information or for errors.

Since there was an interaction between hypnotic ability and visual imagery ability for error rate during waking trials, the author tested for the interaction during hypnosis. Using a 2 x 2 ANOVA with new errors as the dependent measure; no interaction was found. Hypnotic ability was therefore responsible for determining Ss' responses in the hypnosis condition. Author attributes the effect to being hypnotized rather than to individual differences in hypnotizability or to context effects.

## DISCUSSION

Includes the author's delineation of differences between the two experiments that might explain differences in results. The increase in errors that was observed may be due to increased fluency in producing items under hypnosis (Sheehan & Tilden, 1984, 1986) or to a shift in reporting criterion (e.g., M. T. Orne, Soskis, Dinges, & E. C. Orne, 1984).

"Both high and low hypnotizable Ss produced more memories in the task-motivating condition, and low hypnotizables are not totally immune from the effect in the hypnotic context. What the report-criterion hypothesis does not explain is the reason why the memory reports of high hypnotizable Ss are differentially affected by task demands (e.g., task-motivating instructions versus hypnosis in Experiment 1) nor why hypnotized Ss so often seem surprised by the ease with which information seems to be 'recalled' during hypnosis. An alternative hypothesis is that being hypnotized results in a shift to a more imagistic style of information processing. The enhanced vividness of items generated during the retrieval process may convince Ss that these items must have been part of the original stimulus presentation (Dywan, 1985).

"Whatever the mechanisms might be, it is clear that the hypnotic effect is the result of an interaction between contextual factors and pre-existing characteristics of the individual. Moreover, these same mechanisms would likely be at work when hypnosis is actually used in the forensic situation, where the pressure to retrieve information could be more acute than what can be mustered in the experimental context. This should cause some concern because the differential increase in errors did not occur only for the relatively small proportion of Ss who were very high in hypnotic ability. The 'high' hypnotizable group in these experiments consisted of Ss of moderate to high levels of hypnotic ability and so the results can be generalized to at least one-half the population" (p. 323).

"In summary, it would seem that any pressure for Ss to increase their recall--whether it be repeated trials, task-motivating instructions, or hypnotic suggestion--results in higher levels of output and lower levels of accuracy. Repeated recall

attempts lead to increases in recall and in errors. Some Ss (viz., those with high levels of hypnotic ability and low levels of imagery ability) are particularly prone to producing false-positive responses over the course of repeated recall attempts. When Ss are pressed to recall more information, they all try to do so by increasing their output and this increased output is usually accompanied by an increase in error. When hypnosis is introduced, however, those Ss who are hypnotizable show a differential increase in output. The amount of new correct information retrieved by hypnotized Ss is small and not a highly reliable phenomenon. The increase in errors that occurs in the recall of hypnotized individuals, however, is a substantial and highly reliable effect. Irrespective of how many errors were made as a function of repeated recall attempts, hypnosis can be counted on to increase errors over and above the increases in errors that occur when Ss are not hypnotized. Further work is needed to identify the mechanisms involved in the hypnotic distortion of recall. The role that imagery ability might have in the context of waking and hypnotic recall has not been resolved and this also presents an interesting problem for future study" (pp. 323-324).

Gabel, Stewart (1988). The right hemisphere in imagery, hypnosis, rapid eye movement sleep, and dreaming: Empirical studies and tentative conclusions. Journal of Nervous and Mental Disease, 176, 323-331.

Reviews studies that have addressed the issue of whether there is an increased activation or efficiency of right-hemispheric processes during imagery, hypnosis, REM sleep, and dreaming. Evidence strongly supports the notion of increased right-hemispheric activation in simple imaginal or visual states during usual consciousness. There are also studies supporting this view of REM sleep, dreaming, and hypnotic phenomena. It is concluded, however, that the lack of adequate studies, contradictory or negative findings, and moderating variables (e.g., task difficulty, cognitive style) make it difficult to draw definitive conclusions concerning right-hemispheric processes.

Gorassini, Donald R.; Hooper, Cynthia L.; Kitching, Kathleen J. (1988). The active participation of highly susceptible hypnotic subjects in generating their hypnotic experiences. Imagination, Cognition and Personality, 7 (3), 215-226.

Hypnotized individuals have traditionally been considered to be detached from the control of their own suggested behavior. We tested this and the alternative notion that hypnotized subjects attempt to self-generate the experiences (i.e., mainly of involuntariness) as well as produce the behaviors thought to be prototypical of high hypnotic ability. In an experimental investigation, highly susceptible hypnotic subjects were found to engage in the kind of imaginative activity that would be expected of individuals who were attempting deliberately to generate their experiences of involuntariness; they engaged as actively in imagery-generation as did subjects who were specifically instructed to imagine during suggested responding, and they experienced as much involuntariness as subjects in whom suggested movements were produced by an external physical force. The implications

of these findings for the neodissociation and social psychological theories of hypnotic responding are discussed.

**Katsanis, Joanna; Barnard, Joanna; Spanos, Nicholas P. (1988). Self-predictions, interpretational set and imagery vividness as determinants of hypnotic responding. Imagination, Cognition and Personality, 8 (1), 63-77.**

Two studies assessed the effects of self-predictions and interpretations of suggested demands on hypnotizability. Subjects overestimated their responsiveness to suggestions. Those who believed that they would fail all or almost all suggestions invariably attained low hypnotizability scores. However, those who believed that they would be highly responsive exhibited wide variability in their actual hypnotizability. Among subjects who self-predicted high responsiveness, those who adopted a passive "wait and see" interpretation toward suggestions scored significantly lower in hypnotizability than those who believed that they should actively bring about suggested effects. Study 2 also found that the relationship between adopting an active interpretation and hypnotizability was moderated by subjects' level of imagery vividness. Theoretical implications are discussed.

**Kumar, V. K.; Pekala, Ronald J. (1988). Hypnotizability, absorption, and individual differences in phenomenological experience. International Journal of Clinical and Experimental Hypnosis, 36, 80-88.**

The phenomenological effects associated with a baseline condition of eyes- closed and a hypnotic induction condition were compared across individuals of differing absorption capacity and hypnotizability. The results indicated that individuals of differing absorption capacity and hypnotizability reported different intensities of phenomenological experience during the baseline eyes-closed condition. The induction further augmented intensity differences for low, medium, and high absorption and hypnotizable Ss, but more so for high (and medium) than low hypnotizable Ss. The results support both a trait and state interpretation of hypnotizability, and highlight the importance of the interaction between these factors on the resulting hypnotic experience of S.

#### **NOTES**

Based on a review of relevant literature, the authors predicted that (1) during hypnosis and a baseline condition (eyes-closed), high absorption and high hypnotizable Ss will report the phenomenological effects at greater intensity relative to low absorption and low hypnotizable Ss, respectively; (2) hypnotic induction will be associated with increased absorption; greater alterations in awareness and experience; and decreased volitional control, rationality, and memory; (3) phenomenological intensity differences (hypnosis compared to eyes-closed) will be significantly greater for high than for low hypnotizable Ss.

They used the Phenomenology of Consciousness Inventory (PCI) developed by Pekala (1982), which is a 53 item self-report instrument that is completed retrospectively in reference to a preceding stimulus condition. The PCI measures

the following dimensions and subdimensions: internal dialogue; self-awareness; state of awareness; imagery (amount, vividness); positive affect (joy, sexual excitement, love); negative affect (anger, fear, sadness); altered experience (time sense, body image, perception, unusual meanings); attention (absorption, direction); memory; rationality; volitional control; and arousal.

The 217 Ss were administered the Tellegen Absorption Scale, then sat quietly with eyes closed for four minutes, then completed the PCI, Form 1, relative to that 4-minute period. They were administered a slightly shortened version of the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGSHS:A); before the posthypnotic suggestion and amnesia suggestion they experienced another 4-minute silent period during which they were told to 'continue to experience the state you are in right now.' After the HGSHS:A they completed PCI, Form 2, in reference to the silent period during the HGSHS:A, before they completed the 11-point questionnaire on the HGSHS:A.

Subjects who did not have reliable PCI response forms were removed from the sample, leaving 173 Ss who were divided into high, medium, and low Absorption groups, and high, medium, and low hypnotizability groups. The statistical analysis employed MANOVA on intensity scores for first the major PCI dimensions and then the 14 subdimensions using Conditions (eyes closed, hypnosis) and Groups. There were significant main and interaction effects. Subsequent ANOVAs for each (sub)dimension, Conditions by Hypnotizability Groups (2 x 3) were then performed. Hypnosis "was associated with significantly less positive affect (joy, sexual excitement, love); negative affect (anger, sadness); visual imagery (amount, vividness); self-awareness, internal dialogue, rationality, volitional control, and memory; and significantly more altered experience (time sense, perception) and altered state of awareness.

"Significant main effects for Hypnotizability Groups were found for positive affect (joy, love); altered experience (body image, time sense, perception, meaning); attention (direction, absorption); self-awareness; altered state of awareness; rationality; volitional control; and memory.

"Post-hoc comparisons for the eyes-closed condition revealed that high relative to low, hypnotizables reported significantly greater alterations in body image, time sense, meaning, and altered state of awareness. Medium hypnotizable Ss, compared to low hypnotizables, reported significantly increased alterations in body image and state of awareness.

"Post-hoc comparisons for the hypnotic induction condition revealed that high, viz-a-viz low, hypnotizables reported significantly increased absorbed attention; greater altered experience (body image, time sense, perception, meaning); and increased alterations in state of awareness. High hypnotizables also reported significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. Medium hypnotizable Ss, vis-a-vis low hypnotizables, reported significantly more altered experience (body image, time sense, perception, meaning); absorbed attention; and altered state of awareness; and significantly less imagery vividness, self-awareness, rationality, volitional control, and memory. High hypnotizable Ss, relative to medium hypnotizables, reported significantly more altered experience

(perception, meaning) and absorption, and significantly less rationality, volitional control, and memory.

"Concerning the significant interactions ( $\alpha = .01$ ), graphs of the means indicated significant ordinal interactions between Conditions and Hypnotizability Groups for altered experience (perception), imagery (vividness), self-awareness, altered state of awareness, rationality, volitional control, and memory. For all of the PCI (sub)dimensions, the hypnotic induction condition (compared to eyes-closed) was associated with a significantly greater increase in altered experience (perception), and altered state of awareness; and a significantly greater decrease in imagery (vividness), rationality, volitional control, and memory for the high (and medium) hypnotizable groups relative to the low hypnotizable group.

"Significant disordinal interactions were found for absorption and unusual meanings. Whereas high hypnotizable Ss reported a more absorbed attentional focus and more unusual meaning during hypnosis, low hypnotizable Ss reported being less absorbed (or more distracted) during the induction than eyes-closed. Low hypnotizables reported more unusual meanings in reference to eyes closed" (pp. 84-85).

Correlations among the major PCI dimensions, absorption, and hypnotizability differ between the two conditions. In hypnosis, the hypnotizability correlations that reached the .001 level were: --Self Awareness -.55 --State of Awareness .60 --Altered Experience .56 --Inward Absorbed Attention .44 --Rationality -.41 --Volitional control -.65 --Memory -.41 --Arousal -.28

In the eyes closed condition, the only PCI variables that Hypnotizability correlated with, at the .001 level, were: --Positive Affect .26 --Altered Experience .32

MANOVAs and ANOVAs were computed for Absorption groups in a similar fashion. Main effects but not interaction effects were significant. Results are not abstracted here.

In their Discussion, the authors note that "The three hypotheses were supported by the results. Several of the absorption group comparisons obtained in previous research (Pekala et al., 1985) involving alterations in subjective experience (body image, perception, meaning); state of awareness; and volitional control were replicated in the present research" (p. 85).

1988

Lorig, Tyler S.; Schwartz, Gary E. (1988-89). EEG activity during relaxation and focal imagery. Imagination, Cognition and Personality, 8, 201-208.

EEG activity was recorded in nine volunteer subjects while they engaged in eight cognitive tasks. The tasks involved mental arithmetic, relaxation imagery, food imagery and imagery related to "neutral" stimuli (bicycle and automobile). Period analysis of the EEG indicated significant differences in EEG factor activity related to tension and anxiety for the subtraction, relaxation and food imagery trials. Imagery of heaviness and the subject's favorite dessert produced EEG factor activity most characteristic of relaxation. Results of this study are discussed in terms of the relation of odor to food imagery and the ecological validity of the use of food

**NOTES**

Lorig, in a comparison of spectral and period analysis techniques, found that period analysis had greater sensitivity to task-related EEG effects. More recently, Lorig and Schwartz applied factor analysis to EEG period data and found that the factors identified tended to show greater homogeneity and correspondence to self-report than the traditional EEG bands of alpha, theta and beta. Period analysis reduces data to a histogram of the number of waves of various frequencies which occur during each 10 second data collection epoch for each task.

As is evident from Finding 1, the 8 tasks tend to stratify into two groups which either increase or decrease in Factor 1/theta activity over time. Those tasks which decrease over time seem to be performance or practice-related and include Serial subtraction of threes, of sevens, relaxation imagery of heaviness (HVY) and instructions to concentrate on the word "one" as they inhaled and exhaled (BCON). These tasks may change little in their cognitive demands on the subjects over time. The other tasks (imagery of their first bicycle, imagery of their earliest ride in a car, imagery of their favorite main course, imagery of their favorite dessert) may be more evocative to the Ss since they were asked to recall events from their personal experience. The recall of some of these experiences may kindle the subsequent recall of other events and account for the increases in theta and Factor 1. It is also possible that theta and Factor 1 are attention- related. Thus, as the S participates in a task which changes little over time, attention is diminished. If, however, the task continues to evoke other personally relevant events, attention will be maintained and may even increase over time. If this later hypothesis is correct, the Favorite Dessert task may be of use clinically since it produces EEG patterns associated with less tension and anxiety and also less boredom. This task also produced self-reports of greater happiness ( $p = .0001$ ) and was not different from relaxation imagery of heaviness and instructions to concentrate on the word 'one' as they inhaled and exhaled in self reports of relaxation, tension or calm.

The results of this study indicate that imagery of food, especially one's favorite dessert, has relaxation effects apparent in EEG and self-report. These effects may indicate that food-related odorants exert their relaxation effects by producing imagery of food. Such effects should not be surprising given the early history of systematic desensitization training in which food was often used as a competing stimulus for anxiety-provoking stimuli.

Nash, Michael R. (1988). Hypnosis as a window on regression. Bulletin of the Menninger Clinic, 52, 383-403.

Examines the empirical evidence for temporal and topographic regression during hypnosis--which Freud explicitly defined as regressive. A review of more than 100 studies spanning 60 years of research found no convincing evidence that developmentally previous psychological structures are reinstated during hypnosis (temporal regression). In contrast, there is evidence that hypnosis enables subjects to elicit more imagistic, primary process, and affect-laden material (topographic

regression). The author recommends a careful reexamination of two core assumptions underlying the concept of temporal regression: (1) that early structures in human development are imperishable, and (2) that regression necessarily involves reinstatement of infantile psychological structures.

1987

Bandura, A.; O'Leary, A.; Taylor, C. B.; Gauthier, J.; Gossard, D. (1987). Perceived self-efficacy and pain control: Opioid and non-opioid mechanisms. Journal of Personality and Social Psychology, 53, 563-571.

#### NOTES

Subjects who were trained to use psychological coping strategies (e.g. imagery, distraction, dissociation, sensation transformation) had both better pain tolerance on a cold pressor test and higher self efficacy ratings. Those subjects who were given naloxone (which blocks pain reduction effects of beta endorphins) showed more pain tolerance than subjects not given the cognitive training experiences. They attributed much of the pain tolerance increase associated with cognitive interventions to opiate release, suggesting that cognitive interventions may have physiological mediating effects on pain perception.

Boswell, Louis K. (1987). Abstract imaging: Abstract imaging as a mode of personality analysis and adjustment. Medical Hypnoanalysis Journal, 2, 175-179.

Describes the use of abstract imaging during hypnosis to circumvent defense mechanisms and arrive at the initial sensitizing event behind a patient's emotional problems. Case examples illustrate how abstract imaging is also used to explore how the patient relates to the world on a conscious level and forms an idealized self-image to work toward.

Crist, Dwayne Anderson (1987). The effect of suggestibility on the efficacy of relaxation training instruction: A multisession evaluation (Dissertation, University of Alabama). Dissertation Abstracts International, 47 (n9-B), 3950.

Progressive relaxation is a well established procedure used in the treatment of anxiety related disorders. Research has suggested that the muscle tension-release component of progressive relaxation is the critical variable in producing relaxation effects. However, other techniques which do not employ muscle-tension release have proven effective. It has been suggested that treatment type may interact with personality characteristics to produce greater effects. Suggestibility was selected as a personality characteristic that may facilitate or inhibit relaxation effects. Fifty high and 50 low suggestible individuals were selected to participate based on scores from the Creative Imagination Scale. Half of each group as randomly assigned to either a progressive relaxation or imagery relaxation treatment. Subjects received four weekly sessions of relaxation training. The Relaxation Scale was administered before and after each session to assess effects of training. The results indicated that high suggestible individuals had significantly greater increases in relaxation within

session on each of the three scales of the Relaxation Scale, but this appeared to be a result of lower pre-test scores. Only the Physical Assessment scale also demonstrated higher post-test scores for the high suggestible participants. A ceiling effect appeared to be operating for both the Physiological Tension and Cognitive Tension scales. There were no significant differences between the progressive relaxation and imagery relaxation treatments. It appears that muscle tension release may not be a critical variable in relaxation effects" (p. ).

De Sano, Christine F.; Persinger, M. A. (1987). Geophysical variables and behavior: XXXIX. Alterations in imaginings and suggestibility during brief magnetic field exposures. Perceptual and Motor Skills, 64, 968-970.

12 male and 12 female volunteers were evaluated for their suggestibility before and after an approximately 15-min. exposure to either sham, 1-Hz or 4-Hz magnetic fields that were applied across their mid-superior temporal lobes. During the field application subjects were instructed to view a green light that was pulsating at the same frequency as the field and to imagine countering an alien situation. Results were commensurate with the hypothesis that weak brain-frequency fields may influence certain aspects of imaginings and alter suggestibility. NOTES 1: NOTES: "Subjects who had been exposed to the 4-Hz fields showed a significant decrease ... in heart rate compared to those who had been exposed to either the 1 Hz or sham-field conditions. A significant ... interaction of sex by field ... was noted for the change in HIP [Hypnotic Induction Profile] scales. Whereas both men and women in the sham-field condition tended to show less induction (~ 1 unit) on the second occasion ... women showed much greater (8.4 + 1.1) induction (= 3 units) if they had been exposed to the 1-Hz field while men showed much greater (8.0 + 1.5) induction (= 3 units) if they had been exposed to the 4-Hz fields. On the protocols, women reported significantly more fear responses than men. In addition, subjects who were exposed during the imaginings to the 4-Hz field showed more imaginings ... and more references to vestibular experiences (e.g., self or entity rising or floating) ... than those exposed to the other conditions" (p. 969).

"Dissociation scores on the HIP were correlated significantly ... with vestibular (0.44), imagery (0.43), and fear (-0.45) scores from the transcripts. Floating responses on the HIP were correlated with the amount of imagery. (0.46). There was a significant positive Pearson correlation between the compliance measure and the amount of arm levitation during the second induction only. These results suggest that hypnotic susceptibility may be increased following magnetic-field exposure but that the effective frequency is not the same for each sex. In addition, the amount of the imagery (particular vestibular experiences) increased if the person observed a light that was flashing at the same frequency as a 4-Hz applied magnetic field" (p. 969).

Friedman, Howard; Taub, Harvey A.; Sturr, Joseph F.; Monty, Richard A. (1987). Visual information processing speed in hypnotized and nonhypnotized subjects. Journal of General Psychology, 114 (4), 363-372.

Using a backward-masking paradigm with a bias-free and ceiling-free psychophysical task, we tested hypnotized and control subjects for speed of visual information processing. Approximately half of each group received visual imagery suggestions in an attempt to influence attention. Imagery produced no significant differential effect. Although an absence of a hypnotizability-performance relationship was in keeping with findings of a previous study, those subjects in the present study who performed under hypnosis were, as a group, significantly superior to the other subjects in speed of information processing.

Holroyd, Jean (1987). How hypnosis may potentiate psychotherapy. American Journal of Clinical Hypnosis, 29, 194-200.

Hypnotherapy is defined as doing psychotherapy in the hypnotic state. This article reviews cognitive, affective, and motivational changes associated with hypnotic trance, attempting to demonstrate how the hypnotic state might influence ordinary psychotherapy processes. Nine characteristics of trance probably potentiate psychotherapy: (1) changes in attention and awareness, (2) imagery enhancement, (3) increase in dissociation, (4) decrease of reality orientation, (5) increase in suggestibility, (6) increased accessibility of mind-body interactions, (7) diminution of initiative resulting in a sense of nonvoluntariness, (8) increased availability or manipulability of affect, and (9) development of a fusional relationship (rappport). This article touches upon the psychotherapeutic implications of these hypnosis attributes.

Locke, Steven E.; Ransil, Bernard J.; Covino, Nicholas A.; Toczydlowski, Janice; Lohse, Christopher M.; Dvorak, Harold F.; Arndt, Kenneth A.; Frankel, Fred H. (1987). Failure of hypnotic suggestion to alter immune response to delayed-type hypersensitivity antigens. Annals of the New York Academy of Sciences, 496, 745-749.

The ability to alter delayed-type hypersensitivity via hypnotic suggestion was tested in 12 highly hypnotizable, untrained subjects and 30 non-hypnotized controls. Subjects were skin tested bilaterally with a standardized panel of delayed hypersensitivity antigens and instructed either to enhance or suppress the skin test response (STR) unilaterally. Compared to controls, STR's showed no effect of hypnotic suggestion with regard to either the area of induration or the degree of inflammation assessed histologically.

Lynn, Steven Jay; Rhue, Judith W. (1987). Hypnosis, imagination, and fantasy. Journal of Mental Imagery, 11, 101-112.

Considers three questions pertaining to the relationship between hypnotic responsiveness and imaginative processes: Are subjects' nonhypnotic imaginative involvements related to hypnotic susceptibility? Do some fantasy prone subjects share a unique constellation of personality attributes and experiences, including an ability to respond to hypnotic suggestions? What are the childhood developmental antecedents of persons who score at the extremes of hypnotic ability and measures of fantasy and imagination? Reviews literature.

Nadon, Robert; Laurence, Jean-Roch; Perry, Campbell (1987). Multiple predictors of hypnotic susceptibility. Journal of Personality and Social Psychology, 53, 948-960.

Report two experiments in which various measures thought to be related to hypnotizability were analyzed by stepwise discriminant analysis. Absorption and preference for an imagic style of thinking predicted hypnotizability. Addition of 2 other variables in Experiment 2--a Sleep-Dream score derived from Evans's Cognitive Control of Sleep Mentation subscale and Gibson's Dream Questionnaire, and the Belief in the Supernatural subscale of the Taft Experience Questionnaire--increased the correct classification of the medium-hypnotizable subjects from chance levels to 74%. Argue for a confirmatory and hierarchical approach in future studies to explore correlates of hypnotizability more fully. NOTES 1:

#### NOTES

The following notes were made at an SCEH presentation: [Robert Nadon, Hypnotizability: A Correlational Study Involving Experiential, Imagery, and Selective Attention Variables.]

Author used a number of variables that have related to hypnotizability in single measure studies to predict with a multiple r. 30 male and 30 female Ss, given Harvard (?) then screened on Form A, and finally on Form C. Classed as Low (0-2), Medium (5-10 without amnesia), and High (11-12 with amnesia).

Belicki, Kathryn; Belicki, Denis (1986). Predisposition for nightmares: A study of hypnotic ability, vividness of imagery, and absorption. Journal of Clinical Psychology, 42 (5), 714-718.

The relationships of nightmare frequency to hypnotic ability, vividness of visual imagery, and the tendency to become absorbed in fantasy-like experiences were examined. Subjects were 841 undergraduate university students who participated in group tests of hypnotic ability, after which they estimated the number of nightmares that they had experienced in the prior year. In addition, 406 of the subjects completed Marks' Vividness of Visual Imagery Questionnaire, and Rotenberg and Bowers' Absorption scale. Of the subjects, 76% reported experiencing at least one nightmare in the prior year; 8.3% indicated one or more per month. Individuals with frequent nightmares scored higher on hypnotizability, vividness of visual imagery, and absorption.

#### NOTES

620, Belicki & Bowers, 1982 ABSTRACT: Investigated the role of demand

characteristics in dream change by comparing dream report change following pre- and postsleep administrations of instructions to pay attention to specific dream content. This design was based on the assumption that if presleep instructions merely distort dream reports rather than influence actual dreams, report change should be observable following a postsleep instruction. 42 undergraduates were prescreened with the Harvard Group Scale of Hypnotic Susceptibility (Form A), which allowed experimenters to examine the role of hypnotizability in dream change. Significant differences were observed only following the presleep instructions. It is concluded that report distortion as a result of paying attention to a dimension of dream content was insufficient to account for dream report change following presleep instructions. Hypnotic ability correlated significantly with the amount of dream change.

Brink, Nicholas E. (1986-87). Three stages of hypno-family therapy for psychosomatic problems. Imagination, Cognition and Personality, 6, 263-270.

In dealing with psychosomatic complaints it has been found useful and necessary to bring together three stages or techniques of psychotherapy. First, along with teaching relaxation, the therapist directs the client to define the symptom in a symbolic or figurative way describing size, shape, color, consistency, smell, and sound. These descriptors assess intensity and, over time, change in intensity of the symptom. Second, several hypnotic techniques are used to determine the dynamic pattern that has created the symptom. Such uncovered patterns have been found to invariably involve family dynamics. Third, hypnotic and family therapy techniques assist the client in changing the pattern. Examples are presented.

Cole, Ronald William (1986, February). Posthypnotic suggestion and the production of creative imagination imagery (Dissertation, Mississippi State University). Dissertation Abstracts International, 47 (8), 2953-A.

This investigation assessed the effect of posthypnotic suggestions in facilitating creativity in persons highly susceptible to hypnosis. Fifty college-age subjects from educational psychology and psychology classes at Mississippi State University who scored 9 or above on the Harvard Group Scale of Hypnotic Susceptibility were used. Groups of 10 subjects were randomly assigned to one of five conditions: a) hypnosis/creative learning set instructions b) relaxation/creativity learning set instructions c) hypnosis only d) relaxation only e) posttest only "Subjects in the hypnosis/creative learning set instructions group received 25 min. of hypnosis and creativity instruction. The relaxation/creative learning set instructions group received 25 min. of relaxation and creativity instructions. The hypnosis-only group received 25 min. of hypnosis and then completed mazes. The relaxation-only group received 25 min. of relaxation and then completed mazes. And lastly, the control group received the posttest only. All groups were given the Torrance Test of Creative Thinking (TTCT), Verbal and Figural Forms A, 1 week after receiving their treatment conditions. The results indicated that the combination of hypnosis and creativity instructions produced significantly higher mean scores on the Verbal

Form A -- fluency, flexibility, and originality subtests, and Figural Form A elaboration subtest, and lend support to the contention that posthypnotic suggestions can increase creativity (as measured by the TTCT) in high susceptible subjects. The components of both hypnosis and creativity instruction had to be present to increase creative performance. There was a tendency for relaxation combined with creativity instructions to show decreases in creativity scores. "The hypnotic state was seen as necessary for the unconscious acceptance of creativity instructions (low volitional control), while the relaxed state produced conscious contamination of suggestions for creativity (high volitional control). It was postulated that it was the difference in volitional control which produced the positive responses to posthypnotic suggestions to be more creative in the group receiving hypnosis and creativity instructions" (p. 2953).

Crawford, Jeffrey Cleon (1986, February). The effects of hypnosis and imagery on immunity (Dissertation, University of Texas Health Science Center at Dallas). Dissertation Abstracts International, 46, 2800-B.

The present study explored the effects of hypnosis and imagery on Total T-Lymphocytes, T-Helper, T-Suppressor, Natural Killer Lymphocytes and level of Salivary IgA. Twenty-four volunteers (15 females and 9 males) between the ages of 23 and 41, with a mean age of 30, were assigned to an experimental or no-treatment control group in a modified random sequence. Participation was limited to individuals who were clinically free of disease, not using medication known to influence immunity, and scored above the mean on self-report pencil and paper measures of life stress (Life Experiences Survey and Stress Coping Rating Scale). Blood and saliva samples were obtained one day before, immediately before, one hour after, and eight days after a one hour hypnotic session. A relaxation induction, a variation of [H. R.] Hall's method, was utilized to induce hypnosis, and its effect measured by the Long Stanford Scale. The subjects were encouraged to imagine the cells of their immune systems multiplying and destroying pathogens. An adaptation of the IMAGE-CA was used to assess the effectiveness of the imagery. Finally, the experimental subjects were instructed in and asked to practice self-hypnosis and imagery twice daily for a week. The data were analyzed in six two-factor repeated measure analyses of variance, and Newman-Keuls tests were utilized to make multiple comparisons between the levels of Group and Time. The analyses produced no evidence for the confirmation of the overall hypothesis that the experimental group would increase in percent of T-Lymphocytes, percent of T-Helper cells, percent of Natural Killer cells and level of Salivary IgA, and decrease in percent of T-Suppressor lymphocytes. Post-hoc analyses revealed correlations that served as a basis for interesting speculation, but there was no revision in the overall conclusion that there was not evidence that hypnosis and imagery, as employed in this study, influenced in the selected measures of immunity. These results extend, but are not analogous, to the results of previously published studies using "fractional" measures of immunity" (pp. 3055-3056).

Hendler, Cobie S.; Redd, William H. (1986). Fear of hypnosis: The role of labeling in patients' acceptance of behavioral interventions. Behavior Therapy, 17, 2-13.

One hundred and five outpatient cancer chemotherapy patients were interviewed to assess their attitudes toward hypnosis and relaxation as well as to determine their beliefs in and willingness to try a behavioral procedure. Patients were randomly assigned to groups receiving identical descriptions labeled "hypnosis," "relaxation," or "passive relaxation with guided imagery." The description stressed the behavioral components of hypnosis and relaxation rather than the nonbehavioral techniques often associated with hypnosis such as age regression and posthypnotic suggestion. Patients believed hypnosis to be a powerful process that involved loss of control and altered states of consciousness. When compared with a group of college students, patients held significantly more fearful, conservative views about hypnosis. Patients who received a description of an intervention labeled "hypnosis" were significantly less likely to believe the procedure would effectively control their nausea and vomiting and were significantly less likely to state they would try the procedure than patients in the other two label conditions. This reaction to the label occurred independently of patients' degree of nausea, vomiting, and pain due to their chemotherapy treatments.

Holroyd, Jean (1986). Hypnosis applications in psychological research. Imagination, Cognition and Personality, 5, 103-115.

It is proposed that hypnosis leads to altered cognition, affect, or motivation as reflected by changes in 1) reality orientation, 2) attention and awareness, 3) imagery, 4) dissociation, 5) suggestibility, and 6) mind-body interaction. Hypnosis may be used as an experimental method to effect such cognitive, affective and motivational changes in order to pursue research in learning, personality, physiological, and social psychology. Examples of possible applications of hypnosis are provided. The influence of individual differences in hypnotic responsivity on research also is discussed. NOTES 1: NOTES: The author concludes, "Contributions of hypnosis to research in psychology may have been diminished by the confusion inherent in searching for main effects while giving insufficient attention to interaction effects between personality variables and experimental manipulations. As psychology becomes more cognitive in orientation, the phenomena of hypnosis may seem less bizarre and more amenable to inclusion in psychological research. However great care must be taken not to confuse the contributions of hypnosis with the contributions of the hypnotically responsive personality" (p. 109).

Mitchell, George P.; Lundy, Richard M. (1986). The effects of relaxation and imagery inductions on responses to suggestions. International Journal of Clinical and Experimental Hypnosis, 34, 98-109.

Theoretical attempts to understand the meaning and importance of induction procedures in producing hypnotic phenomena suggest that 2 critical components,

relaxation and imagery, should be isolated and their relative effect on hypnotic responding studied. Objectively and subjectively scored responses to 12 hypnotic suggestions, which had followed relaxation, imaginal, or combined inductions, were obtained from 59 Ss, divided into 3 levels of hypnotizability. Regardless of hypnotizability level, the combined induction led to a greater subjective report of hypnotic response than did either the relaxation or the imagery inductions; and the relaxation led to a greater subjective report than the imagery induction. It may follow that the subjective experience of hypnosis is facilitated by inductions which include relaxation. The inductions were equally effective in producing objectively measured behavioral responses. There were no significant interactions found between induction type and hypnotizability level. NOTES 1:

#### NOTES

(From the Discussion Section).

As suggested by Sacerdote (1970), the combination procedure was the most generally effective in producing hypnotic responses. The difference between combined and imagery inductions reached statistical significance on four dependent variables, and the difference between combined and relaxation reached significance on three. It may also be of interest that Ss receiving the combined procedure scored consistently higher on all nine dependent variables.

A somewhat unexpected finding was that the relaxation induction produced scores on four of the dependent variables that were statistically higher than the imagery induction scores. Considering the difficulty of isolating relaxation and imagery components, it is quite noteworthy that these differences between inductions were found.

The four variables in which the combination and relaxation conditions produced significantly higher scores than the imagery condition were subjective reports--subjective score, degree hypnotized, response volition, and Field Inventory. In contrast to Ss in the imagery induction, Ss in the other two induction conditions believed that they were responding more, felt that their responses were more nonvolitional, and felt that they were more deeply hypnotized.

The fact that relaxation instructions were present in both conditions that were superior to the imagery condition would appear to support Edmonston's (1981) position which posits relaxation as essential for the production of the state of neutral hypnosis. For Edmonston the condition of neutral hypnosis is defined as the relaxed state and precedes other phenomena, such as dissociation and increased suggestibility, which other theoreticians may include in the definition of hypnosis.

However, the statistically significant superior effect of the combined over the relaxation induction on three measures casts doubt on Edmonston's position. The S believes that he or she is more deeply hypnotized and is responding less volitionally when an imagery component is combined with relaxation. The Ss also responded more to the Field Inventory when the combined induction was used.

Another explanation for imagery's relatively poor showing may lie in Ss' differential expectations. The Ss, especially those with previous experience with a traditional hypnotic induction, as was the case in the present study, may not expect to be hypnotized when presented with an imagery alone induction. Such expectations, of

course, might reduce responses. On the other hand, there is no reason to believe that the reduced expectation in the imagery condition would not affect the behavioral responses as well, and such was not the case.

Thus, we may be left with the explanation that relaxation adds to the subjective experience of hypnosis. This is in keeping with Edmonston's (1981) position as well as with previous research, such as that by Hilgard and Tart (1966), which finds traditional inductions, with their relaxation components, superior to nontraditional inductions, such as fantasy or task-motivational. If future research should find that bodily involvements such as the physical exertion or repetitive motor behavior (Banyai and Hilgard, 1976) lead to the same level of subjective experience as relaxation did, then we may need to broaden the concept of the somatic component beyond relaxation alone.

In terms of the behavioral compliance of Ss, the results of the present study are in accord with some previous studies in finding all procedures equally effective. Neither imagery, relaxation, nor the combined procedure was superior for the behavioral measure.

Personality factors (social desirability, internality/externality, and absorption) did not affect the basic findings. To the degree that the Tellegen scales measure the ability to engage in imagery there seems to be little basis for believing that imagery ability is related to the general findings.

Sarbin (1983) would call the inductions studied here 'entrance rituals,' and he has recently asked in his review of Edmonston's book, "Which ritual is more suitable... [p. 58]' for preparing S to respond in various hypnotic ways? One answer from the present results is that an entrance ritual should include muscular relaxation if one wants a better subjective response from S. From Sarbin's point of view, the relaxation component may be more ego-involving, producing more subjective experience and meaning for S.

If one wants to produce only a behavioral response, either a relaxation or imagery ritual will serve.

1985

Acosta, Enrique; Crawford, Helen J. (1985). Iconic memory and hypnotizability: Processing speed, skill or strategy differences?. International Journal of Clinical and Experimental Hypnosis, 33, 236-245.

The purported relationship between hypnotizability and speed of information transfer from iconic to short-term memory was studied in a comparison of 12 low and 12 high hypnotizable Ss. As in Ingram, Saccuzzo, McNeill, and McDonald (1979), high hypnotizable Ss showed less interference from a visual mask in the report of a briefly presented item than did low hypnotizable Ss when the mask delays were predictable. When the delay of the mask could not be anticipated, however, differences between high and low hypnotizable Ss disappeared. It is suggested that differences in information processing related to hypnotizability may be due to differences in strategy, skills, or other factors, rather than underlying information processing speed.

## NOTES

Hypnosis may require concentrative or selective attention, which usually is measured by self-report (e.g. Absorption) or by experimental measures. Several investigations indicate that high hypnotizable people are better than low hypnotizables at focusing on a task and ignoring extraneous information (Brown, Crawford, Smith, Leu, & Brock, 1983; Graham & Evans, 1977; Karlin, 1979; Miller, 1975; Wallace, 1979; Wallace, Garrett, & Anstadt, 1974; Wallace, Knight, & Garrett, 1976). One way to study attentional processes is through the effect of presenting a mask (e.g. \$\$\$\$) shortly after presenting a stimulus (e.g. ABCDE). Ingram (1979) found that highs had faster information processing, but that might be due to anticipation bias associated with the method of limits employed. This study uses both an ascending method of limits, like Ingram, and a condition in which the mask delays were presented randomly within another block of trials.

## RESULTS

"While the present study replicated Ingram et al.'s (1979) findings when an ascending method of limits was used (the same used by Ingram et al.) differences were not found in processing when ISIs were presented randomly. Thus, these results suggest that high and low hypnotizable Ss do not differ in their information transmission rates, but rather they may differ in other aspects which mediate performance in this task" (pp. 241- 242).

"Several lines of evidence point towards strategy or skill differences between high and low hypnotizable Ss as a possible explanation for the present findings. First, it was found that when Ss could anticipate the mask delay (the ascending condition), high hypnotizable Ss outperformed the low hypnotizables. When this anticipation was controlled, as in the random condition, the two groups did not differ when the data were scored by serial position. When the data were scored by a free recall scheme, there was a nonsignificant trend for high hypnotizable Ss to score higher than did the low hypnotizables. This trend suggests that high hypnotizable Ss may be more willing to guess, and to guess more accurately than low hypnotizables, when they have partial information about a letter, and/or they may have greater skill in perceiving incomplete information. The latter suggestion finds indirect support from Crawford (1981) who reported that high hypnotizable Ss can process fragmented stimuli (Gestalt Closure tests, see Thurstone & Jeffrey, 1966), significantly better than can low hypnotizables. High imagers have been shown also to perform significantly better than low imagers in Gestalt Closure tasks (Ernest, 1980). At a speculative level, given that recent research has suggested that iconic memory may be a right hemisphere phenomenon (e.g. Cohen, 1976, but also see DiLollo, 1981), and high hypnotizable Ss outperform low hypnotizables on certain right hemisphere tasks (e.g. Crawford, 1981), it may be asked if the trends found with the free recall scoring scheme in the present study might be a reflection of differential right hemisphere processing. Such a hypothesis could be investigated in future research by comparing the performance of high and low hypnotizable Ss, as possibly moderated by visuo-spatial ability, for stimuli presented to the left versus the right visual hemifield (Ernest, 1983).

"A second set of evidence in favor of strategy differences was found in Saccuzzo et al. (1982) which was published after the data for the present experiment were collected. In the Saccuzzo et al. (1982) paper, which was an extension and replication of Ingram et al. (1979), the same mask delay was used throughout a 10-trial block. The order of the blocks (i.e., the mask delays) was random. Thus, while S did not know which mask delay was used in the first trial of a block, the remaining 9 trials were the same and could be anticipated. During the first session, high hypnotizable Ss outperformed the low hypnotizables, but these differences disappeared on the second testing session. These results suggest that practice may have affected performance, rather than any underlying information processing speed differences" (pp. 242-243).

Gibson (1985). Dreaming and hypnotic susceptibility: A pilot study. Perceptual and Motor Skills, 60, 387-394.

Previous experimental work has indicated that certain stable personality characteristics are reliably associated with differential susceptibility to hypnosis. It is suggested that people who are more susceptible will be characterized by an awareness of dreaming more frequently, vividly and creatively. This study describes the construction of a Dream Questionnaire and the relations of the scores obtained on it to scores previously obtained on the Harvard Group Scale of Hypnotic Susceptibility. Sex differences were noted in response to the questionnaire. For women, a global score was derived from the questionnaire, and this was positively and significantly associated with hypnotic susceptibility. Men responded rather differently to the questionnaire and as hypnotic susceptibility scores were available for only a more limited number, further analysis was postponed until more data from men may become available. Some suggestions for research are discussed, and the relations between sleep research and hypnosis research are briefly considered.

#### NOTES

This article provides an example of dissociation-hypnosis contribution to sleep research:

"There has hitherto been little link between research on sleep and on hypnosis. Cartwright's (1978) review of dream research makes no mention of hypnosis, but a little common ground is referred to in Ernest Hilgard's (1975) review of hypnosis research. More recently, Belicki and Belicki (1984) and Perreault and Montplaisir (1984) have renewed the effort to link the two areas. Such research may not begin to pay off in terms of delineating more fully the traits of personality which refer to dissociative ability both in sleep and in wakefulness. It is hoped that the pilot questionnaire provided by the present study will serve to further such research."

[Note that in Nadon, Hoyt, & Kihlstrom, 1987, some questions from Evans' sleep questionnaire were predictive of hypnotizability.]

Kelly, Paul James (1985, November). The relationship between hypnotic ability and hypnotic experience (Dissertation). Dissertation Abstracts International, 46 (5), 1690-B.

This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experiences were: dissociation, the experience of involuntariness, altered state effects, such as perceptual alterations and diminished reality sense rapport, transference-like involvement with the hypnotist, and relaxation. A 47-item scale, the Hypnotic Experience Questionnaire was developed to measure types of hypnotic experience. It was given to 484 subjects and then to a subsample of 272 students. When the scale was factored, four stable factors emerged: Nonconscious/Trance, Rapport, Relaxation, and Cognitive Rumination. A Group Profile Scale was also developed to measure students and when it was factor analyzed four factors were extracted: Hallucinations and Fantasies, Amnesias and Post-Hypnotic Compulsions, Motor Inhibition, and Direct Motor Suggestion. "Two statistical approaches were used to investigate the connections between hypnotic ability and hypnotic experience . Canonical analysis was used to identify the main relationships between hypnotic ability and hypnotic experience and factor analysis was used to explore the relationship among measures of hypnotizability and hypnotic experience. Two canonical variates from the canonical analysis were significant. The first variate was characterized by a dissociative-imaginative involvement process, and the second variate tapped a rapport-social compliance process. "When 25 variables, representing components of hypnotic ability and hypnotic experience, were factored, five factors were extracted. Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. The results of the factor analysis suggested that dissociative experience and altered state experience are related to hypnotic ability but rapport and relaxation are not. "The results of study, taken as a whole, suggest that relaxation and rapport may happen in the hypnotic situation, but neither experience is related to the condition of being hypnotized in any essential way. The results suggest that the hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. From a theoretical point of view, the results strongly supported Hilgard's theory, partially supported Shor's theory, and failed to support Edmonston's theory" (p. 1690).

Nogrady, Heather; McConkey, Kevin M.; Perry, Campbell (1985). Enhancing visual memory: Trying hypnosis, trying imagination, and trying again. Journal of Abnormal Psychology, 94 (2), 195-204.

Tested visual recall memory of high (n = 24) and low (n = 24) hypnotizable undergraduates (screened under the Harvard Group Scale of Hypnotic Susceptibility and the Stanford Hypnotic Susceptibility Scale) for black and white line drawings of common objects in either hypnosis, imagination, or control conditions. Memory performance in terms of both correct and incorrect items increased appreciably across the recall tests. Neither hypnosis nor imagination enhanced recall beyond that of normal repeated testing. Hypnotizability was not related to the amount of correct material recalled but was related to the amount of incorrect material reported. High hypnotizable Ss in the hypnosis condition were more likely than other Ss to confidently rate the incorrect material as correct.

Findings are discussed in terms of the impact of hypnosis on and the relevance of hypnotizability to enhancing visual memory.

Achterberg, J. (1984, October). Cancer, immunology, psychological factors, and imagery. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

#### NOTES

Author developed a way of scoring imagery (which will be published in *Imagery and Disease*). In terms of predicting who will die and who will survive, the content of the images doesn't seem to be as important as the quality (strength, vividness, etc.), which supports Bernauer Newton's (1984) findings. "The image seems to be a basic pre-verbal component of our species that has survival value."

D'Eon, Joyce Lillian (1984). Response to pressure pain as moderated by hypnotic susceptibility, type of suggestion strategy, and choice (Dissertation, Concordia University, Canada). Dissertation Abstracts International, 45 (n4-B), 1313-1314.

The present study examined the relationship between hypnotic susceptibility and ability to control pain, by comparing high and low susceptible subjects' response to pressure pain when these subjects employed either an imagery or a distraction pain attenuating strategy. The effect of providing subjects with a choice of which strategy to employ was investigated. In addition, the subjects' imagery ability and the types of cognitive strategies they engaged in were assessed. Subjects who scored either 9 or above or 4 and below on the Harvard Group Scale of Hypnotic Susceptibility: Form A, were asked to participate in a pain study. All 84 subjects first received a baseline trial on a modified version of the Forgione-Barber Strain Gauge Pain Stimulator, within susceptibility levels. Subjects who were able to keep their finger in the apparatus for 60 seconds were randomly assigned to a Choice, a No Choice, or a Control condition. The 36 high and low susceptible subjects in the Choice condition were given the option of using either an imagery suggestion strategy or a low distraction strategy on the second trial. The 32 high and low susceptible subjects in the No Choice condition were told about both strategies but were assigned randomly to either the imagery or the distraction strategy group. The 16 subjects in the Control group did not receive a strategy. Both pain intensity and pain tolerance were measured. Results indicated that an equivalent number of high and low susceptible subjects, given a choice of strategy, chose the imagery and distraction strategies. There were no differences in either pain intensity or pain tolerance between high and low susceptible subjects in the Choice conditions. The Choice condition subjects exhibited significant pain reductions from the first to the second trial. No Choice and Control subjects did not reduce pain significantly. In addition, high and low susceptible subjects who chose the imagery strategy did not have higher imagery scores than those subjects who chose the distraction strategy. Subjects in the No Choice condition used fewer coping strategies than subjects in the

Choice condition, on the second trial. The implication of these results and directions for future research are discussed" (p. ).

Gott, Peggy S.; Hughes, Everett C.; Whipple, Katherine (1984). Voluntary control of two lateralized conscious states: Validation by electrical and behavioral studies. Neuropsychologia, 22 (1), 65-72.

A subject is described who can voluntarily select and hold either of two qualitatively different states of consciousness. Evidence is presented which confirmed differential left or right hemisphere dominance in each state. Asymmetries of EEG alpha and task performance scores indicated a state-dependent shift in functional lateralization. Evoked response studies showed directional changes in rate of interhemispheric transmission correlated with state-related hemisphere dominance. These findings demonstrated the capability for voluntary endogenous control of cerebral dominance under natural conditions.

#### NOTES

A personal communication (letter) from Gott indicates the S switches from one state to the other by visualizing her surroundings and imagining what it would look like in the other state. Immediately she finds herself in that other state. Her drawings demonstrate that her perspective must differ in the two states.

Gould, Sol S.; Tissler, Doreen M. (1984). The use of hypnosis in the treatment of herpes simplex II. American Journal of Clinical Hypnosis, 26, 171-174.

Hypnosis training was used to treat the painful lesions and emotional symptoms associated with Herpes Simplex II in two females, ages 32 and 26. Three weekly sessions of hypnosis and daily practice sessions were initiated in the first case. During this time, the patient experienced a decline in the subjective level of pain and severity of the lesions, as well as an elevation in mood level. On three-month followup, she reported no pain or skin eruptions and significantly less feelings of stress and anxiety. The second case utilized two sessions of hypnosis and daily practice sessions, and similar results were obtained. A traumatic event caused a relapse in the latter patient, but she was again able to use hypnosis to bring the virus back under control and to experience an elevation in mood level as well. A seven-month follow-up indicated no eruptions and an improvement in self-esteem.

#### NOTES

In the first case the tape included ego-strengthening suggestions (Hartland, 1971); another tape used the patient's fantasy of water and snow skiing. The patient felt that hypnosis helped her acquire a more positive attitude toward herself and relief of guilt and blame, as well as an improved ability to cope with the unpleasant sensations.

In treatment session, ego strengthening suggestions were followed by 2 minutes of quiet for integration of suggestions, then visualization used in cancer therapy (Simonton): suggestions of a strong cell structure, perfect skin, hormonal balance, cleanliness, and a cooling refreshed feeling in the area of the vagina and perineum; imagery of internally controlled friendly white sharks was used to "devour" the

virus; of water and snow skiing, imagery of cool breezes, white refreshing snow, clean fresh water; visualized herself forgiving and releasing her previous boyfriend of guilt, thereby allowing her anger to abate.

For second patient it was similar, plus visualization of being bathed in white lights and traveling through concentric circles radiating peace and protection, being purified as she traveled through the circles until she emerged as flawless as a diamond, reflecting only clarity and light. Both patients scored 4 on Spiegel's Hypnotic Induction Profile (HIP).

Hall, Howard R. (1984, October). Hypnosis, imagery, and the immune system. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

#### NOTES

Studied the relationship of hypnosis to immune functions, using imagery methods like the Simontons did with their cancer patients. Twenty normal volunteers were hypnotized and asked to imagine their white blood cells (WBCs) attacking weak germs like strong sharks would attack something, and they were told that the sharks would continue working after they came out of hypnosis (a post-hypnotic suggestion). They were asked to "feel it and experience it any way you can," to avoid emphasizing visual imagery too much. Then they were taught self hypnosis and sent home to practice twice a day for a week.

Three blood measures increased after hypnosis: --B-cells increased with pokeweed stimuli (an allergen) for younger Ss, not older Ss --WBC's increased for highly hypnotizable Ss who were young, not for poor hypnotizable Ss or for any older Ss (Age range was 22-80.) --Lymphocyte count increased, approaching significance for highly hypnotizable Ss who were young but not for poor hypnotizable Ss or for older Ss. A personality test administered before the hypnosis, the SLC-90, suggested that the higher the distress level, the lower the lymphocyte count before hypnosis training. Two scores that summed up the distress level correlated -.49 and -.53, respectively. The psychological distress measured by the personality test decreased after the week of self-hypnosis practice. Of the two scores that summed up distress, one decreased for everyone (General Severity Index) and the other decreased only for highly hypnotizable Ss (Positive Symptom Total). Thus, a week of self hypnosis with imagining one's WBC's eating up weak germs in the blood led to both an increase in immune response indicators and a decrease in psychological distress. Psychological distress decreased as lymphocytes increased.

Dr. Hall repeated these procedures with a small number of Ss who were told just to "lie down and rest" rather than being hypnotized and given instructions to imagine their WBC's increasing. None of the above changes occurred. However, he cautions that his research doesn't indicate whether the positive effects are due to relaxation, imagery, or hypnosis since all three were involved.

Handelsman, Mitchell M. (1984). Self-hypnosis as a facilitator of self-efficacy: A case example. Psychotherapy, 21 (4), 550-553.

This article presents the four-session treatment of Elaine, using self- hypnosis to facilitate the mourning process. It is argued that self-hypnosis-- rather than

enhancing imagery-- increases self-efficacy, a person's feeling that he/she can perform behaviors that lead to desired outcomes. Elaine's sense of self-efficacy was increased by allowing her to choose scenes from her life to be explored in the context of the use of imagery. Elaine imagined events surrounding her father's death, and "rewrote history" in an attempt to permit herself the direct expression of emotions.

Kearns, John S.; Zamansky, Harold S. (1984). Synthetic versus analytic imaging ability as correlates of hypnotizability. International Journal of Clinical and Experimental Hypnosis, 32, 41-50.

It was hypothesized that synthetic imaging ability, but not analytic imaging ability, is positively related to hypnotizability. The correlation of scores on a paired-associates task, used as a measure of synthetic imaging ability, with scores on the Stanford Hypnotic Susceptibility Scale, Form C (SHSS:C) of Weitzenhoffer and Hilgard (1962), indicated a statistically nonsignificant trend in the predicted direction. 2 measures of analytic imaging ability, as well as Sheehan's (1967) revision of the Betts (1909) Questionnaire Upon Mental Imagery, a measure of vividness of imagery, did not correlate significantly with SHSS:C. The results are discussed in terms of their relation to studies of creativity and goal-directed fantasy.

#### NOTES

The authors review the literature on imagery and hypnotizability and propose that an important variable in hypnosis is an ability to expand imaginatively upon a given verbal input (synthetic imaging ability), akin to Spanos' (1971) concept of goal-directed fantasy. They cite studies relating creativity ("essentially a synthetic process") to hypnotizability, and predict that skill in solving spatial relations problems (analytic imaging ability) is not correlated with hypnotizability because it involves "accurately scanning visual images and converging on solutions to specific problems," (p. 42) rather than creative fantasy characteristic of hypnotic behavior. Forty Subjects had two sessions each: imagery tests in #1 and SHSS:C in #2. Imagery tests included, in this order: 1. Paired Associates (Paivio, 1972; a test of synthetic imaging), in which paired words are learned and later recalled; Experimental Ss were to learn them by combining them into an image, while Control Ss were to simply try to learn them. The nouns differed in imagery strength (potential for stimulating images). 2. Nonsense Forms (a test of analytic imaging), in which Subjects trace with their fingers an irregularly shaped Masonite form, blindfolded, and then choose one of 5 drawings that best matches the form. 3. Cube Visualization (a test of analytic imaging), in which Ss imagine a 2" wooden cube painted red on all faces, that had been sawed into 1" cubes; they are to say how many of the smaller cubes would be red on 3 faces, 2 faces, one face, and none of the faces. 4. Betts QMI.

The Paired Associates (PA) scores were a ratio of high imagery words recalled to low imagery words recalled, intended to reflect the impact of imagery availability on memory. There was a trend for hypnotizability to correlate with PA ratio scores, regardless of whether intermediate or low imagery nouns were used as baseline ( $\rho = .37$  and  $.34$ ,  $p < .10$ ) in the experimental group ("Use imagery to learn."), a trend

that was not found in the control group (no imagery instructions). Neither measure of analytic imaging ability (Nonsense Forms, Cube test) correlated with hypnotizability.

In their Discussion, the authors write, "The common factor in successful performance of both imagery-mediated paired associates learning tasks and hypnotic suggestions appears to be the ability to expand imaginatively upon a given verbal input" (p. 47). They cite the literature relating hypnotizable and creative performance (p. 47). "The present findings with the Nonsense Forms Test and the Cube Visualization Test, both of which failed to correlate significantly with SHSS:C, support the hypothesis that hypnotizability is not related to analytic, spatial-imagining skills" (p. 47). "The nonsignificant correlation between Betts QMI and SHSS:C adds to the growing body of inconsistent findings observed with Betts QMI" (p. 47).

"Given the complex nature of hypnotic susceptibility and of imagery (Monteiro et al., 1980), it is perhaps not surprising that studies attempting to relate the two variables directly frequently yield only modest relationships. Very likely, the inclusion of appropriate mediating variables would serve to clarify and, in particular instances, augment the relationships observed between hypnotic responsiveness and imaging ability. One such variable may be the capacity to become fully involved in everyday nonhypnotic experiences, commonly called absorption. This variable has been shown in numerous studies to be related to hypnotizability (e.g. Tellegen & Atkinson, 1974), as well as to creativity and vividness of imagery (P. Bowers, 1978, 1979; Monteiro et al., 1980). Even more relevant to the present study is the possible interaction between level of hypnotic susceptibility and the relationship between synthetic imaging ability and SHSS:C scores. It may be, for example, that the contribution of synthetic imaging ability becomes more critical in eliciting hypnotic behavior from Ss who are only moderately susceptible to hypnosis. Such an analysis was not possible in the present experiment, since the number of high, medium, and low susceptible Ss was approximately equal, and, therefore, the number of Ss at each level was insufficient for an adequate subgroup analysis. Clearly, however, future studies of the role of imaginal skills in hypnotic responsivity must move in directions such as these" (p. 48).

Kelly, Paul James (1984, December). The relationship between hypnotic ability and hypnotic experience. Newsletter of Division 30, Psychological Hypnosis, of the American Psychological Association, 5.

This study investigated the relationship between four types of hypnotic experience and hypnotic ability. The types of experience were: dissociation, the experience of involuntariness; altered state effects, such as perceptual alterations and diminished reality sense; rapport, transference-like involvement with the hypnotist; and relaxation. A sample of 230 students was given the HGSHS:A, a group version of the SHSS:C, and the Hypnotic Experience Questionnaire (Kelly, 1984), a 47-item multidimensional scale of hypnotic experience. Items were taken from these tests to form 11 hypnotic ability variables (Positive Hallucinations, Dreams and

Regressions, Post- Hypnotic Compulsions, Amnesia (HGSHS:A), Amnesia (SHSS:C), Arm Rigidity, Arm Immobilization, Other Motor Inhibitions, Head Falling, Moving Hands Together, and Hand Lowering). Fourteen hypnotic experience variables were also formed (Generalized Dissociative Effects, Dissociative Inhibition, Trance, Unawareness, Transference-like Involvement, Trust, Friendliness, Physical Relaxation, Mental Relaxation, Imagery Presence, Imagery Vividness, Imagery Detail, Self Consciousness, and Analytic Thoughts). The 25 variables were intercorrelated and factored with principal axis factoring. Five factors with eigenvalues greater than 1 were extracted and rotated to varimax criteria. These factors, which accounted for 54.4 percent of the variance, were called: Imaginative Involvement, Ideomotor Response, Rapport, Cognitive Inhibition, and Relaxation. Hypnotic ability variables loaded significantly on three of the factors (Imaginative Involvement, Ideomotor Response, and Cognitive Inhibition) and these three factors also tapped some aspect of altered state experience and/or dissociative experience. It was concluded therefore that dissociative experience and altered state experience are related to hypnotic ability. The remaining two factors, Rapport and Relaxation, showed significant loadings only for rapport variables and relaxation variables, respectively. Neither of these two factors were related to any of the traditional measures of hypnotic ability or to the experience of dissociative effects or altered state effects. The results of this study suggest that rapport and relaxation may happen in the hypnotic situation but neither experience is related to the condition of being hypnotized in any essential way. The hypnotic condition is characterized by dissociative experience, altered state experience, and by successful performance on hypnotic ability tasks. The results also raise questions about Edmonston's (1981) theory that relaxation is the essence of hypnotic responsiveness. The finding that the experience of relaxation is unrelated to hypnotic ability is more congruent with Hilgard's (1977) view that relaxation is a nonhypnotic process. NOTES 1:

#### NOTES

This is an abstract of an unpublished Ph.D. dissertation, University of Waterloo, 1984. It won the American Psychological Association Division 30 award for Best Student Paper at the 1984 APA Convention.

Kohen, D.; Olness, K.; Colwell, S.; Heimel, A. (1984). The use of relaxation-mental imagery (self-hypnosis) in the management of 505 pediatric behavioral encounters. Journal of Developmental and Behavioral Pediatrics, 5, 21-25.

This report assessed outcomes of hypnotherapeutic interventions for 505 children and adolescents seen by four pediatricians over a period of one year and followed from four months to two years. Presenting problems included enuresis, acute pain, chronic pain, asthma, habit disorders, obesity, encopresis, and anxiety. Using strict criteria for determination of problem resolution (e.g., all beds dry) and recognizing that some conditions were intrinsically chronic, the authors found that 51% of these children and adolescents achieved complete resolution of the presenting problem; an additional 32% achieved significant improvement, 9% showed initial or some

improvement; and 7% demonstrated no apparent change or improvement. Children as young as three years of age effectively applied self-hypnosis techniques. In general, facility in self-hypnosis increased with age. There was an inverse correlation ( $p$  less than 0.001) between clinical success and number of visits, suggesting that prediction of responsivity is possible after four visits or less. NOTES 1:

#### NOTES

Discusses the treatment of 505 pediatric patients with a variety of problems (enuresis, pain, obesity, anxiety reactions, habit problems, encopresis, headache, fear of pelvic examinations).

Krenz, Eric W. (1984). Improving competitive performance with hypnotic suggestions and modified autogenic training: Case reports. American Journal of Clinical Hypnosis, 27, 58-63.

Although traditionally trainers of athletes have emphasized physiological refinements for the optimal performance of complex motor skills, research has revealed that heightened levels of stress and anxiety may adversely affect performance. As a result, many athletic training programs, taking into consideration the complex interrelationship of the mind and the body, include "mental training" in an attempt to reduce the negative effects of excess stress. These programs have incorporated various psychological interventions such as post hypnotic suggestions, sensory conditioning, and mental imagery and rehearsal. Modified Autogenic Training, a teaching model based on Standard Autogenic Training, synthesizes the strengths of hypnotic techniques to achieve optimal athletic performance. Athletes trained in these concepts can manage unexpected incidences during competition. The concepts of Modified Autogenic Training are described and four case studies are reported.

Newton, Bernauer (1984, October). The use of imagery in the treatment of cancer patients. [Paper] Presented at the annual meeting of the Society for Clinical and Experimental Hypnosis, San Antonio, TX.

Several hundred cancer patients were treated with the Simonton visualization method, with the additional factor that they were hypnotized for the visualization. In a long term follow-up study, those patients who were treated for at least 6 months and are still alive had imagery that was vivid, persistent, positive, and passive ("passive" here meaning an underlying sense of calm). Those who died had the opposite kind of images, and retrospective review of clinical notes indicates their aggressive images reflected desperation. Of the patients who were treated less than six months, a few lived. Their images also were vivid, persistent, and positive.

1983

Crawford, Helen J.; Allen, Steven N. (1983). Enhanced visual memory during hypnosis as mediated by hypnotic responsiveness and cognitive strategies. Journal of Experimental Psychology: General, 112 (4), 662-685.

To investigate the hypothesis that hypnosis has an enhancing effect on imagery processing, as mediated by hypnotic responsiveness and cognitive strategies, four experiments compared performance of low and high, or low, medium, and high hypnotically responsive subjects in waking and hypnosis conditions on a successive visual memory discrimination task that required detecting differences between successively presented picture pairs in which one member of the pair was slightly altered. Consistently, hypnotically responsive individuals showed enhanced mean number of correct performance during hypnosis, whereas nonresponsive ones did not. Hypnotic responsiveness correlated .52 ( $p < .001$ ) with enhanced performance during hypnosis, but it was uncorrelated with waking performance (Experiment 3). Reaction time was not affected by hypnosis, although high hypnotizables were faster than lows in their responses (Experiments 1 and 2). NOTES 1:

#### NOTES

Subjects reported enhanced imagery vividness on the self-report Vividness of Visual Imagery Questionnaire during hypnosis. The differential effect between lows and highs was in the anticipated direction but not significant (Experiments 1 and 2).

Two cognitive strategies appeared to mediate visual memory performance: (a) detail strategy (memorization and rehearsal of individual details) and (b) holistic strategy (looking at and remembering the whole picture with accompanying imagery). Both lows and highs reported predominantly detail-oriented strategies during waking; however the highs shifted to a more holistic strategy during hypnosis. It appears that high hypnotizables have a greater capacity than lows for cognitive flexibility (Battig, 1979).

Results are discussed in terms of Paivio's (1971) dual coding theory and Craik and Tulving's (1975) depth of processing theory. The authors also discuss whether hypnosis involves a shift in cerebral dominance, as reflected by the cognitive strategy changes and enhanced imagery processing.

Farthing, G. William; Venturino, Michael; Brown, Scott W. (1983). Relationship between two different types of imagery vividness questionnaire items and three hypnotic susceptibility scale factors: A brief communication. International Journal of Clinical and Experimental Hypnosis, 31, 8-13.

122 Ss were administered the Harvard Group Scale of Hypnotic Susceptibility, Form A (HGS: A) of Shor and E. Orne (1962), the Tellegen Absorption Scale (Tellegen & Atkinson, 1974), and 2 tape-recorded questionnaires on vividness of mental imagery. On 1 imagery questionnaire the items were impersonal, objective visual scenes (MIQ:VS), whereas on the other questionnaire the items involved discrete personal actions which elicited a combination of visual and kinesthetic imagery (MIQ:PA). Imagery vividness scores from both questionnaires correlated significantly with hypnotizability scores. MIQ:VS vividness scores were better than

MIQ:PA vividness scores at predicting cognitive factor item scores of HGSHS:A, but not ideomotor or challenge factor items scores. Multiple correlations involving MIQ:VS vividness and the Tellegen predicted cognitive factor scores better than ideomotor or challenge factor scores.

Harris, Gina M.; Johnson, Suzanne Bennett (1983). Coping imagery and relaxation instructions in a covert modeling treatment for test anxiety. Behavior Therapy, 14, 144-157.

The present study compared the efficacy of instructing test anxious subjects to use personalized coping imagery based on nonacademic experiences of competence with coping imagery based on academic experiences of competence. The effect of relaxation was also examined and the relationship of imagery elaborateness and content to treatment effectiveness was assessed. Sixty-three subjects were randomly assigned to one of four treatments or a waiting list control group. Test anxiety as measured by a self-report instrument significantly decreased in all treatment groups. Improvement in grade point average occurred for all treatment groups except for academic coping imagery without relaxation which was also the least efficient treatment. The waiting list control group significantly deteriorated in academic performance. Relaxation training did not appear to enhance treatment effectiveness or influence the elaborateness or content of the imagery used. Test anxiety scenes elicited highly response-oriented images by all subjects. However, the stimulus/response content of the subjects' images was not influenced by treatment outcome. In contrast, successful treatment was primarily associated with reduction in negative coping imagery descriptions, although an increase in positive coping statements cured as well.

Myles, (1983, April). Cognition, hypnotic susceptibility, and laboratory induced pain (Dissertation, University of Waterloo). Dissertation Abstracts International, 43 (10), 3360-B.

Individuals' experiences of pain, and responses to pain treatments vary greatly. This study attempted to relate two areas of research concerned with this variation: (a) cognitions and pain (thoughts, images, etc.), in particular, catastrophizing versus coping; and (b) hypnotic susceptibility and analgesia. "Subjects were preselected for high or low hypnotic susceptibility. Susceptibility assessment was divorced from the laboratory study to minimize the potential bias of expectancies concerning hypnosis. High hypnotic susceptibility was expected to potentiate therapeutic effects of hypnotic-like treatment that did not involve a hypnotic induction. "Ten high and ten low-susceptible subjects were assigned to each of three groups: (a) a cognitive treatment, encouraging subjects to reduce spontaneous catastrophizing and increase self-generated coping cognitions; (b) a dissociative imagery treatment, encouraging subjects to engage in self-generated engrossing images; (c) an attention- placebo manipulation. "Pre and post-treatment assessments involved tolerance and pain-report measures during the cold-pressor task, and interview and questionnaire information concerning cognitions. "No treatment effects were evident on measures

of pain. Cognitive data indicated less catastrophizing and more coping during the post-treatment stressor across all groups. Subjects in the dissociative imagery group did report more imagery during the post-treatment assessment than subjects in the other groups, but this increased use of imagery was not associated with a decrease in pain. "Interview and questionnaire data supported prior reports that catastrophizing is related to increased pain. Low catastrophizing was associated with a high sense of control, high use of a variety of coping strategies, and lower pain reports. These relationships were altered following treatment, however, leading to a caution in generalizing about such variables. "High susceptibility did not potentiate therapeutic effects for either experimental treatment. Nor was susceptibility related in any other consistent way to pain, although high susceptibility was associated with more extensive use of post-treatment imagery. "Methodological inconsistencies and problems in laboratory pain research were discussed, and suggestions made for future work in the area" (p. 3360).

1982

Blum, Gerald S.; Nash, John K. (1982). EEG correlates of posthypnotically controlled degrees of cognitive arousal. Memory and Cognition, 10, 475-478.

Experimental control over five degrees of cognitive (as opposed to organismic) arousal has been developed by hypnotic programming techniques. Previously these posthypnotic manipulations have been applied to the investigation of diverse topics such as visual discrimination, performance on the Stroop test, selective concentration on color versus form of consonants, and cognitive "reverberation." The present study explored EEG correlates of the five degrees of cognitive arousal in a task requiring participants to visualize objects for one-minute periods while lying on a couch with eyes closed. Analysis of data from the occipital area in left and right hemispheres revealed that the highest degree of arousal was accompanied by larger amplitudes of alpha and beta power and smaller amplitudes of theta. This pattern of results was similar in both hemispheres, although more marked in the left. The findings, which provide an independent source of support for validity of the hypnotic programming, are discussed in relation to EEG literature on cognitive activity.

#### NOTES

Hypnosis doesn't enhance imagery. It provides the conditions under which mental alertness may be manipulated, and very clear imagery is associated with the alert condition whereas blurry imagery is associated with the lowest cognitive arousal condition. The other impression comes from clinical work, i.e. that hypnosis enhances imagery. This article is an example of hypnosis used in other research--see last page.

Bowers, Patricia G. (1982). The classic suggestion effect: Relationships with scales of hypnotizability, effortless experiencing, and imagery vividness. International Journal of Clinical and Experimental Hypnosis, 30 (3), 270-279.

How well the Stanford Hypnotic Susceptibility Scales assess what Weitzenhoffer (1978) terms the "classic suggestion effect" is addressed by developing an index of nonvolitional behavior (N-VB) for a group form of the Stanford Hypnotic Susceptibility Scale, Form C of Weitzenhoffer and Hilgard (1962) given to 43 Ss. The N- VB index, reflecting the classic suggestion effect's dual criteria of both behavioral responsiveness to suggestion and nonvolition ratings, was correlated highly with the traditional scoring of the group SHSS:C and moderately with the Harvard Group Scale of Hypnotic Susceptibility, Form A. Effortless experiencing of imagination and imagery vividness relate similarly to traditional and N-VB scores of hypnotizability. In addition, the relationship between involuntary ratings and passing and failing an item of the group SHSS:C was examined for each of the 10 items. There was a significant relationship for 7 of the items.

Brown, Daniel P.; Forte, Michael; Rich, Philip; Epstein, Gerald (1982-83). Phenomenological differences among self hypnosis, mindfulness meditation, and imaging. Imagination, Cognition and Personality, 2 (4), 291-309.

A survey of 122 subjects was conducted to investigate the differences in the phenomenological quality of the experiences engendered by three types of awareness discipline: self-hypnosis (21 Ss), waking dreaming (49 Ss) and mindfulness meditation (25 Ss from a 2-week retreat, and another group of 27 Ss from a 2-day weekend retreat). A questionnaire, the profile of Trance, Imaging, and Meditation Experience (TIME) was used in the survey. Discriminant analyses were used to construct models of the differences in the phenomenological quality of the experiences among the three groups. A number of phenomenological dimensions, in the major areas of attention, thinking, memory, imagery, body sensations, emotions, time sense, reality sense, and sense of self, were found which could accurately distinguish among the experiences of practitioners of the three types of awareness training. Results show that while self hypnosis involves self-referential thinking, memory changes, and intense emotions, waking dreaming emphasizes the immediate impact of emerging images, which unfold in a thematic manner and have a sense of their own reality. Mindfulness meditators have difficulty managing distractions, but with experience learn greater awareness of bodily processes, and experience changes in the perception of time and self; mental processes seem to slow down, and awareness assumes an impersonal quality. No attributions as to the causes or sources of these phenomenological differences are made, as the survey was not large enough to provide comparison groups, subject matching, or other statistical controls necessary for causal analyses.

(Information taken from a pre-publication manuscript.)

Crawford, Helen J. (1982). Cognitive processing during hypnosis; much unfinished business. Research Communications in Psychology, Psychiatry and Behavior, 7, 169-179.

Studies of cognitive processing during hypnosis per se are reviewed suggesting that hypnotically responsive individuals not only experience subjective changes during

hypnosis that are seen as often being discontinuous from their normal consciousness but also may exhibit measurable cognitive changes. Evidence (ego functioning changes, enhanced creativity, enhanced imagery processing, etc.) is presented to support the hypothesis that hypnosis may involve a shift in cognitive functioning away from a verbal, detail-oriented strategy towards a more imaginal, non-analytic, holistic-oriented strategy. Limitations of present research and potentially valuable research areas are discussed. NOTES 1:

#### NOTES

The author reviews evidence for cognitive changes during hypnosis--evident especially in high hypnotizables but also to some degree in moderate hypnotizables. She concludes that there may be changes in ego functioning, imagery functioning, creativity, and strategy preferences and that high hypnotizables are more flexible in cognitive processing . "The question remains whether or not there are accompanying objectively measurable cognitive changes during hypnosis" (p. 170).

"In normal waking consciousness, the hypnotically responsive individual is typically found to be more involved in nonhypnotic imaginative activities and experiences (Hilgard, 1979; Tellegen & Atkinson, 1974), more able to image things (for review, see Sheehan, 1979) and daydream vividly and positively (Crawford, 1982), more able to perceive gestalt closure figures (Crawford, 1981), more able to divert attentional process (e.g., Karlin, 1979), and more creative on certain tasks (e.g., P. Bowers, 1979). Experiential reports indicate that it is these very cognitive processes, amongst others, which are perceived to be enhanced or changed during the hypnotic state" (p. 170).

"Levin and Harrison (1976) found that hypnosis ego changes occurred most in those individuals who also demonstrated good capacity for adaptive regression in the waking state" (p. 171).

"Dave (1979) compared hypnotically induced dreams with rational-cognitive treatment as to their effects on creative problem solving of the problems or projects. 'Conditional support' was given to the significantly stronger effect form the hypnotically induced dreams" (p. 172).

There are many investigations of the effect of hypnosis on imagery, with a number of methodological problems. "Self-reports can be criticized on the grounds that they are easily subject to demand characteristics, subject expectations, and social desirability influences. Coe et al. (1980) found order of condition influenced their findings, while Crawford (1979) found that imagery rating scales suffered from a low ceiling effect among high imagers" (pp. 172-173).

"Surprisingly, while the field of cognitive psychology has devoted extensive attention to the study of the enhancing effects of imagery upon memory, few of their paradigms have been applied to the study of hypnotic processing of information. Germaine to the field of hypnosis are three operational approaches to the investigation of imagery: (a) the manipulation of the availability of imagery as a coding device, such as varying the degree to which stimuli may evoke imagery, (b) the manipulation of the processing strategy in cognitive performance, such as asking subjects to use imagery in the mediation of stimuli information, and (c) the

comparing of information processing strategies and performance in subjects who are low and high in imagery ability (Paivio, 1971)" (p. 173).

"Several studies (Nomura, Crawford, & Slater, 1981; Walker, Garrett, & Wallace, 1976; Wallace, 1978) found that a very few high hypnotizables can successfully produce eidetic imagery, using nonfakable stereograms, during hypnosis even though they cannot during waking. Spanos, Ansari, & Stam (1979) were unable to replicate these findings. It was only self-reported childhood eidetikers who exhibited eidetic imagery during hypnosis, and then only a few. This research suggests that hypnosis permits certain individuals to access the "lost" ability to image eidetically, possibly through a shift in cognitive strategies" (p. 174).

"An underlying emphasis of this paper is the need for hypnotic investigators to integrate findings from cognitive psychology into their research, as well as apply the many new approaches to understanding brain functioning which are now being developed, in their search for a better understanding of what occurs during hypnosis" (p. 176).

Crawford, Helen J. (1982). Hypnotizability, daydreaming styles, imagery vividness, and absorption: A multidimensional study. Journal of Personality and Social Psychology, 42 (5), 915-926.

In 25 male and 31 female university student and staff volunteers, the interrelationships between the following measures were studied: hypnotic susceptibility (SHSS:A and C), imagery vividness (VVIQ), involvement in everyday activities (TAS), and daydreaming styles (28 scales of Singer & Antrobus's Imaginal Processes Inventory). Factor analysis produced a factor characterized as a positively vivid and absorptive imagination style. Hypnotic susceptibility, VVIQ, TAS, and positive-affect daydreaming styles all loaded on this factor. Two other factors were a dysphoric daydreaming style and a lack-of-attentional-control style. Stepwise multiple regressions suggested that males and females, at least within this sample, exhibit different relationships between hypnotic susceptibility and predictor variables. Similar differences were found for the VVIQ and the TAS and their daydreaming-scale predictor variables.

Farthing, G. William; Brown, Scott W.; Venturino, Michael (1982). Effects of hypnotizability and mental imagery on signal detection sensitivity and response bias. International Journal of Clinical and Experimental Hypnosis, 30, 289-305.

It was hypothesized that the ability to selectively concentrate attention on mental images would be greater among high hypnotizable Ss than among low hypnotizable Ss, as indicated by a greater interference with visual signal detection by concurrent visual mental imagery in response to specified nouns. This hypothesis was not supported in the overall results, though the finding of a significant interference effect among the high hypnotizable female Ss, but not among other subgroups, indicates that further research with a more refined procedure might be worthwhile. On the control trials without images, the high hypnotizable Ss made more false alarms than lows, and had a significantly different bias index indicating that high

hypnotizable Ss were more likely than lows to respond "yes" when uncertain about whether the signal was present; false alarms can be interpreted as a nonhypnotic measure of suggestibility. The high and low hypnotizable Ss did not differ in their times to generate images in response to the specified nouns.

#### NOTES

This is a controlled clinical outcome study of psychotherapy involving the use of hypnosis

Dosamantes-Alperson, Erma (1981). Experiencing in movement psychotherapy. American Journal of Dance Therapy, 4, 33-44.

Experiencing is a process variable in psychotherapy which deals with the manner with which individuals use their internal, ongoing bodily-felt flow of experience to gain self-awareness and to communicate about themselves. A consistent finding across research process studies in psychotherapy is that successful clients start, continue, and end therapy at higher experiencing levels than do less successful clients. The implication of this finding for all therapists, irrespective of their theoretical framework, is that they need to help their clients process the content they raise in therapy at a high level of experiencing throughout the course of therapy. This paper discusses and demonstrates several body movement based procedures that enhance clients' experiencing level while working within the context of experiential movement psychotherapy, a form of psychotherapy which emphasizes the acquisition of personal meanings by clients from any of the following three experiential and expressive modalities: body movement, kinetic imagery, or verbal communication.

Fromm, Erika; Brown, Daniel P.; Hurt, Stephen W.; Oberlander, Joab Z; Boxer, Andrew M.; Pfeifer, Gary (1981). The phenomena and characteristics of self-hypnosis. International Journal of Clinical and Experimental Hypnosis, 29 (3), 189-247.

Self-hypnosis and hetero-hypnosis were compared, and self-hypnosis was studied longitudinally. Results indicated that absorption and the fading of the general reality orientation are characteristics of both hetero-hypnosis and self-hypnosis. The differentiating characteristics lie in the areas of attention and ego receptivity. Expansive, free-floating attention and ego receptivity to stimuli coming from within are state-specific for self-hypnosis, while concentrative attention and receptivity to stimuli coming from one outside source--the hypnotist on whom the subject concentrates his attention--are state-specific for laboratory defined hetero-hypnosis. Attempts to produce age regression and positive or negative hallucinations are markedly more successful in hetero-hypnosis. Imagery is much richer in self-hypnosis than in hetero-hypnosis. Self-hypnosis requires adaptation to the state: in

the beginning of self-hypnosis there is a good deal of anxiety and self-doubt. As the subject feels more comfortable in the self-hypnotic state, he spends less time worrying about failures in self-suggestion, his ability to enter trance quickly and easily increases, as does the fading of the general reality orientation, trance depth, and absorption. An attempt was also made in the present study to find personality characteristics related to the ability to experience self-hypnosis.

Houston, Rodney Earl (1981). The effects of autohypnosis, imagery, or single suggestion on pain threshold and tolerance (Dissertation, University of Cincinnati). Dissertation Abstracts International, 42 (5), 1961-A.

#### NOTES

Pain threshold, pain tolerance, and subject's subjective opinion of the pain were studied in 94 volunteer subjects (75 female, 19 male), who had been randomly assigned to three treatment groups (self hypnosis, in-vivo imagery, single suggestion) and a control group. (The original randomized sample included 124 Ss, but 30 were lost to the study-- 22 because of initial baseline scores being above maximum, 2 after reading the consent form, and 6 not returning for post-testing.) Mean age was 25; age range was 18-59 years.

The pain stimulus was 33 degree F. ice water in which the dominant hand was submerged for as long as the subjects were able. Subjects were told to nod when pain was first felt (threshold), and remove their hand when the pain was more than they could tolerate (tolerance). They were then asked to rate the pain on a 7-point scale, from 'none' to 'extreme.' Thus the three outcome measures were threshold time, tolerance time, and degree of perceived pain.

During the week between pretesting and posttesting, the self hypnosis group was to listen to a tape training them in self hypnosis at least twice; the imagery group was to listen to their imagery training tape at least twice; the simple suggestion group received no training. Posttesting was the same as pretesting, except that the simple suggestion group was given the single waking suggestion, "You will be able to withstand the pain much longer this time."

The experimental predictions were that treatment groups would increase in threshold levels and tolerance levels more than the control group; and that the treatment groups would decrease more than the control group in reported pain level. Multivariate analysis of variance of difference scores (pre- to posttest) demonstrated significant differences on the three dependent measures when comparing the three treatment groups to the control group. " Significant differences were also found when comparing treatment groups, autohypnosis and imagery to those given the single suggestion. No significant differences were found when comparing the autohypnosis to the imagery treatment.

"The results indicate that training in autohypnosis and in-vivo imagery has an effect on threshold, tolerance and pain levels. The results also indicate that the use of a single suggestion may not have an effect on threshold, tolerance, and pain levels" (p. 1961).

Coe, William C.; St. Jean, R. L.; Burger, J. M. (1980). Hypnosis and the enhancement of visual imagery. International Journal of Clinical and Experimental Hypnosis, 28, 225-234.

The enhancing effect of hypnosis on the vividness and the control of imagery was investigated. In 1 experiment, Ss who volunteered to be hypnotized were administered 2 measures of imagery, 1 under hypnotic conditions and 1 under imagination instructions while waking (counter-balanced). In another experiment, the imagery of 2 independent samples of Ss (waking or hypnotized) who volunteered for an imagery experiment was evaluated. Of the samples, hypnosis enhanced the vividness and control of imagery in only 1 -- the sample with Ss who volunteered for hypnosis and were first administered a test of imagination while awake. Between the 2 independent samples, control of imagery was reduced in the hypnotized sample. There were no differences in the findings on vividness and control of imagery across high, medium, and low susceptible Ss. Combining all Ss, the correlation between vividness of visual imagery and hypnotic responsiveness was significant for males ( $r = .52$ ) and the total sample ( $r = .33$ ) but not for females ( $r = .15$ ). Similar correlations for the control of imagery were not significant for males or females alone, but they were for the total sample ( $r = .18$ ). The implications of the results are discussed in light of their relevance to theory, future research, and clinical practice.

1979

Beers, Thomas M.; Karoly, Paul (1979). Cognitive strategies, expectancy, and coping style in the control of pain. Journal of Consulting and Clinical Psychology, 47, 179-180.

Measures of tolerance, self-reported pain threshold, and overall discomfort of cold-pressor pain were obtained from 114 male subjects in a pretest-training-posttest experiment. Training consisted of brief practice in one of four cognitive strategies: rational thinking, compatible imagery, incompatible imagery, and task-irrelevant cognition. Analyses of covariance indicated (a) that cognitive-imaginal strategies facilitated endurance of pain and raised self-reported threshold, (b) that rational thinking and compatible imagery were generally the most effective treatments, (c) that expectancy alone was not a significant pain-attenuating factor, (d) that treatments did not affect discomfort ratings, and (e) that individual differences in imaginal ability and coping style did not correlate with changes in any of the dependent measures.

1978

Bowers, Patricia G. (1978). Hypnotizability, creativity and the role of effortless experiencing. International Journal of Clinical and Experimental Hypnosis, 26, 184-202.

Creative people and highly hypnotizable people describe their experience of finding creative solutions or responding to hypnotic suggestions as "effortless." It is suggested that receptiveness to subconscious work accounts for the experience of

effortlessness in both tasks. An experiment using 32 high and low hypnotizable men and women was designed to explore the hypothesis that the aptitude for such effortless experiencing accounts for the relationship found between creativity and hypnotizability.

Analyses of variance indicate highly significant effects of level of hypnotizability on composite scores reflecting effortless experiencing of several tasks and creativity. Intercorrelations of these indices are about .60. As predicted, effortless experiencing accounts for much of the relationship between high versus low hypnotizability and composite creativity. The role of imagery vividness and of absorption in both hypnotizability and creativity were also explored.

Dyckman, John M.; Cowan, Philip A. (1978). Imaging vividness and the outcome of in vivo and imagined scene desensitization. Journal of Consulting and Clinical Psychology, 46 (5), 1155-1156.

This study reexamined the role of imaging vividness in desensitization success. Scores on the Betts Questionnaire on Mental Imagery were used to divide 48 snake-phobic subjects into high, medium, and low vivid groups, who were assigned to imagined scene or in vivo desensitization treatments. Imaging vividness was assessed at scheduled points during therapy. Significant decreases in behavioral and self-reported fear were observed after both treatments, though in vivo desensitization produced significantly greater fear reduction. In therapy imaging vividness scores were significantly correlated with therapeutic success and were superior to pretherapy ratings as predictors of outcome.

Hiscock, Merrill (1978). Imagery assessment through self-report: What do imagery questionnaires measure?. Journal of Consulting and Clinical Psychology, 46, 223-229.

Four studies examined imagery questionnaires and addressed issues of reliability, agreement among different questionnaires, social desirability, and construct validity. The Betts, Paivio, and Gordon scales were examined. In two studies the Betts and Paivio correlated .45-.50, but correlations involving the Gordon were inconsistent from one study to the next. Imagery measures generally were not influenced by social desirability. Factor analysis indicated that subjective and objective measures of visualization are independent. Concludes that imagery is not a unitary construct and that criteria other than visuospatial tests may be appropriate for validating imagery questionnaires.

Buckner, Linda G.; Coe, William C. (1977). Imaginative skill, wording of suggestions and hypnotic-susceptibility. International Journal of Clinical and Experimental Hypnosis, 25, 27-36.

3 groups of 20 s based on preselected imaginative capacity were administered either a hypnotic susceptibility scale containing item wording that suggested a goal-directed fantasy or one that did not. Preselected imaginative ability did not predict

hypnotic susceptibility or the production of goal-directed fantasies during hypnosis. However, Ss who received the hypnotic scale containing item wording that suggested goal-directed fantasies reported more goal-directed fantasies than Ss who received the other scale. Limitations of the study are discussed and the causal role of goal-directed fantasy in hypnotic responsiveness is questioned.

1976

Dugan, Michelle; Sheridan, Charles (1976). Effects of instructed imagery on temperature of hands. Perceptual and Motor Skills, 42, 14.

Sixteen college student volunteers were involved in the research. Subjects were randomly assigned to two groups, either to warm or to cool their hands. All 10 subjects attempting to cool their hands were able to cool at least one hand, and six people cooled both hands. For those trying to warm their hands, five warmed at least one hand and one was able to warm both hands. Four people were able to cool their hands without hypnosis, conditioning, or feedback.

Gur, R. C.; Reyher, J. (1976). Enhancement of creativity via free-imagery and hypnosis. American Journal of Clinical Hypnosis, 18, 237-249.

Thirty-six male, highly susceptible subjects, divided into hypnosis, simulation and waking groups, were given the Torrance Test of Creativity with modified instructions requiring them to wait passively for visual images in response to the test stimuli. Twelve waking subjects received the same test under standard instructions. The hypnotized group scored higher than all control groups on over-all creativity and on Figural creativity, but not on Verbal creativity. The results seem to support the application of the ego-analytic concept of 'adaptive regression' to both hypnosis and creativity. They also seem to confirm the association found between hypnosis and the activation of the non-verbal cerebral hemisphere.

1972

Greene, R. J.; Reyher, J. (1972). Pain tolerance on hypnotic analgesic and imagination states. Journal of Abnormal Psychology, 79 (1), 29-38.

Found that a hypnotic-analgesic-plus-pleasant-imagery condition was not as effective as was an analgesia suggestion only, in modifying tolerance.

1970

Davis, Daniel; McLemore, Clinton W.; London, Perry (1970). The role of visual imagery in desensitization. Behaviour Research and Therapy, 8 (1), 11-13.

## NOTES

Summary: a measure of visual imagery ability was obtained for 33 females who and participated in desensitization therapy for snake phobia. Visual imagery was positively related to pretherapy performance (closeness of approach to a live snake), but not to improvement. On the basis of these results and the results of two other

studies, it was hypothesized that the fear of good imagers tends to be based on imagination while that of poor imagers tends to be based on sensory experience. Most psychologists now recognize behavior therapy as effective in alleviating a wide variety of fears, but the nature of the processes underlying the various methods remains an open issue. Imagery has been of particular interest as a possible common denominator among various desensitization techniques. Lazarus (1961), for example, asserts that a "prerequisite for effective application of desensitization is the ability to conjure up reasonably vivid images," and Wolpe (1961) claims, "it is essential for visualizing to be at least moderately clear." London suggests that theoretically opposed treatments such as reciprocal inhibition (Wolpe, 1958) and implosion (Stampfl and Levis, 1967) may both be facilitated by repeated imagery which "produces a discrimination set such that the patient learns to distinguish between the imaginative, cognitive, affective aspects of experience, and the sensory and overt muscular aspects" (1964, p. 130). However, no systematic studies linking visual imagery to desensitization have been reported. This study examined the relationship between visual imagery and success in desensitization therapy.

Fromm, Erika; Oberlander, Mark I.; Gruenewald, Doris (1970). Perceptual and cognitive processes in different states of consciousness: The waking state and hypnosis. Journal of Projective Techniques and Personality Assessment, 34, 375-387.

Hypnosis was assumed to influence perceptual and cognitive functioning in the direction of increased primary process ideation and adaptive regression. The Rorschach test was administered to 32 Ss in the waking state and under hypnosis in counterbalanced order. Hypnosis was induced by a standardized procedure. Ss received identical instructions for the Rorschach in both conditions. Protocols were scored according to Holt's system for manifestations and control of primary process. Hypnotic Rorschachs showed an increase in primary process manifestations, but no changes in defensive and coping functioning, and no overall changes in the Adaptive Regression Score. However, the nature of the data was found to be influenced by Ss' sex and level of adjustment.

#### NOTES

The authors used High hypnotizables (SHSS>9) in this investigation.

Klempner, Edith (1962). Projective phenomena in hypnoanalysis. International Journal of Clinical and Experimental Hypnosis, 10 (3), 127-133. (Abstracted in Psychological Abstracts 63: 5228)

During hypnoanalysis patients who have been age-regressed may perceive themselves as experiencing childhood experiences and also as simultaneously watching these experiences from a distance. This 2nd projected personality may be in the guise of an adult, adolescent, child, or even an incorporeal being. In some patients it may occur with regularity, in others not at all. Representative case

histories and possible dynamic mechanisms are discussed. (PsycINFO Database Record (c) 2002 APA, all rights reserved)

1961

Halpern, Seymour (1961). On the similarity between hypnotic and mescaline hallucinations. International Journal of Clinical and Experimental Hypnosis, 9, 139-149.

The hypnotically-induced visual percepts of one subject are presented and discussed. These percepts reputedly bore a close resemblance to mescaline hallucinations. It is argued that no essential qualitative difference exists between psychogenic and toxicogenic hallucinations. It was hypothesized that all perceptions including dreaming, hallucinating, imagining and hypnotic perceiving are explainable in terms of perceptual-conceptual reciprocity understood as a neuropsychological function of consciousness. 1960

Naruse, Gosaku (1960). The abstract image in the post hypnotic state. International Journal of Clinical and Experimental Hypnosis, 8, 213-229.

(Author's Summary)

In the present paper, the experimental production of abstract image in PHHS was examined by the image conditioning method in a hypnotic trance. The comparison

of conditioning procedure was made between the buzzer sound or verbal sign as CS, and circle, numeral letter, or alphabetical letter as UCS. The main results of the study are as follows:

- (1) To evoke at will the abstract image, it is necessary to establish a corresponding relationship between the context of Cs and that of UCS by a conditioning method.
- (2) To establish the corresponding relationship, it is necessary to use the context conditioning procedure and not the single or differentiated conditioning.
- (3) In establishing the context conditioning, the more meaningful the stimulus used, the easier the relationship, and vice versa. The context conditioning is more easily accomplished by verbal signs than by buzzer sounds in CS and by numeral or alphabetical letters than by circles in USC [sic].
- (4) When the trance is too light, it is difficult for the post hypnotic image to appear. On the other hand, when the trance is too deep, while the image is clear and like the originals, the production of abstract image is difficult. The abstract image is, therefore, most easily produced in a middle or somnambulistic trance state between the lighter and the deeper trance.
- (5) The greater the number, the less certain or the more difficult the subconscious operates, especially in counting, for the hypnotic subject. It is assumed that the accuracy of subconscious, spontaneous counting is generally lower than that in consciousness.
- (6) All of the relative workings in order to produce the abstract image, were made in the subject's subconscious and even though the abstract image was achieved correctly, the subjects in normal consciousness or in the post hypnotic hallucinatory state were not generally aware of how or why it was formed, or what meaning it had.

1955

Klempner, Edith (1955). The spontaneous self-portrait in hypnoanalysis. Journal of Clinical and Experimental Hypnosis, 3 (1), 28-33. (Abstracted in Psychological Abstracts 55: 8621)

#### NOTES

Author presents descriptions patients gave of themselves in hypnoanalysis and compares them with material obtained with Dr. Walter Boernstein's Verbal Self-Portrait Test. On that test, the patient is asked, 'If you were an accomplished artist, how would you paint yourself?' The author concludes, "In summarizing I wanted to show that patients in hypnoanalysis can use the symbolical representation of their body as a means of bringing to the fore psychic traits, conflicts, and unconscious forces motivating them. They can even picture through it the complications of their life histories. In other words, the personality projection as it is revealed in the Spontaneous Self-Portrait here serves as a tool for the recognition and understanding of the neurotic structure" (p. 33).

## NOTES

### Summary

This is a report of the studies continued from the previous work, as regards the mode and law of modification of images, by experiments on the image-fusion which is observed in a post-hypnotic hallucinatory state. The writers investigated the configuration law of the Gestalt school, also whether there was nothing other than the overlapping of images. Various experiments were performed using accorded figures (Fig.1), discorded figures (Fig. 3), the composed image partly changed in size (Fig. 4), the incomplete figures with concrete meaning (Fig. 5,A) and the figures in which the perception and meaning were discorded with each other (Fig. 6). The results were as follows:

(1) There were some subjects whose images were clear, and others whose images were vague. In general, the images were clear in deep hypnotic trance, and vague in the medium trance.

(2) In the case of the clear images, they were prominently overlapping while in the case of the vague images, they overlapped one another and were disjointed or integrated.

(3) After conditioning two kinds of figures with two kinds of sounds, a composed image could be aroused by the two stimuli; in this case, by changing the tempo of one kind, a part of the composed image was changed. This fact would prove that the composed images were combinations of elements.

(4) In the case of the integrated images, the modification of both clear and vague images could be explained satisfactorily not by the Gestalt theory but by the intervention of the meaning. Moreover, the hypothesis of the integration or hierarchy of cerebral functions corresponding to these phenomena was possible.

(5) Modification through meaning was more frequent in the vague images than in the clear ones.

(6) The spontaneous effect of meaning of the image was dependent on the depth of trance. This effect was comparatively weak in deep trance and strong in medium trance. It was assumed that in medium trance which reproduced the integrated images, meaning activity still remained.

(7) Having presented incomplete figures with concrete meanings to examine the effect of meaning, it was clear that the modification of images by meaning took place distinctly under the influence of suggestion.

(8) If perception and meaning of the figure were made to be in discord with each other, the meaning suggested at the time of conditioning produced more effect on the modification of the image than that at the time of recall" (p. 22).

1953

Naruse, Gosaku; Obonai, Torao (1953). Decomposition and fusion of mental images in the drowsy and post-hypnotic hallucinatory state. Journal of Clinical and Experimental Hypnosis, 1 (4), 23-41.

### Summary of Part I

"From the above we can conclude the following main facts.

- 1) When one sensory stimulus is given to a subject in a drowsy state, images of other objects associated with it often appear.
- 2) These images sometimes have forms, and sometimes are devoid of forms, only light and color being present. This phenomenon resembles the experience of color-hearing, and is called a new type of synaesthesia [sic] by Bachen.
- 3) These images are sure to disappear when they are observed attentively, a passive attitude being necessary for the image observation.
- 4) The remarkable character of these images are such that elements of forms and colors of various objects have been disjointed and connected with each other in different relationships which construct new images.
- 5) The longer and stronger persistence of stimulus, the more easily and clearly conditioned images appear. Conversely if the stimulus is momentary, the recalled images appear also momentarily.
- 6) Not only the visual images but also the sensory images can be elicited in a similar way" (p. 25).

### **Summary of Part II**

"The chief results of Naruse's experiments with the various subjects are as follows:

1. When one stimulus (C.S.) is given in the normal waking state after a conditioning procedure in which a conditioned bond is formed between two sensory stimuli in deep hypnotic trance, a mental image corresponding to the other stimulus (U.C.S.) appears with amnesia for the conditioning situation. When the stimulus is removed, the image also disappears.
2. The images attained have various degrees of clearness which may be classified on a continuum from hallucinations to memory images.
3. Such images tend to disappear when subjects try to observe them attentively.
4. Images which are broken into elements of the original figure appear as distinct images.
5. Modifications of images may be made by distortion, vagueness of the image, and by decomposition of the image.
6. When two C.S.'s, which were already conditioned individually to two U.C.S.'s are presented at the same time, the images corresponding to each stimulus appear to overlap. This is the composed image.
7. In image composing, which involves the strong-weak stimulus relationship or the spatial positions of two C.S.'s, the clear-vague or positional relationships of the composed images are changed.
8. In the complex of meaningful images, there are two types, primarily. The one grasps the image as a whole, the other observes it in many mosaic elements. The latter can recall the original figure more correctly in an image form than the former.
9. Some positive and negative reports on sensory conditioning in the normal waking state are reviewed" (p. 36).

### **NOTES**

The investigators do not show that hypnosis enhances imagery, compared with the waking state. They studied sensory-sensory conditioning under hypnosis, with

amnesia suggestions, followed by testing for the conditioning effect. This study is relevant to studies of amnesia, "repression." In some studies they paired sound of a buzzer or metronome (the Conditioned Stimulus) with images (the Unconditioned Stimuli) as in [Oo, X]; other studies compared a color patch (CS) with an image (Oo, X). Some studies presented both CS's together, in different spatial arrangements (in the instance of the color patch CS).

Results (partial) included: "1. When one stimulus (CS.) Is given in the normal waking state after a conditioning procedure in which a conditioned bond is formed between two sensory stimuli in a deep hypnotic trance, a mental image corresponding to the other stimulus (UCS) appears with amnesia for the conditioning situation. When the stimulus is removed, the image also disappears. 2. The images attained have various degrees of clearness which may be classified on a continuum from hallucinations to memory images. 3. Such images tend to disappear when Ss try to observe them attentively. ... 5. Modifications of images may be made by distortion, vagueness of the image, and by decomposition of the image. 6. When two CS's, which are already conditioned individually to two UCS's, are presented at the same time, the images corresponding to each stimulus appear to overlap. ..." (P. 36).

#### **IMAGERY ABILITY.**

Eimer, Bruce. N. (2000). Clinical applications of hypnosis for brief and efficient pain management psychotherapy. American Journal of Clinical Hypnosis, 43 (1), 17-40. (July)

This paper describes four specific clinical applications of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and more efficient: (1) the assessment of hypnotizability; (2) the induction of hypnotic analgesia and development of individualized pain coping strategies; (3) direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing during the trance state of emotional factors in the patient's experience of chronic pain. Important theoretical and clinical issues regarding the relationship between hypnotizability to the induction of hypnotic analgesia are presented, and attempts to individualize pain treatment strategies on the basis of assessed differences in hypnotizability and patients' preferred coping strategies are described. Some ways are also presented of integrating direct hypnotic suggestion, COGNITIVE-EVALUATIVE reframing, hypnotic metaphors, and imagery for alleviating the SENSORY and AFFECTIVE-MOTIVATIONAL components of pain, with an exploratory, insight-oriented, and brief psychodynamic reprocessing approach during trance for resolving unconscious sources of resistance to treatment, and reducing the emotional overlay associated with chronic pain. Some basic assumptions underlying the use of this approach are discussed, and a brief step-by-step protocol is outlined.

## NOTES

1:

"Pain Management Psychotherapy" (PMP) provides a clear and methodical look at pain management psychotherapy beginning with the initial consultation and work-up of the patient and continuing through termination of treatment. It is a thoughtful and thorough presentation that covers methods for psychologically assessing the chronic pain patient (structured interviews, pain assessment tests and rating scales, instruments for evaluating beliefs, attitudes, pain behavior, disability, depression, anxiety, anger and alienation), treatment planning, cognitive-behavioral therapy techniques, and a range of hypnotic approaches to pain management. The book covers both traditional (cognitive and behavior therapy, biofeedback, assessing hypnotizability, choice of inductions, designing an individualized self-hypnosis exercise) as well as newer innovative techniques (e.g., EMDR, pain-relief imagery, hypno-projective methods, hypno-analytic reprocessing of pain-related negative experiences). An extensive appendix reproduces in their entirety numerous forms, rating scale, inventories, assessment instruments, and scripts.

The senior author, Bruce Eimer, states in his online comments on Amazon.com that "most therapists hold the belief that 'real' chronic pain patients are quite impossible to help. This book attempts to dispel these misguided beliefs by providing a body of knowledge, theory, and techniques that have proven value in understanding and relieving chronic physical pain." He also states that "the challenge for the therapist is to persuade the would-ne patient/client that he or she has something to offer that can help take way pain and bring back more pleasure. This challenge is negotiated through the therapeutic relationship. However, the therapist just can't be 'warm, accepting, non-judgmental and empathic'. The therapist must also have knowledge and skills relevant to relieving pain. Only then can the therapist impart such knowledge, and in teaching these skills to the pain patient, help the patient become something of a 'self-therapist'. . . I dedicate this book to everyone who wants to find ways to make living with pain more comfortable, and to the ongoing search for better ways to relieve pain."

Kogon, Manuela M.; Jasiukaitis, Paul; Berardi, Annamaria; Gupta, Malkeet; Kosslyn, Stephen M.; Spiegel, David (1998). Imagery and hypnotizability revisited. International Journal of Clinical and Experimental Hypnosis, 46 (4), 363-370.

The objective of this study was to correlate computer-generated imagery tasks and a self-report measure of imagery ability with hypnotizability, hypothesizing that computer-generated imagery tasks would be better predictors of hypnotizability than will the self-report measure. Hypnotizability of 43 subjects was assessed using the Hypnotic Induction Profile and the Stanford Hypnotic Susceptibility Scale, Form C. Imagery ability was assessed by the Visual Vividness Imagery Questionnaire (VVIQ) and by computer-generated imagery tasks measuring the ability to generate, maintain, and transform images. Although there was no correlation between the VVIQ and hypnotizability, the less hypnotizable subjects

made twice as many mistakes in the spatial imagery tasks than did the more hypnotizables, but this difference was not statistically significant. The relationships among hypnotic performance, hypnotizability, and imagery functions are complex.
